To simplify the architecture of GMSK demodulator, the PDGMSK was proposed. Figure 24 shows the data processing in a PDGMSK modulator and the *return-to-zero* (RTZ) data stream input to generate a PDGMSK signal (Hetling and Rhodes 1998). For PDGMSK, $B_b T_b$ is the same as that of the GMSK. The corresponding stream of rectangular pulses $r(t) = \sum_n a_n \cdot p(t - nT_b)$ where

$p(t) = 1/T_b$ when $|t| < T_b/2$, otherwise $p(t) = 0$. For the bipolar waveform, a_n belongs to the set $\{-1, +1\}$, but for the unipolar waveform, it is from the set $\{0, 2\}$. As the symbol rate decreases, the input sequence will change to a bipolar

RTZ sequence (Figure 25). However, it will become a series of pulses with a unipolar RTZ sequence (Figure 26).

Consequently, the output signal of the PDGMSK modulator can be expressed as

$$s(t) = \sqrt{\frac{2E_b}{T_b}} \cos[2\pi f_c t + \pi \cdot \sum a_n q(t - nT_b)] \quad (30)$$

Normally, phase transition function is defined as $q(t) = \int_{-\infty}^t g(\tau) d\tau$. The instantaneous frequency response of the Gaussian $g(t)$ is the same as Equation 25.

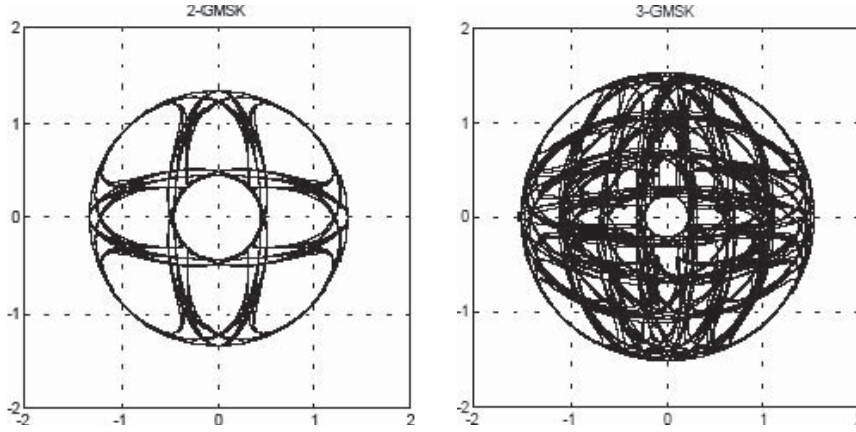

Figure 27: N-GMSK signal constellation diagrams (Javornik, Kandus, and Burr 2001)

N-GMSK

Just as its name implies, the N-GMSK signal is the superposition of N GMSK signals with different amplitudes. When $N = 1$, N-GMSK is the same as the conventional GMSK. Therefore, the N-GMSK signal can be written as

$$s(t, \alpha_1, \alpha_2, \dots, \alpha_n) = \frac{\sum_{i=1}^N s(t, \alpha_i)}{\sqrt{\sum_{i=1}^N 2^{2(i-1)}}} \quad (31)$$

where $s(t, \alpha_i) = 2^{i-1} \sqrt{2E_b/T_b} \cos(2\pi f_c t + \Phi(t, \alpha_i) + \Phi_i)$ is the i th GMSK component and $\{\alpha_i\}$ is an infinitely sequence of independent data symbols with $\alpha_i \in \{-1, +1\}$,

$i \in N \cdot \Phi(t, \alpha_i) = \pi \sum_{k=-\infty}^n \alpha_k q(t - kT_b)$, $nT_b \leq t \leq (n+1)T_b$. The phase response $q(t)$ is defined as

$$q(t) = \begin{cases} \frac{1}{2T_b} \int_0^t Q\left(2\pi B_b \frac{\tau - T_b/2}{\sqrt{\ln 2}}\right) d\tau \\ - Q\left(2\pi B_b \frac{\tau + T_b/2}{\sqrt{\ln 2}}\right) d\tau & t \geq 0 \\ 0 & t < 0 \end{cases} \quad (32)$$

where $Q(t) = \frac{1}{\sqrt{2\pi}} \int_t^\infty e^{-\frac{\tau^2}{2}} d\tau$ and B_b is the bandwidth of a

LPF having a Gaussian shaped spectrum.

Figure 27 shows the scattering diagrams for 2-GMSK and 3-GMSK with $B_b T_b = 0.3$. It is clear that the N-GMSK signals never reach the zero signal energy, which can improve the signal performance in nonlinear channels. The power spectra of the N-GMSK signals depend on modulation level and bandwidth of the Gaussian prefilter.

CONCLUSION

The fundamentals, implementations, and system impacts of MSK and GMSK have been reviewed. The overall performances of MSK and GMSK—including the coherent

and noncoherent demodulations, implementation penalty, and tolerance to transmission impairments—have been comprehensively evaluated. Some forward-looking extensions of MSK and GMSK have been briefly discussed, and they are expected to be a promising modulation format for modern wireless communication systems.

GLOSSARY

Additive white Gaussian noise (AWGN): AWGN is one channel model in which only impairment is the linear addition of wideband or white noise with a constant spectral density and a Gaussian distribution of amplitude.

Binary frequency shift keying (BFSK): A form of frequency modulation that modulates input signals by 0- and 180-degree phase shifts.

Continuous phase frequency shift keying (CPFSK): A variation of frequency shift keying; its phase is continuous.

Continuous phase modulation (CPM): A method for modulation of data commonly used in wireless modems with continuous phase.

Frequency modulation (FM): A form of modulation that represents information as variations in the instantaneous frequency of a carrier wave.

Frequency shift keying (FSK): A form of frequency modulation; its modulating signal shifts the output frequency between predetermined values.

Gaussian minimum shift keying (GMSK): A special kind of MSK; it can improve the spectral efficiency by using a Gaussian-shaped impulse response filter

I component: In-phase component

Minimum shift keying (MSK): A type of continuous phase frequency shift keying; it is encoded with bits that alternate between quaternary components, with the Q component delayed by one-half the symbol period.

Multi-amplitude minimum shift keying (MAMSK): Superposition of some MSK signals.

Non-return-to-zero (NRZ): A data transmission method in which the 0's and 1's are represented by different polarities, typically positive for 0 and negative for 1.

Offset quadrature phase shift keying (OQPSK): A variant of phase shift keying modulation; it usually

uses four different values of the phase to transmit information.

Optical minimum shift keying (OMSK): A type of continuous phase modulation used in optical communication systems in which narrower frequency deviation equals one-quarter of symbol period.

Phase-locked loop (PLL): An electronic control system that generates a signal that is locked to the phase of an input signal.

Phase shift keying (PSK): A digital modulation scheme that conveys data by changing or modulating the phase of a input signal.

Pulse-driven Gaussian minimum shift keying (PDGMSK): A special GMSK demodulator; its signal is generated by a return-to-zero (RTZ) data stream.

Q component: Quadrature component

Quadrature phase shift keying (QPSK): A form of phase modulation; it can be viewed as a quaternary modulation that uses four points on the constellation diagram that are equally spaced around a circle.

Staggered quadrature phase shift keying (SQPSK): Namely, QPSK; it is a variant of phase shift keying modulation using four different values of the phase to transmit.

Voltage controlled oscillator (VCO): An electronic oscillator specifically designed to be controlled in oscillation frequency by a voltage input.

INTRODUCTION

Evolution of Optical Transport Networks

Optical transport networks are evolving quickly to adapt to the ever-increasing demands of telecommunication needs, as most noticeably seen in the explosive growth in transmission capacity demands. The channel data rate in modern optical transport networks is migrating from 2.5 Gb/s to 10 Gb/s. A data rate of 40 Gb/s per channel is also on the horizon for commercial deployment. In addition to increases in data rate per channel, the number of channels per fiber is also increased through *wavelength-division multiplexing* (WDM) or *dense wavelength-division multiplexing* (DWDM) to further improve overall transmission capacity. Besides the demand for high capacity, optical transport networks desire long unregenerated optical transmission distance to effectively support metropolitan, regional, and national network applications. Moreover, flexible wavelength management, enabled by elements such as *reconfigurable optical add-drop multiplexers* (ROADM), is often utilized to make optical networks transparent and scalable. Optical transport networks are expected to continue to evolve to offer higher capacity, longer reach, and more flexible wavelength management and to do so with minimized operational expenditure and capital expenditure.

The evolution of optical transport networks is empowered by technological innovations in several key elements of an optical communication system, one of which is the *optical transponder*. An optical transponder consists of a transmitter that encodes information on a light wave through optical modulation and a receiver that recovers the information. An essential part of an optical transponder is its modulation format, which defines how the information is encoded at the transmitter and how it is recovered at the receiver. Furthermore, modulation format has strong system-level implications because the transmission performance of an optical signal in an optical network is related to how the signal is modulated. Different

modulation formats have different receiver sensitivities that relate to the required *optical signal-to-noise ratio* (OSNR), different spectral efficiencies, and different tolerances to transmission impairments such as *chromatic dispersion* (CD), *polarization mode dispersion* (PMD), optical filtering, and fiber nonlinearity (Forghieri, Tkach, and Chraplyvy 1997). This chapter is devoted to a specific type of optical modulation format—namely, *optical differential phase shift keying* (ODPSK).

Overview of Optical Modulation Formats

Generally, there are four basic physical attributes of a light wave that can be used through optical modulation to carry information: amplitude, phase, frequency, and polarization. The most common optical modulation format is *intensity modulation with direct detection* (IM-DD) (often called *on-off keying*, or OOK), in which the light intensity is turned on and off to represent the 1 and 0 states of a digital signal. Even though OOK has poor receiver sensitivity as compared to most other modulation formats, it is widely used in optical communications because of its simple transmitter and receiver configurations. Another common type of optical modulation is *phase modulation*. *Optical phase shift keying* (OPSK) utilizes the phase of a light wave to carry information. To recover the information, an OPSK receiver uses *homodyne detection* or *heterodyne detection* with the help of an *optical local oscillator* (OLO). The use of an OLO increases the receiver complexity and cost as compared to direct-detection receivers that do not need OLOs. Homodyne detection, however, offers superior receiver sensitivity and other benefits.

In ODPSK, information is encoded onto a light wave by the phase difference between adjacent bits and recovered by an optical demodulator followed by a direct-detection circuitry. A digital precoder is needed to ensure that the recovered data are the original data. *Optical frequency shift keying* (OFSK) and polarization shift keying are less commonly used, mainly because appropriate transmitters and

Figure 1: Constellation diagrams of OOK, duobinary, ODBPSK, ODQPSK, OD8PSK, and ODQPSK + PAM2. The average signal power is normalized to unity

receivers are less readily available and often exhibit poorer transmission performance. More than one of the four physical attributes may be simultaneously modulated to either carry more information bits per symbol or mitigate a certain transmission penalty. Ho (2005 “Phase”) provides more details on various optical modulation formats.

Constellation diagrams are often used to illustrate different modulation formats. In a constellation diagram, the real and imaginary parts of the complex fields of a modulated optical signal at the centers of bit periods are plotted. Figure 1 shows the constellation diagrams of OOK, duobinary (Price and Le Mercier 1995), *optical differential binary phase shift keying* (ODBPSK) (Giles and Reichmann 1987; Tamura et al. 1990), *optical differential quadrature phase shift keying* (ODQPSK), *optical differential eight-level phase shift keying* (OD8PSK), and a combined *ODQPSK and two-level pulse amplitude modulation* (ODQPSK+PAM2). Note that the ODPSK constellation diagrams are identical to their OPSK counterparts. By creating more states in the symbol constellation, it is possible to increase spectral efficiency or the amount of information carried in each time slot, but this approach also tends to increase the required OSNR for a given *bit error rate* (BER) because of a reduced separation between symbols. Note that the constellation diagrams, although informative, are of limited use. Details about the modulation format, such as the intensity and phase profiles over each bit period and how the symbols are distinguished from each other, are not conveyed. The following sections of this chapter present detailed descriptions on different variants of ODPK.

Figure 2: Schematic of an ODBPSK transmitter

OPTICAL DIFFERENTIAL BINARY PHASE SHIFT KEYING Implementation

This section describes the implementation of ODBPSK, including various transmitter and receiver configurations.

The ODBPSK transmitter generally consists of three components: a laser, a digital precoder, and an optical phase modulator (Gnauck and Winzer 2005) as shown in Figure 2. The laser output serves as an optical carrier, with a requirement on the maximal allowable laser linewidth. Finite laser linewidth causes phase noise that in turn causes an OSNR penalty. The penalty resulting from a given laser linewidth will be discussed in a later section. A digital precoder, which performs the differential precoding, is needed so that the recovered data are the original data. The key component of an ODBPSK transmitter is the optical phase modulator needed for optical encoding. For ODBPSK, digital data 1 or 0 is encoded as an optical phase difference of 0 or π between adjacent bits. Optical phase modulation can be realized through an electro-optical material such as lithium niobate (LiNbO_3) or gallium arsenide (GaAs), whose indexes of refraction change with an applied voltage (Heismann, Korotky, and Veselka 1997).

Two common types of modulators effectively realize phase modulation. The first is based on a single waveguide made of an electro-optical material, which is referred to as a *single-waveguide phase modulator*. The second is based on a zero-biased Mach-Zehnder interferometer with one such waveguide in each of its two arms, which is often referred to as a *Mach-Zehnder phase modulator*. Figure 3 shows the schematic diagrams of the two types. Assuming an unlimited modulator bandwidth, the output optical field from a Mach-Zehnder modulator that is biased at null can be expressed as

$$\begin{aligned}
 E_{\text{output}}(t) &= E_{\text{input}}(t) \cdot \left[e^{j \frac{V_1(t)}{V_\pi} \pi} - e^{j \frac{V_2(t)}{V_\pi} \pi} \right] / 2 \cdot e^{-j \frac{\pi}{2}} \\
 &= E_{\text{input}}(t) \cdot \sin \left[\frac{V_1(t)}{V_\pi} \pi \right]
 \end{aligned} \quad (1)$$

Figure 3: Schematic of optical phase modulators based on single-waveguide (a) and Mach-Zehnder (b) configurations

Figure 4: Operation principle of the Mach-Zehnder phase modulator for ODBPSK

where $V_1(t)$ and $V_2(t) = -V_1(t)$ are the time-varying drive voltages applied to the first and second arms of the Mach-Zehnder interferometer and V_π is the voltage needed to introduce an optical phase change of π on the optical wave passing through each of the two arms. Here an extra phase delay of $-\pi/2$ between the output and the input fields is used for convenience. Evidently, an optical phase change of exactly π is obtained when the drive voltages change signs. In addition, with a voltage swing of V_π applied to each arm, the output signal intensity is maximized. Figure 4 shows the operation principle of the Mach-Zehnder phase modulator. The dual-drive configuration can be replaced by a single-drive configuration with an internal push-pull design, in which case a voltage swing of $2V_\pi$ is desired and the modulator driver power consumption increases. The single-drive configuration removes the requirement of the precise timing alignment between V_1 and V_2 . For LiNbO_3 -based modulators, the dual-drive configuration is implemented with z -cut LiNbO_3 waveguides and the single-drive configuration with x -cut LiNbO_3 waveguides.

The single-waveguide phase modulator has the advantages of low loss, no need for bias control, and an absence of modulator bandwidth limitation-induced signal amplitude fluctuations. However, it has the drawbacks of the presence of modulator bandwidth limitation-induced phase fluctuations and a stringent drive voltage requirement for realizing the exact π phase shift. On the other hand, the Mach-Zehnder phase modulator has the advantages that the exact π phase shift can be obtained even with nonexact drive voltages, and there is no modulator bandwidth limitation-induced signal phase fluctuations. However, the use of the Mach-Zehnder phase modulator requires an accurate bias control (at extinction or null) and causes some signal amplitude fluctuations because of

limited modulator bandwidth that can be suppressed by operating the modulator in the saturation ranges of its intensity transfer function. Typically, the bias needs to be controlled within $\pm 0.1V_\pi$ around the null point to avoid noticeable penalty. Overall, the Mach-Zehnder phase modulator, because of its capability of generating exact phase modulations, is preferred over the single-waveguide phase modulator in high-speed ODBPSK transmissions.

Return-to-zero (RZ) pulse formatting is usually used in association with ODBPSK to improve its transmission performance (Xu, Liu, and Wei 2004; Gnauck and Winzer 2005). Unlike *non-return-to-zero* (NRZ) pulse formatting, RZ pulse formatting minimizes the optical intensity between any adjacent bits and offers higher receiver sensitivity and a higher degree of immunity to *intersymbol interference* (ISI), which may result from linear and nonlinear transmission effects. RZ-ODBPSK has become the modulation format of choice for many record-setting high-capacity, long-haul transmissions (Gnauck and Winzer 2005). The generation of an RZ-ODBPSK signal usually requires one modulator for pulse generation and another modulator for phase modulation as shown in Figure 5a. RZ pulse formats also have several variants such as *chirp-free RZ*, *chirped RZ* (CRZ), *carrier-suppressed RZ* (CSRZ), and $\pi/2$ *alternate-phase RZ* $\pi/2$ -AP RZ (Gnauck et al. 2004 “Comparison”). Different RZ formats have different spectral profiles that lead to different tolerances to chromatic dispersion, optical filtering, and so on. Chirped RZ format may also offer higher tolerance to nonlinear effects (Mu et al. 2002). Fully phase-correlated RZ-ODBPSK signals at 80 Gb/s and 160 Gb/s have also been demonstrated (Möller et al. 2003; Möller et al. 2004). For RZ-ODPSK, the centers of the bits need to be aligned with the peaks of the RZ pulse train. Typically, the alignment accuracy needs to be

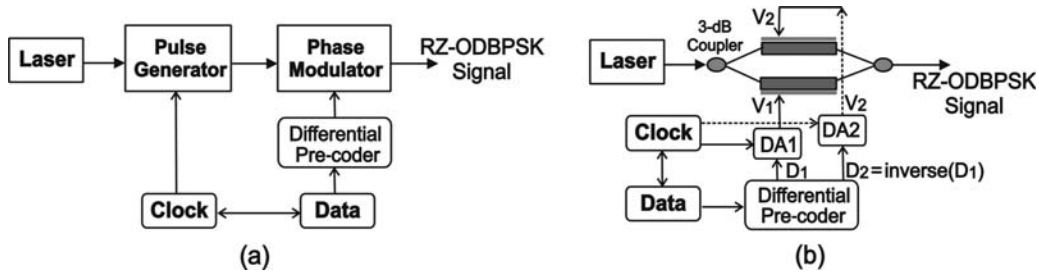

Figure 5: (a) Schematic of a RZ-ODBPSK transmitter based on two modulators; (b) schematic of a CRZ-ODBPSK transmitter based on a single dual-driver Mach-Zehnder modulator

within 20 percent of the pulse duration to avoid noticeable penalty.

To reduce the complexity of an RZ-ODPSK transmitter, a single Mach-Zehnder modulator has been used to simultaneously perform the RZ pulse formatting and phase modulation functions based on different methods (Liu and Kao 2005). Both chirp-free and chirped RZ-ODBPSK signals have been generated. Figure 5b shows the schematic of a single modulator-based chirped RZ-ODBPSK transmitter. The original data are first differentially encoded to form two complementary NRZ signal streams, D1 and D2, which are later converted to RZ format by two differential amplifiers, DA1 and DA2, with two clock signals whose frequency equals the *bit rate* (BR) (Liu and Kao 2005). The two RZ drive signals provide voltages V_1 and V_2 , which are synchronously applied to the two arms of the MZM, which is biased at null, to modulate the light from the CW laser to generate the CRZ-ODPSK signal. In this driving scheme, neither V_1 nor V_2 can be nonzero or zero simultaneously. This is because when $V_2 \neq 0$, the inverted data bit is 1 or the data bit is 0, and thus V_1 (which is the logical AND operation result for the data bit and the clock whose peak is aligned with the bit center) should be 0 and vice versa. The optical intensity transfer function can be expressed as

$$\left| \frac{E_{\text{output}}(t)}{E_{\text{input}}(t)} \right|^2 = \begin{cases} \sin^2 \left[\pi \frac{V_2(t)}{2 \cdot V_\pi} \right] & \text{when } V_1(t) = 0; \\ \sin^2 \left[\pi \frac{V_1(t)}{2 \cdot V_\pi} \right] & \text{when } V_2(t) = 0. \end{cases} \quad (2)$$

The signal optical phase can be written as

$$\text{phase}(t) = \begin{cases} \tan^{-1} \left\{ \frac{\sin[\pi \cdot V_2(t) / V_\pi]}{\cos[\pi \cdot V_2(t) / V_\pi] - 1} \right\} & \text{when } V_1(t) = 0; \\ \pi + \tan^{-1} \left\{ \frac{\sin[\pi \cdot V_1(t) / V_\pi]}{\cos[\pi \cdot V_1(t) / V_\pi] - 1} \right\} & \text{when } V_2(t) = 0. \end{cases} \quad (3)$$

Apparently, there is an identical phase variation or chirp across each bit when V_1 and V_2 have the same nonzero temporal profile. Upon differential detection, what matters

Figure 6: Schematic of an ODBPSK receiver

is only the phase difference between adjacent bits, which is either 0 or π , as needed for ODBPSK encoding. The sign and magnitude of the chirp can be changed by varying V_1 and V_2 .

An interesting variant of DBPSK is $\pi/2$ -ODBPSK (Wei et al. 2003). The $\pi/2$ -ODBPSK format differs from ODBPSK in that the phase between successive bits always changes by plus or minus 90 degrees. A $\pi/2$ -RZ-ODBPSK format has been realized by ODBPSK combined with $\pi/2$ -AP RZ pulse formatting. This format has been shown to yield slightly better receiver sensitivity when tight optical filtering is used, as well as better tolerance to polarization mode dispersion when filtering is present (Wei et al. 2003).

The ODBPSK receiver generally consists of three components: a one-bit *optical delay interferometer* (ODI), a balanced detector, and *clock and data recovery* (CDR) circuitry, as shown in Figure 6. The one-bit ODI is needed for demodulating the ODBPSK signal into two complementary OOK signals that can be directly detected by intensity detectors. The signal is first split into two paths that have a certain path difference so that the signal at the end of one path is delayed by approximately one bit period, denoted as T , with respect to that of the other path. This effectively causes two adjacent bits to interfere with each other; depending on their phase difference of 0 or π , they interfere constructively or destructively. The constructively and destructively interfered signal components exit the ODI through its constructive and destructive output ports, respectively, and are detected by a balanced detector that consists of two matched photodiodes. The photocurrents generated by the two matched photodiodes are subtracted, and the current difference is then converted to a voltage difference before it is used for CDR with a nominal decision threshold at approximately zero. The CDR circuitry can be similar to those conventionally used for OOK detection. Mathematically, the *decision variable* (DV) can be expressed as

$$DV_{\text{ODBPSK}}(t) = \text{Re}[E_{\text{RX}}(t) \cdot E_{\text{RX}}^*(t - T)] \quad (4)$$

where E_{RX} is the normalized optical field of the ODBPSK signal entering the receiver, $\text{Re}[x]$ is the real part of a complex variable x and $*$ denotes to complex conjugate.

The ODIs are commonly made based on an all-fiber design, a planar light wave circuit design, a free-space optics design (Liu et al. 2005 “Athermal”), or a LiNbO₃ platform (Cho et al. 2004). Note that a precise phase control of the phase difference between the two optical paths of the ODI is required. The penalty associated with a nonexact phase difference will be discussed in a later section. Because the phase difference may be changed by environmental temperature, accurate temperature control and stabilization of the ODI are usually required. Athermal ODIs have been demonstrated by using a free-space optics design. They are capable of demodulating 40-Gb/s ODBPSK signals that are on the ITU 50-GHz grid over the entire C+L band in the temperature range of 0 to $\sim 70^\circ\text{C}$ (Liu et al. 2005 “Athermal”). In addition to temperature changes, laser frequency drifts also affect the phase difference, so the ODI is desired to be able to track the laser frequency drifts and adjust the phase difference accordingly.

Balanced detectors are usually used for ODBPSK in order to take advantage of the higher receiver sensitivity offered by ODBPSK over OOK. Without taking the receiver sensitivity advantage, an ODBPSK signal can be received by a single detector that detects the signal component from either the constructive port or the destructive port of the ODI. Effectively, the signal components from

the constructive and destructive ports are of the optical duobinary format and the alternating mark-inversion format (Gnauck et al. 2004 “Comparison”), which exhibit unique spectrum characteristics. Figure 7 shows typical simulated optical spectra of an ODBPSK signal, and its filtered components from the constructive and destructive ports of a one-bit ODI. Figure 8 shows the simulated ODBPSK eye diagrams measured by a balanced detector and a single detector. The optical and electronic bandwidths of the receiver are assumed to be $2\times$ and $1\times$ the signal data rate, respectively. The eye diagrams measured at the constructive and destructive ports of the ODI are different because of the NRZ formatting of the ODBPSK signal and the optical filtering induced destructive interference between any adjacent bits that are out of phase by π . The special optical duobinary signal format is also referred to as *DI-duobinary*, which, like conventional optical duobinary, offers high tolerance to chromatic dispersion tolerance and optical filtering.

Back-to-Back Performance

In this section, we evaluate the performance of ODBPSK in the back-to-back configuration without considering optical fiber transmission penalties. Because optical *amplified spontaneous emission* (ASE) noise is the predominate noise source in optical transport systems where optical amplifiers are extensively used, we evaluate receiver

Figure 7: Typical spectra of an ODBPSK signal and its filtered components from the constructive and destructive ports of a one-bit ODI. The spectral resolution is 5 percent of the BR

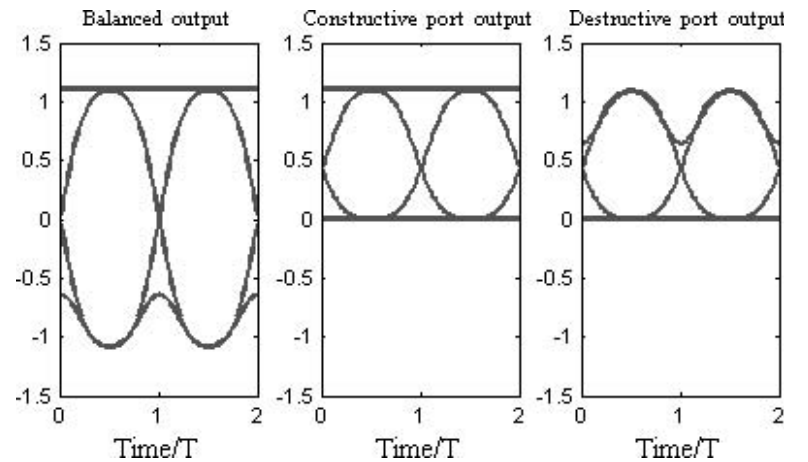

Figure 8: Typical ODBPSK eye diagrams detected by a balanced detector, and a single detector at the constructive and destructive ports of the ODI

sensitivity in terms of the required optical signal-to-noise ratio for a given bit error rate and assess the performance degradation caused by a given impairment in terms of the increase in the required OSNR (or the OSNR penalty) it causes. We first briefly introduce the common numerical methods for performance evaluation of ODPSK and then describe the ideal receiver sensitivity of ODBPSK, followed by implementation penalties caused by various imperfections in the transmitter and receiver designs.

Numerical methods for performance evaluation of a given optical modulation format are important because they provide a theoretical guidance on the upper bond of the performance of the format, as well as the individual and combined impacts of various degradation sources. Numerical performance evaluation often provides insights that are not readily available from experimental investigations. There are three main categories of numerical methods based on analytical modeling, semi-analytical modeling, and Monte Carlo simulation. Among the three categories, methods based on Monte Carlo simulation are most versatile because they are capable of taking into consideration virtually all of the system aspects, including various nonlinear effects. They are, however, most time-consuming. They are thus often used for evaluating system performance at high BER values (e.g., higher than $1\text{E-}5$). This may be sufficient for optical transport systems that adopt *forward error correction* (FEC), and the raw BER values of interest are in the range between $1\text{E-}2$ and $1\text{E-}5$. A new type of Monte Carlo simulation method called the *multicanonical Monte Carlo* (MMC) method (Yadin, Shtaif, and Orenstein 2005) has been shown to provide a relatively more efficient way of estimating system performances at low BER values. The MMC method is based on an iterative technique that is designed to more quickly obtain the probabilities of rare events by applying proper biasing to randomly generated noise vectors in Monte Carlo simulations.

Analytical methods, on the other end of the spectrum, provide especially fast performance evaluations and often offer clear physical intuitions on the impacts of individual impairments. The trade-off is that assumptions, sometimes oversimplified, have to be made to derive analytical descriptions of an optical transmission system. For example, matched optical filtering is usually assumed in the receiver in order to obtain analytical description of the *probability density function* (PDF) of the decision variable. Simplified fiber transmission-link configurations are often used to analytically describe nonlinear effects. A simple yet useful performance indicator of an ODPSK signal is the differential phase Q-factor introduced by Wei, Liu, and Xu (2003 “Q factor”). When the phase noise can be approximated as Gaussian-distributed, it offers quick assessment of the signal quality in both linear (Wei et al. 2003 “Q factor”) and some nonlinear regimes (Wei, Liu, and Xu 2003 “Numerical”).

Semi-analytical methods are between the analytical and Monte Carlo methods in terms of needed computational efforts. Most linear and nonlinear impairments result in bit pattern-dependent ISI. Semi-analytical methods can take into consideration the bit pattern-dependent ISI by averaging the BERs over all possible bit patterns while each BER may be analytically calculated with a known

PDF of the decision variable. When only linear effects are considered and the noise is Gaussian-distributed, there is a useful technique called the *Karhunen–Loève series expansion* (KLSE). In the KLSE, the signal and noise are expanded into Karhunen–Loève series (Proakis 2000) so that the *moment generation function* (MGF) of the decision variable, which is related to the PDF through Laplace transformation, can be expressed in a closed form. The BER values can then be obtained through numerical integrations. The KLSE method is applicable for assessing the impact of various linear effects such as optical and electrical filtering in the receiver (Winzer, Chandrasekhar, and Kim 2003; Bosco and Poggiolini 2005), chromatic dispersion, and PMD (Wang and Kahn 2004).

For simplicity and clarity, most performance assessments presented in this chapter will be based on analytical methods, particularly when discussing linear effects. Semi-analytical and Monte Carlo methods will be used primarily for studying nonlinear effects.

Receiver sensitivity indicators are useful for representing the performance of a receiver for a signal with a certain modulation format. In an optically pre-amplified receiver, its receiver sensitivity is usually indicated by the required *signal-to-noise ratio per bit*, SNR_b , for achieving a given BER. The SNR_b is defined as

$$\text{SNR}_b = \frac{\varepsilon_b}{N_0} = \frac{P_s}{N_0 \cdot BR} \quad (5)$$

where ε_b is the signal energy per bit, P_s is the signal power, N_0 is the ASE noise spectrum density per polarization, and BR is the bit rate of the signal. The physical meaning of the SNR_b is the ratio between the signal power and the power of the single polarized optical noise within a bandwidth of the signal bit rate.

A conventionally used term to represent the SNR in optical fiber communications is OSNR, defined as the ratio between the signal power and the power of optical noise of two polarization states within a fixed bandwidth of 0.1 nm (or 12.5 GHz at a signal wavelength of approximately 1550 nm). OSNR relates to SNR_b as

$$\text{OSNR} = \frac{\text{SNR}_b \cdot BR}{2 \cdot 12.5 \text{ GHz}} \quad (6)$$

As an example, at bit rates of 10 Gb/s and 40 Gb/s, the OSNR values are approximately -4 dB and 2 dB higher than the SNR_b values, respectively.

Another commonly used indicator for the receiver sensitivity of an optically pre-amplified receiver is the required number of *photons per bit* (PPB) to achieve a given BER. The PPB of the input signal is related to the SNR_b of the amplified signal as

$$\text{PPB} = n_{sp} \times \text{SNR}_b \quad (7)$$

where n_{sp} is related to the *noise figure* (NF) of the optical pre-amplifier. For an ideal optical pre-amplifier which has a NF of 3 dB or $n_{sp} = 1$ (Ho 2005 “Phase”), SNR_b and PPB happen to be equal.

Optimal receiver sensitivity is obtained when the receiver uses a matched optical filter and no postdetection electrical filter (Proakis 2000; Ho 2005 “Phase”). For homodyne or heterodyne OBPSK, we have the following dependence of BER on SNR_b :

$$\text{BER}_{\text{OBPSK}} = \frac{1}{2} \text{erfc}(\sqrt{\text{SNR}_b}) \quad (8)$$

For direct-detection ODBPSK with polarization filtering at the receiver so that only the noise component whose polarization is aligned with that of the signal is detected with the signal, we have

$$\text{BER}_{\text{ODBPSK}_{1p}} = \frac{\exp(-\text{SNR}_b)}{2} \quad (9)$$

For direct-detection ODBPSK without polarization filtering at the receiver, we have

$$\text{BER}_{\text{ODBPSK}_{2p}} = \frac{\exp(-\text{SNR}_b)}{2} \left(1 + \frac{\text{SNR}_b}{4} \right) \quad (10)$$

For direct-detection OOK with polarization filtering at the receiver, we have

$$\text{BER}_{\text{OOK}_{1p}} = \frac{1}{2} \left[1 - Q \left(2\sqrt{\text{SNR}_b}, 2\sqrt{\text{SNR}_b \cdot V_{th}} \right) \right] + \frac{1}{2} \exp(-2\text{SNR}_b \cdot V_{th}) \quad (11)$$

where V_{th} is the decision threshold normalized to the signal peak power, and $Q(a, b)$ is the first-order Marcum Q function (Weisstein 2005):

$$\begin{aligned} Q(a, b) &= e^{-(a^2+b^2)/2} \cdot \sum_{m=0}^{\infty} \left(\frac{a}{b} \right)^m I_m(ab), \quad a \leq b \\ &= 1 + e^{-(a^2+b^2)/2} I_0(ab) \\ &\quad - e^{-(a^2+b^2)/2} \cdot \sum_{m=0}^{\infty} \left(\frac{b}{a} \right)^m I_m(ab), \quad a > b \end{aligned} \quad (12)$$

Figure 9: The optimal BER performances of OBPSK, ODBPSK, and OOK with and without polarization filtering (PF)

where $I_m(x)$ is the m th-order modified Bessel function of the first kind. The optimal decision threshold satisfies

$$I_0 \left(4\text{SNR}_b \cdot \sqrt{V_{th}} \right) \exp(-2\text{SNR}_b) = 1 \quad (13)$$

The optimal BER for direct-detection OOK can thus be numerically calculated by solving Equations 11 through 13.

For direct-detection OOK without polarization filtering at the receiver, we have (Ho 2005 “Phase”)

$$\begin{aligned} \text{BER}_{\text{OOK}_{2p}} &= \frac{1}{2} \left[1 - Q_2 \left(2\sqrt{\text{SNR}_b}, 2\sqrt{\text{SNR}_b \cdot V_{th}} \right) \right] \\ &\quad + \frac{1}{2} \exp(-2\text{SNR}_b \cdot V_{th}) \cdot (1 + 2\text{SNR}_b \cdot V_{th}) \end{aligned} \quad (14)$$

where

$$Q_2(a, b) = Q(a, b) + \frac{b}{a} e^{-(a^2+b^2)/2} \cdot I_1(ab) \text{ and the optimal decision threshold can be numerically calculated.}$$

Figure 9 shows the BER performances of OBPSK, ODBPSK, and OOK with and without *polarization filtering* (PF). Table 1 summarizes the receivers’ sensitivities at $\text{BER} = 1\text{E-}3$ and $1\text{E-}9$ for the above signal formats.

Table 1: Receiver Sensitivity Comparison among Different Binary Signal Formats

		ODBPSK			OOK	
		OBPSK	with PF	no PF	with PF	no PF
$\text{BER} = 10^{-9}$	PPB	18	20	22	38.3	40.7
	SNR_b	12.5 dB	13 dB	13.4 dB	15.8 dB	16.1 dB
	$\text{OSNR}_{10\text{G}}$	8.5 dB	9 dB	9.4 dB	11.8 dB	12.1 dB
$\text{BER} = 10^{-3}$	PPB	4.8	6.2	7.2	11.2	12.7
	SNR_b	6.8 dB	8 dB	8.6 dB	10.5 dB	11 dB
	$\text{OSNR}_{10\text{G}}$	2.8 dB	4 dB	4.6 dB	6.5 dB	7 dB

Ideal optical pre-amplifier with $\text{NF} = 3$ dB assumed. $\text{OSNR}_{10\text{G}}$ is the required OSNR values for a 10-Gb/s signal.

With polarization filtering at the receiver, the receiver sensitivity of ODBPSK is slightly worse than that of the OBPSK: approximately 0.45 dB at $\text{BER} = 10^{-9}$. This penalty is often referred to as *the differential detection penalty*. The differential detection penalty increases for ODPSK formats that have more than two symbols per bit, as will be discussed in later sections. Without polarization filtering, the receiver sensitivity of ODBPSK is further worsened by approximately 0.4 dB at $\text{BER} = 10^{-9}$. Two commonly used modulation and detection configurations are direct-detection ODBPSK and OOK that does not have the polarization filtering. The ODBPSK outperforms the OOK by approximately 2.7 dB at $\text{BER} = 10^{-9}$: This is commonly referred to as the *3-dB advantage of ODBPSK over OOK* in optical transmissions.

Implementation impairments result in degradations in receiver sensitivity. The most significant impairment in a back-to-back ODBPSK transmitter-receiver configuration is the phase error resulting from nonexact phase matching between the two arms of the ODI. The phase error usually comes from temperature-induced phase mismatch or laser frequency offset from the passband center of the ODI. With the consideration of the phase error, we have for direct-detection ODBPSK with polarization filtering at the receiver (Ho 2005 "Phase")

$$\begin{aligned} \text{BER}_{\text{ODBPSK}_1p} &= Q(a, b) - \frac{1}{2} e^{-(a^2+b^2)/2} \cdot I_0(ab), \\ a &= \sqrt{2\text{SNR}_b} \left| \sin(\phi_e / 2) \right|, \\ b &= \sqrt{2\text{SNR}_b} \left| \cos(\phi_e / 2) \right|, \end{aligned} \quad (15)$$

where ϕ_e is the phase error, and $I_0(x)$ is the zero-order modified Bessel function of the first kind, and $Q(a, b)$ is the first-order Marcum Q function.

For direct-detection ODBPSK without polarization filtering at the receiver, we have

$$\begin{aligned} \text{BER}_{\text{ODBPSK}_2p} &= Q(a, b) - \frac{1}{2} e^{-(a^2+b^2)/2} \cdot I_0(ab) \\ &\quad + \frac{1}{8} e^{-(a^2+b^2)/2} \left(\frac{b}{a} - \frac{a}{b} \right) \cdot I_0(ab), \end{aligned} \quad (16)$$

where the last term on the right-hand side of the equation represents the error contribution from the noise component whose polarization is orthogonal to that of the signal. When the phase error becomes zero, Equations 15 and 16 reduce to Equations 9 and 10, respectively. Figure 10 shows the OSNR penalty as a function of the phase error for direct-detection ODBPSK.

The phase error that results from laser frequency offset, f_e , can be expressed as

$$\phi_e = 2\pi \frac{f_e}{\text{FSR}} \approx 2\pi \frac{f_e}{\text{BR}} \quad (17)$$

where FSR is the free spectral range of the ODI. Usually, the FSR of the ODI equals the bit rate of the ODBPSK signal, and thus the phase error resulting from a same laser frequency offset or uncertainty decreases as the bit

Figure 10: The OSNR penalty as a function of the phase error for direct-detection ODBPSK without polarization filtering at $\text{BER} = 10^{-9}$ and $\text{BER} = 10^{-3}$

Figure 11: The OSNR penalty (at $\text{BER} = 10^{-3}$) as a function of the laser frequency offset in 10-Gb/s and 40-Gb/s ODBPSK system using one-bit ODIs. No polarization filtering is used

rate of the ODBPSK signal increases. Note that any laser has a finite linewidth or frequency jitter that causes random phase errors with a given distribution (e.g., the Lorentzian distribution) and degrades the performance of ODPSK. The linewidth of commonly used DFB lasers is on the order of a few megahertz, which causes negligible penalty for ODPSK signals with bit rates of multigigabits per second. However, laser frequency drift resulting from temperature and aging may cause sufficiently large frequency offset (e.g., > 1 GHz) and severe degradation of the ODPSK performance. Figure 11 shows the OSNR penalty as a function of the laser frequency offset in 10-Gb/s and 40-Gb/s ODBPSK systems. In addition, the phase error because of a certain temperature change of the ODI is proportional to the length difference between the two arms of the ODI, which is inversely proportional to the signal bit rate. So the higher the signal rate, the higher the tolerance of the direct-detection ODBPSK to laser frequency uncertainties and temperature changes at the receiver. This makes ODBPSK particularly suitable for high-speed optical transmissions.

Another receiver imperfection is the nonexact one-bit delay of the ODI. ODBPSK is more tolerant to the delay mismatch than RZ-ODBPSK. Negligible OSNR penalty was observed when an ODI with a FSR of 50 GHz was used for demodulating a 42.7-Gb/s ODBPSK signal (Liu et al. 2005 “Athermal”). The use of 50-GHz ODI, when its passband is also locked on the ITU grid, has the advantage of being able to demodulate any or multiple ITU-specified WDM ODBPSK channels.

Other receiver imperfections such as the arrival time mismatch and amplitude mismatch between the two electrical signals detected by the balanced detector and receiver also contribute to the degradation of the ODBPSK receiver sensitivity. Generally, the associated penalties become negligible when the time and amplitude mismatches are less than 5 percent of the bit period and nominal amplitude, respectively (Gnauck and Winzer 2005). Because the amplitude mismatch is related to the finite common-mode rejection of the balanced detector, so the required common-mode rejection is desired to be higher than approximately 13 dB.

Transmission Performance

Generally, optical signals experience loss, chromatic dispersion, polarization mode dispersion, and fiber nonlinearity during propagation in fiber. The propagation equations governing the evolution of the slow varying amplitudes of the two polarization components of an optical field, A_x and A_y , satisfy (Agrawal 2001)

$$\begin{aligned} \frac{\partial A_x}{\partial z} + \beta_{1x} \frac{\partial A_x}{\partial t} + \frac{j}{2} \beta_2 \frac{\partial^2 A_x}{\partial t^2} + \frac{\alpha}{2} A_x \\ = j\gamma \left(|A_x|^2 + \frac{2}{3} |A_y|^2 \right) A_x + \frac{j\gamma}{3} A_x^* A_y^2 \exp(-2j\Delta\beta z) \\ \frac{\partial A_y}{\partial z} + \beta_{1y} \frac{\partial A_y}{\partial t} + \frac{j}{2} \beta_2 \frac{\partial^2 A_y}{\partial t^2} + \frac{\alpha}{2} A_y \\ = j\gamma \left(|A_y|^2 + \frac{2}{3} |A_x|^2 \right) A_y + \frac{j\gamma}{3} A_y^* A_x^2 \exp(2j\Delta\beta z) \end{aligned} \quad (18)$$

where $\Delta\beta = \beta_x - \beta_y$ is the wave-vector mismatch between the two polarization components, α is the fiber loss coefficient, β_2 is related to fiber chromatic dispersion coefficient as

$$D(z) = -\frac{2\pi c}{\lambda^2} \beta_2(z) \quad (19)$$

β_{1x} and β_{1y} , and is related to *differential group delay* (DGD) between the two polarization components as

$$\text{DGD}(z \rightarrow z + dz) = |\beta_{1x} - \beta_{1y}| dz \quad (20)$$

and γ is the fiber nonlinear coefficient. The conventional units for the fiber CD coefficient, DGD (or first-order PMD), and fiber nonlinearity are ps/km/nm, ps, and W/km, respectively.

Tolerance of ODBPSK to Chromatic Dispersion

Chromatic dispersion causes pulse broadening in the time domain that leads to ISI and consequently degrades the receiver sensitivity of an optical signal. The tolerance to CD is usually defined as the allowed CD range, $[CD_{\min}, CD_{\max}]$ (in units of ps/nm), within which the receiver sensitivity penalty is less than a given value—for example, 2 dB. For signals with chirp-free modulation formats, $CD_{\max} = -CD_{\min}$, and

$$CD_{\max} = \frac{P}{SR^2} \quad (21)$$

where SR is the symbol rate of the signal and p is a factor that depends on the signal pulse format and modulation format. The SR of a signal is its bit rate divided by $\log_2(N_s)$, where N_s is the number of the symbols in the constellation diagram of the signal format. The CD tolerance decreases quadratically with the increase of the signal bit rate for a same format. NRZ pulse-formatted signals, because of their relatively narrow optical spectra, usually have higher CD tolerance than RZ pulse-formatted signals. Optically filtered signals usually also offer higher CD tolerance than unfiltered or less filtered signals. The CD tolerance of ODBPSK is found to be higher than that of OOK (Wang and Kahn 2004). This can be partially attributed to the fact that in ODBPSK, a moderate CD causes primarily phase distortions instead of amplitude distortions, and the phase distortions on adjacent bits are correlated (Liu, Mollenauer, and Wei 2004).

Tolerance of ODBPSK to Polarization Mode Dispersion

Polarization mode dispersion is one of the major obstacles in high-speed (e.g., 40-Gb/s) long-haul transmissions. ODBPSK is found to have a slightly higher PMD tolerance than OOK (Xie et al. 2003). Because of the stochastic nature of PMD and its wavelength dependence, PMD mitigation is normally done on a per-channel basis through *PMD compensation* (PMDC). From a system perspective, cost-effective PMD mitigation is essential. Although forward error correction is effective in correcting random errors, it is ineffective in the presence of PMD-induced burst errors. It is found that substantial improvement in PMD tolerance can be achieved over a broad bandwidth by using *distributed fast polarization scramblers* (D-FPSs) and FEC (Liu et al. 2005 “Demonstration”). The D-FPSs physically change the instantaneous PMD of an optical link in a time interval shorter than the FEC code’s *burst error correction period* (BECP) so that PMD-induced burst errors can be effectively corrected. It is also shown that this PMD mitigation scheme is even more effective for ODBPSK with balanced detection than for OOK. Substantial improvement in PMD tolerance was achieved in an ODBPSK system that uses a standard *Reed-Solomon FEC code* (RS-FEC) and an *enhanced FEC* (eFEC) code with a 7 percent overhead (Liu et al. 2005 “Improved”). It was also found that the PMD mitigation scheme remains effective in the presence of moderate polarization-dependent loss (Liu et al. 2005 “Demonstration”). Figure 12 shows the simulated relative required OSNR as a function of the

Figure 12: Simulated relative required OSNR at $\text{BER} = 10^{-15}$ versus $\langle \text{DGD} \rangle$ in NRZ-DPSK systems that use the RS-FEC or the eFEC

Table 2: PMD Tolerance of NRZ-DPSK (at 2-dB Penalty)

	Without FEC	With RS-FEC	With eFEC
Without D-FPSs	$0.185 T$	$0.170 T$	$0.155 T$
With D-FPSs	$0.185 T$	$0.310 T$	$0.375 T$

mean DGD divided by the bit period T , denoted as DGD/T . Table 2 summarizes the PMD tolerance in ODBPSK systems that employ the RS-FEC or eFEC code without and with the use of D-FPSs. The targeted output BER is 10^{-15} . Evidently, the improvements in PMD tolerance are further increased by D-FPSs in systems that use eFEC than in systems that use RS-FEC. Note also that without the use of D-FPSs, the PMD tolerance of systems with the eFEC is actually lower than that with the RS-FEC.

Tolerance of ODBPSK to Optical Filtering

Optical filters are widely used in optical transport systems. Optical filters are often used in wavelength routing elements for optical add drop functions. High tolerance to optical filtering is desired for modern networks because signals tend to pass multiple *optical add drop multiplexers* (OADMs) with many filters. Generally, the signal quality is affected by the passband characteristics of a filter in terms of its bandwidth, loss ripple, and phase ripple or *group-delay ripple* (GDR). ODBPSK with balanced detection is found to be more tolerant of tight optical filter bandwidth than conventional OOK with the same data rate (Gnauck and Winzer 2005). This is related to the high tolerance of ODBPSK to ISI (Gnauck and Winzer 2005). Loss ripple and phase ripple are common imperfections of optical filters. The signal degradation resulting from these ripples depends on the ripple period, ripple magnitude, and how the signal center frequency is located with respect to the ripple peaks. The degradation can become most severe when the ripple period coincides with the signal bit rate. It is also found that the degradation

resulting from the ripple is dependent on the phase relationship among the signal bits (Liu, Mollenauer, and Wei 2004). Therefore, the loss and phase ripples influence ODBPSK signals differently as compared to OOK signals. For example, ODBPSK, unlike OOK, is highly tolerant to phase ripple when a peak or valley is aligned with the signal center frequency. As another example, optical duobinary signal has a compact optical spectrum and high tolerance to narrow optical filter bandwidth, but it is especially sensitive to phase ripple. In an optical transmission system with multiple optical filters, judicious control of the loss and phase ripples in filters is necessary to minimize the overall penalty of a given signal because of the concatenated filtering. Finally, optical filters generally exhibit finite extinction ratios that may cause coherent cross talk that is detrimental to signal quality. ODPSPK is found to have higher tolerance to coherent cross talk than OOK (Liu et al. 2004 “Tolerance”), which makes it a good candidate in transparent optical networks with multiple filters.

Tolerance of ODBPSK to Fiber Nonlinearity

Nonlinear effects in WDM optical transmissions can be categorized into intrachannel nonlinear effects and interchannel effects (Essiambre, Raybon, and Mikkelsen 2002). Interchannel effects include *cross-phase modulation* (XPM) and *four-wave mixing* (FWM) among different wavelength channels, and intrachannel effects include *self-phase modulation* (SPM), *intrachannel XPM* (IXPM), and *intrachannel FWM* (IFWM). For ODPSPK, there is a unique type of nonlinear effect, commonly referred to as the *Gordon-Mollenauer effect*, which was first reported by Gordon and Mollenauer (1990). The Gordon-Mollenauer effect causes nonlinear phase noise by converting the ASE noise-induced signal amplitude fluctuations to phase fluctuations through SPM. The Gordon-Mollenauer effect can be extended to the generation of nonlinear phase noise resulting from the interaction of ASE noise and the XPM. Generally, these nonlinear effects degrade signal quality by introducing distortions and noises in signal amplitude and phase. Phase distortions and noises are minor concerns in OOK, but they are important and sometimes major concerns for ODBPSK. The importance of each nonlinear effect in a particular optical transmission system depends on the system parameters. The FWM among different wavelength channels is usually managed to have minimal impact in modern dispersion-managed WDM transmission systems. For WDM systems with tighter channel spacing, the XPM among wavelength channels becomes more important. For single-channel effects, SPM and Gordon-Mollenauer effect are of primary concerns in systems where adjacent optical pulses are not severely overlapping during transmission, as in most 10 Gb/s systems, while the IFWM and IXPM become primary concerns in systems where adjacent optical pulses are severely overlapping during transmission, as in most 40 Gb/s systems. A simple assessment of the signal quality after nonlinear transmission is given by the differential phase Q factor (Wei, Liu, and Xu 2003 “Q factor”) described next. The impact of the Gordon-Mollenauer phase noise and the IFWM-induced phase and amplitude distortions on ODBPSK will be briefly discussed.

The differential-phase Q factor is defined as

$$Q_{\Delta\phi} = \frac{\pi}{\sigma_{\Delta\phi,0} + \sigma_{\Delta\phi,\pi}} \quad (22)$$

where $\sigma_{\Delta\phi,0}$ and $\sigma_{\Delta\phi,\pi}$ are, respectively, the standard deviations of the differential phase between two adjacent bits on the 0 and π rails, where the phase noise is caused by the ASE noise and the Gordon-Mollenauer effect. The bit error rate of the signal can be obtained by

$$\text{BER} = \text{erfc}\left(\frac{Q_{\Delta\phi}}{\sqrt{2}}\right) \quad (23)$$

The simple method assumes that the nonlinear phase noise is Gaussian-distributed, which is an approximation that is valid in some nonlinear transmission systems. In Gordon-Mollenauer noise-limited systems, this method is found to qualitatively reproduce the result obtained from the direct error counting method except for a relatively small offset. This method captures the essence of the SPM penalty in ODPSK systems and predicts the optimum launch power quite accurately. The optimum signal power in a DPSK system is found to correspond to a mean SPM-induced nonlinear phase shift of approximately 1 radian (Gordon and Mollenauer 1990; Wei, Liu, and Xu 2003 “Numerical”). The nonlinear phase noise from single-channel Gordon-Mollenauer effect can be effectively reduced by a lumped *nonlinear phase shift compensation* (NPSC) scheme (Liu et al. 2002; Hansryd, van Howe, and Xu 2005). Signal Q-factor improvement of as much as 6 dB can be realized by NPSC. The effectiveness of NPSC is reduced in DWDM transmission, particularly when the channel spacing is small, because interchannel XPM-induced phase noise cannot be compensated by NPSC.

In dispersion-managed 40-Gb/s transmissions, the Gordon-Mollenauer effect is usually much reduced because of strong pulse breathing. A major nonlinear penalty in 40-Gb/s ODBPSK is IFWM-induced phase and amplitude distortions. Remarkably, it is found that ODBPSK suffers less IFWM penalty than OOK with the same average power. This is attributed to the fact that signal peak power is lower in ODBPSK than OOK with the same average power,

and there exists a correlation between the IFWM-induced nonlinear phase shifts of any two adjacent bits (Wei and Liu 2003). Figure 13 shows the simulated phasor diagrams of a 40-Gb/s RZ-OOK signal and a 40-Gb/s RZ-ODBPSK signal that have the same average power after transmission over a symmetrically dispersion-managed link. The simulated signal pattern is a PRBS of length $2^9 - 1$, which is sufficient for capture most of the intrachannel nonlinear interactions in the dispersion-managed transmission. Evidently, there is a severe eye-closure penalty in the OOK signal because of the generation of ghost pulses while ODBPSK suffers relatively smaller eye closure in the phase domain (see the center subplot). It is interesting that the variance of differential phase, as shown in the right subplot, is almost the same as (instead of twice as large as) that of the absolute phase, showing a strong correlation between the IFWM-induced phase noises of two adjacent bits. Experimentally, ODBPSK is also found to offer higher tolerance to nonlinear effects than OOK in most pulse-overlapped 40-Gb/s transmissions (Gnauck and Winzer 2005).

A semi-analytical method has been developed to estimate the BER of an optical channel by taking into consideration the deterministic phase and amplitude distortions resulting from the IFWM (Ho 2005 “Error”; Wei et al. 2006). The overall BER can be obtained by

$$\text{BER} = \sum_{i=1}^N \text{BER}_i \quad (24)$$

where BER_i is the expected BER for the i th bit out of a simulated N -bit sequence, which can be analytically calculated by

$$\text{BER}_i = Q(a_i, b_i) - \frac{1}{2} e^{-(a_i^2 + b_i^2)/2} I_0(a_i b_i) \quad (25)$$

where $Q(a, b)$ is the first-order Marcum Q function described in Equation 12 and

$$a_i = \sqrt{\frac{\text{SNR}_b}{2}} |\Delta u_i - \Delta u_{i-1}|, \quad b_i = \sqrt{\frac{\text{SNR}_b}{2}} |2 + \Delta u_i + \Delta u_{i-1}| \quad (26)$$

Figure 13: Simulated phasor diagrams showing the amplitude and phase at the centers of signal bits in RZ-OOK (left) and RZ-ODBPSK (center), and the mean amplitude of adjacent bits and differential phase between them in RZ-ODBPSK (right) after pulse-overlapped nonlinear transmission

where Δu_i is the normalized complex amplitude of the IFWM-induced ghost pulse in the i th bit, which can be obtained by numerically solving the governing signal propagation equation (e.g., Equation 18) with the ASE noise excluded. It is found that the IFWM penalty depends on a dispersion map, and a symmetric dispersion map gives smaller IFWM penalty than a nonsymmetric dispersion map (Wei et al. 2006). This is attributed to the absence of the IFWM-induced amplitude fluctuations when a symmetric map is used.

OPTICAL DIFFERENTIAL MULTILEVEL PHASE SHIFT KEYING

Optical differential quadrature phase shift keying (ODQPSK) is a promising modulation format (Griffin 2005) that offers doubled spectral efficiency as compared to ODBPSK and suffers only slightly in terms of receiver sensitivity.

Implementation of ODQPSK

The transmitter for ODQPSK is similar to that for ODBPSK except that the phase modulator should be able to generate four differential-phase levels ($0, \pi/2, \pi$, and 1.5π) rather than two levels (0 and π) as in ODBPSK; a different precoder is also needed. These four phase levels can be generated by using a nested Mach-Zehnder modulator or using a Mach-Zehnder modulator together with a single-waveguide phase modulator that encodes a 0 or $\pi/2$ phase modulation. A nested Mach-Zehnder modulator is usually preferred because exact phase levels are more readily achievable as discussed earlier. Figure 14 shows the schematic of an ODQPSK transmitter consisting of a nested Mach-Zehnder modulator for phase encoding. Figure 14 also shows the schematic of an ODQPSK receiver, which consists of two ODIs to demodulate the *in-phase* (I) and *quadrature* (Q) tributaries of the signal and two balanced detectors. Mathematically, the two decision variables can be expressed as

$$\begin{aligned} DV_I(t) &= \text{Re}[e^{j\pi/4} E_{RX}(t) \cdot E_{RX}^*(t-T)] \\ DV_Q(t) &= \text{Im}[e^{j\pi/4} E_{RX}(t) \cdot E_{RX}^*(t-T)] \end{aligned} \quad (27)$$

where E_{RX} is the normalized optical field of the ODQPSK signal entering the receiver, and $\text{Re}[x]$ and $\text{Im}[x]$ are,

respectively, the real and imaginary parts of a complex variable. Note that the ODQPSK demodulator can be simplified by using an optical hybrid with a single optical delay (Cho et al. 2004; Doerr et al. 2005)

For the optical encoding and detection configurations shown in Figure 14, the relations among the precoder outputs and the original data are shown in Table 3 (Ho 2005 “Phase”). The precoder outputs at the k th bit, p_k and q_k , can be obtained by performing the following logic operations on the original data at the k th bit, a_k and b_k , and the previous outputs of the precoder, p_{k-1} and q_{k-1} , according to the following equation

$$\begin{aligned} p_k &= \bar{a}_k \bar{b}_k \bar{p}_{k-1} + \bar{a}_k b_k q_{k-1} + a_k \bar{b}_k \bar{q}_{k-1} + a_k b_k p_{k-1} \\ q_k &= \bar{a}_k b_k \bar{q}_{k-1} + \bar{a}_k b_k \bar{p}_{k-1} + a_k b_k p_{k-1} + a_k b_k q_{k-1} \end{aligned} \quad (28)$$

Back-to-Back Performance of ODQPSK

For reference, we first describe the optimal receiver sensitivities. For homodyne or heterodyne OQPSK, we have (Proakis 2000).

$$\text{BER}_{\text{OQPSK}} = \frac{1}{2} \text{erfc}\left(\sqrt{\text{SNR}_b}\right) \quad (29)$$

For direct-detection ODQPSK with polarization filtering at the receiver, we have

$$\begin{aligned} \text{BER}_{\text{ODQPSK}_1p} &= Q(a, b) - \frac{1}{2} e^{-(a^2+b^2)/2} I_0(ab), \\ \text{with } a &= \sqrt{2\text{SNR}_b} (1 - 1/\sqrt{2}), \text{ and} \\ b &= \sqrt{2\text{SNR}_b} (1 + 1/\sqrt{2}). \end{aligned} \quad (30)$$

Similar to Equation 16, for direct-detection ODQPSK without polarization filtering at the receiver, we have

$$\begin{aligned} \text{BER}_{\text{ODQPSK}_2p} &= Q(a, b) - \frac{1}{2} e^{-(a^2+b^2)/2} \cdot I_0(ab) \\ &\quad + \frac{1}{8} e^{-(a^2+b^2)/2} \left(\frac{b}{a} - \frac{a}{b} \right) \cdot I_1(ab), \end{aligned} \quad (31)$$

where a and b are the same as those given in Equation 30. Figure 15 shows the BER performances of OQPSK and

Figure 14: Schematic of an ODQPSK transmitter based on a nested Mach-Zehnder phase modulator and an ODQPSK receiver

Table 3: Relations among Precoder Outputs and Original Data for ODQPSK Transmitter and Receiver Configuration in Figure 14 (Ho 2005 “Phase”)

Original data ($a_k b_k$)	Optical phase difference	First precoder output, p_k	Second precoder output, q_k
(00)	π	\bar{p}_{k-1}	\bar{q}_{k-1}
(01)	$\pi/2$	q_{k-1}	\bar{p}_{k-1}
(10)	1.5π	\bar{q}_{k-1}	p_{k-1}
(11)	0	p_{k-1}	q_{k-1}

**Figure 15:** The optimal BER performances of OQPSK and ODQPSK without polarization filtering, as compared to those of OBPSK and ODBPSK

ODQPSK without polarization filtering, as compared to those of OBPSK and ODBPSK. The OQPSK performs the same as the OBPSK, while the ODQPSK (without polarization filtering) exhibits a differential detection penalty of ~ 2.4 dB. Comparing the ODQPSK with the ODBPSK, the relative sensitivity penalty of the ODQPSK is ~ 1.5 dB at $\text{BER} = 10^{-9}$ and ~ 0.8 dB at $\text{BER} = 10^{-3}$. These performance differences were experimentally verified (Gnauck et al. 2006). In optical transmission systems with modern FEC codes, the raw BER of interest is high, and the receiver sensitivity disadvantage of the direct-detection ODQPSK as compared to the ODBPSK becomes small.

Similar to ODBPSK, ODQPSK also suffers from implementation imperfections. Particularly, ODQPSK is highly sensitive to the phase errors. The BER of an ODQPSK signal in the presence of a phase error, ϕ_e , is

$$\text{BER}_{\text{ODQPSK-}\phi_e} = \frac{1}{2} [\text{BER}_{\text{ODQPSK}}(a_+, b_+) + \text{BER}_{\text{ODQPSK}}(a_-, b_-)],$$

$$\text{with } a_{\pm} = \sqrt{2\text{SNR}_b \left[1 - \cos\left(\frac{\pi}{4} \pm \phi_e\right) \right]}, \text{ and } (32)$$

$$b_{\pm} = \sqrt{2\text{SNR}_b \left[1 + \cos\left(\frac{\pi}{4} \pm \phi_e\right) \right]},$$

where $\text{BER}_{\text{ODQPSK}}()$ is obtained from Equation 30 or 31, depending on whether there is polarization filtering at the receiver. Figure 16 shows the OSNR penalty (at $\text{BER} = 10^{-9}$) of a 40-Gb/s ODQPSK as a function of the laser

frequency offset, as compared to that of a 40-Gb/s ODBPSK signal. ODQPSK requires approximately 5.5 times tighter laser frequency accuracy (Kim and Winzer 2003).

Transmission Performance of ODQPSK

For the same symbol rate, multilevel formats usually have lower CD tolerance than binary formats. However, for the same bit rate, multilevel formats are more tolerant to CD. ODQPSK, by encoding two bits per symbol, offers higher tolerance to CD and PMD than ODBPSK. At 42.7 Gb/s, the CD-induced penalty reaches 2 dB at approximately ± 130 ps/nm (Gnauck et al. 2006). The PMD tolerance of ODQPSK is approximately twice as large as that of ODBPSK (Gnauck et al. 2006). RZ-ODQPSK is also found to have good tolerance to fiber nonlinearity and optical filtering (Cho et al. 2003; Gnauck et al. 2004 “Spectrally”). The disadvantages of ODQPSK as compared to ODBPSK include slightly lower receiver sensitivity and higher sensitivity to the phase error. ODQPSK is attractive for systems where high spectral efficiency and high tolerance to CD and PMD are desired.

Generalized ODMPSK

Higher spectral efficiency can be obtained by using ODMPSK formats with more phase levels. *Optical differential 8-ary PSK* (OD8PSK) has been proposed and demonstrated by (Kim and Li 2004). Generally, for an ODMPSK transmitter, $\log_2(M)$ binary phase modulators are usually needed to encode the M phase levels, or $\log_2(M)$ binary data tributaries. For an ODMPSK receiver, a series of

Figure 16: The OSNR penalty (at BER = 10^{-9}) as a function of the laser frequency offset in 40-Gb/s ODQPSK and ODBPSK systems using one-bit ODIs. No polarization filtering is used

decision variables are needed to decode the $\log_2(M)$ binary data tributaries. A straightforward demodulation scheme is to use $M/2$ ODIs with the following different phase offsets (between the two arms of each ODI):

$$\Delta\phi_{\text{ODI}}(m) = \frac{[1 - 2(m-1)]\pi}{M}, \text{ with } m = 1, 2, \dots, \frac{M}{2} \quad (33)$$

For the demodulation of OD8PSK, four ODIs are needed, and the phase offsets in the ODIs are $\pi/8$, $-\pi/8$, $-3\pi/8$, and $-5\pi/8$, respectively. Because there are correlations among the decision variables obtained by the $M/2$ ODIs, the number of the needed ODIs may be reduced with the help of analog radio frequency components (Han, Kim, and Li 2004).

The receiver sensitivity of an OMPSK signal can be straightforwardly estimated from the minimum Euclidean distance between the two closest symbols in its constellation diagram. The receiver sensitivity penalty (in dB) of OMPSK as compared to OBPSK can be approximated as (Ho 2005 “Phase”)

$$\Delta\text{SNR}_b(\text{OMPSK} \Leftrightarrow \text{OBPSK}) \approx -20 \log_{10} \left[\sin\left(\frac{\pi}{M}\right) \cdot \sqrt{\log_2(M)} \right] \quad (34)$$

For ODMPSPSK signals, the errors are dominated by differential phase noise. We define an effective “differential-phase distance” between the two closest symbols of ODMPSPSK signal in its constellation diagram as

$$d_{\Delta\phi}(\text{ODMPSPSK}) = \frac{2\pi}{M} \cdot \frac{1}{\sqrt{2}} = \frac{\sqrt{2}\pi}{M} \quad (35)$$

where the factor of 2 comes from the fact that the differential-phase deviation is 2 times as large as the absolute phase deviation, assuming that the optical noise-induced phase fluctuations in adjacent signal bits are independent Gaussian random variables. At low BERs, we can express the receiver sensitivity penalty (in dB) of ODMPSPSK as compared to the OBPSK as

$$\begin{aligned} \Delta\text{SNR}_b(\text{ODMPSPSK} \Leftrightarrow \text{OBPSK}) &\approx -20 \log_{10} \left[\frac{d_{\Delta\phi}}{2} \cdot \sqrt{\log_2(M)} \right] \\ &= -20 \log_{10} \left[\frac{\pi}{\sqrt{2}M} \cdot \sqrt{\log_2(M)} \right] \end{aligned} \quad (36)$$

Figure 17 shows the receiver sensitivity penalties of OMPSK and ODMPSPSK as compared to OBPSK versus the number of phase levels. The sensitivity penalties are large (>3 dB) for formats with $M > 4$. In addition, the differential detection penalty approaches 3 dB as M increases. This suggests that ODMPSPSK formats with $M > 4$ are only viable in systems with sufficiently high OSNR.

Combined ODMPSPSK and Pulse Amplitude Modulation

Another way to achieve high spectral efficiency is by combining ODMPSPSK with PAM. The simplest such format is

Figure 17: The receiver sensitivity penalties of OMPSK and ODMPSPSK as compared to OBPSK as a function of the number of phase levels. The symbols are for ODMPSPSK/PAM- N formats

the combination of ODBPSK and a two-level PAM (Liu et al. 2003). For an ODMPSK/PAM- N signal, its ideal receiver sensitivity is optimized when the Euclidean distances between two adjacent PAM levels in its constellation diagram not only are equal but also equal to the effective “differential-phase distance” between the two closest symbols. The optimal locations of the $M \times N$ symbols of an ODMPSK/PAM- N signal are thus

$$s(m, n) = c \cdot \exp\left(j \frac{2\pi m}{M}\right) \cdot \left(1 + \frac{\sqrt{2\pi n}}{M}\right), \text{ with} \\ m = 0, 1, \dots, M-1, \text{ and } n = 0, 1, \dots, N-1 \quad (37)$$

where c is a normalization factor. It can be estimated that the receiver sensitivity penalty of the ODMPSK/PAM- N as compared to the OBPSK is

$$\Delta \text{SNR}_b (\text{ODMPSK/PAM-}N \Leftrightarrow \text{OBPSK}) \approx \\ -10 \log_{10} \left\{ \left(\frac{d_{\Delta\phi}}{2} \right)^2 \cdot \left[\frac{1 + (N-1)d_{\Delta\phi}}{+ \frac{1}{6}(N-1)(2N-1)d_{\Delta\phi}^2} \right]^{-1} \cdot \log_2(M \cdot N) \right\} \\ = -10 \log_{10} \left\{ \frac{\pi^2}{2M^2} \cdot \left[\frac{1 + (N-1)\frac{\sqrt{2\pi}}{M}}{+ (N-1)(2N-1)\frac{\pi^2}{3M^2}} \right]^{-1} \cdot \log_2(M \cdot N) \right\} \quad (38)$$

ODQPSK/PAM-2 is a three-bit/symbol format that has been demonstrated (Hayase et al. 2004). The theoretical receiver sensitivity penalty as compared to OBPSK (having the same bit rate) is 4.7 dB, approximately 1.7 dB smaller than OD8PSK, which is also a three-bit/symbol format. At four and five bits per symbol, the ODMPSK/PAM- N offer higher optimal receiver sensitivities than ODMPSK, as shown in Figure 17. However, ODMPSK/PAM- N generally suffers more implementation penalty and nonlinear penalty (because of SPM-induced phase offsets between symbols with different intensities) than ODMPSK.

Polarization Multiplexed ODPSK

A commonly used means to double spectral efficiency is via *polarization multiplexing*, with the trade-off of increased complexity at both the transmitter and receiver. Because the polarization of a signal after fiber transmission is uncertain and time-varying, polarization monitoring and tracking are required for polarization demultiplexing. Furthermore, in WDM transmissions, interchannel XPM may lead to nonlinear polarization scattering, which causes the polarization to vary on a bit-by-bit basis and may make polarization demultiplexing impossible. ODPSK, by having nearly identical intensity profiles in all of the bit slots, exhibits smaller XPM effects and smaller nonlinear polarization scattering than OOK (Liu, Xu, and Wei 2004). High spectral-efficiency transmissions have been demonstrated using polarization multiplexing and ODQPSK (Wree et al.

2003; Cho et al. 2004). A special case of polarization multiplexing is *polarization bit interleaving*, which is used to mitigate intrachannel nonlinear penalties rather than doubling spectral efficiency. Note that large PMD can severely degrade the performance of polarization-multiplexed signals.

FORWARD-LOOKING TOPICS

As ODPSK is evolving to be a potential candidate for many applications in optical communications, there are many forward-looking topics that deserve further study. A few are briefly mentioned in the following.

Improved Detection of ODPSK

As shown in a previous section, there exists a differential detection penalty for the receiver sensitivity of direct-detection ODPSK as compared to homodyne or heterodyne OPSK. The differential detection penalty can be reduced by expanding techniques used in wireless communications such as multichip ODPSK (Nazarathy and Simony 2005) and data-aided multisymbol phase estimation (Liu 2006) to ODPSK. With multichip detection or multisymbol phase estimation, a more accurate phase reference can be obtained so that the performance of ODPSK can approach that of homodyne-detection OPSK. By extracting a more accurate phase reference, the tolerance of ODPSK to nonlinear phase noise (e.g., resulting from the Gordon-Mollenauer effect) can also be increased (Nazarathy and Simony 2005; Liu 2006). With the advances of high-speed electronics, future efforts are expected to improve the detection of ODPSK through high-speed analog-to-digital conversion and *digital signal processing* (DSP), even in the presence of transmission impairments. Note that DSP techniques can also be applied to improve the homodyne detection of OPSK. Soft detection can also be used in combination with FEC to further improve the performance of ODQPSK (Kramer et al. 2003; Mizuochi et al. 2004).

Wavelength Conversion and Optical Regeneration of ODPSK

Wavelength conversion and optical regeneration are emerging techniques in modern optical transport networks. Unlike OOK, ODPSK encodes data in optical phase, so wavelength conversion of ODPSK has to be phase preserving. Similarly, the regeneration of an ODPSK signal has to include restoration in optical phase in addition to *reamplification* in signal intensity, *reshaping* of signal waveform, and *retiming* (3R) that are sufficient in the regeneration of an OOK signal. A regenerative all-optical wavelength conversion scheme, based on a Mach-Zehnder interferometer with differentially driven semiconductor optical amplifiers, was demonstrated for a 40-Gb/s ODBPSK signal (Kang et al. 2005). A regenerative amplification scheme for ODBPSK that is capable of suppressing both phase and amplitude noises has also been demonstrated (Shin et al. 2006). More efforts may be seen in cost-effective implementations of the wavelength conversion and regeneration of ODSPK in future optical networks.

Optical Packet Switching Based on ODPSK

Optical packet switching (OPS) and *optical burst switching* (OBS) are regarded as promising transport technologies. In OPS and OBS systems, a challenging issue is the need of burst-mode receivers that are capable of fast resynchronization to different data packets or bursts with different amplitudes and timings. Direct-detection ODPSK with balanced detection has a fixed optimal decision threshold at approximately zero and may allow burst-mode detection to be more easily implemented than in the OOK case. Optical label switching is an interesting switching method. Orthogonal ODPSK modulation and intensity modulation have been used for encoding payload and label signals on a same wavelength channel (Liu et al. 2004 "Transmission"). ODPSK is expected to play an important role in future high-speed OPS and OBS networks.

CONCLUSION

The fundamentals, principles, implementations, and system impacts of ODPSK have been reviewed. The overall performance of ODPSK, including optimal receiver sensitivity, implementation penalty, and tolerance to transmission impairments, are comprehensively evaluated. Some forward-looking topics have been briefly discussed. ODPSK, by exhibiting several advantages over OOK, is expected to be a promising modulation format for modern optical transport networks.

ACKNOWLEDGMENT

The progress on ODPSK summarized in this chapter implicitly represents the works of many researchers and developers around the world, and in this limited space the author was unable to include all of the contributions. The author is especially grateful to his colleagues working in this field in the Bell Laboratories for fruitful collaborations and valuable discussions. Among them are S. Chandrasekhar, C. R. Doerr, D. A. Fishman, D. M. Gill, A. H. Gnauck, I. Kang, Y.-H. Kao, G. Kramer, J. Leuthold, C. J. McKinstrie, L. F. Mollenauer, L. Möller, Y. Su, A. J. van Wijngaarden, X. Wei, P. J. Winzer, C. Xie, and C. Xu. The author is also indebted to C. R. Giles and A. R. Chraplyvy for their support.

GLOSSARY

Bit error rate (BER): The ratio between the number of bits that are incorrectly received and the number of the total bits that are transmitted over a given period of time in a communication system.

Chromatic dispersion (CD): An effect that causes different optical wavelength components to travel at different speeds.

Cross-phase modulation (XPM): A nonlinear optical effect that imposes a change in optical phase on an optical signal by another optical signal via the optical Kerr effect.

Forward error correction (FEC): A digital communication technique for error control whereby the sender adds redundant data to its messages, which allows the receiver to detect and correct errors.

Intrachannel four-wave mixing (IFWM): The four-wave mixing interaction among different symbols in a same wavelength channel.

Non-return to zero (NRZ): A pulse format used in telecommunication signals in which the signal power does not drop to zero after each symbol that has a nonzero power.

On-off keying (OOK): A modulation format that represents digital data as the presence (on) or absence (off) of a carrier wave.

Optical delay interferometer (ODI): An optical interferometer having two interference paths whose optical lengths are different.

Optical differential binary phase shift keying (ODBPSK): An optical modulation format that represents digital data by two possible differences between the optical phases of two adjacent symbols, 0 and π .

Optical differential multilevel phase shift keying (ODMPSK): An optical modulation format that represents digital data by M possible differences between the optical phases of two adjacent symbols, 0, $2\pi/M$, $4\pi/M$, ..., and $2\pi(M-1)/M$.

Optical differential phase shift keying (ODPSK): An optical modulation format that represents digital data by the difference between the optical phases of two adjacent symbols.

Optical differential quadrature phase shift keying (ODQPSK): An optical modulation format that represents digital data by four possible differences between the optical phases of two adjacent symbols: 0, $\pi/2$, π , and $3\pi/2$.

Optical phase shift keying (OPSK): An optical modulation format that represents digital data by the optical phase of a carrier wave.

Optical signal-to-noise ratio (OSNR): The ratio between the signal power and the power of optical noise of two polarization states within a fixed bandwidth of 0.1 nm (or 12.5 GHz at a signal wavelength of approximately 1550 nm).

Photons per bit (PPB): The number of optical photons used to carry each information bit.

Polarization mode dispersion (PMD): A form of modal dispersion in which two different polarizations of light in a waveguide, which normally travel at the same speed, travel at different speeds because of random imperfections and asymmetries, causing random spreading of optical pulses.

Pulse amplitude modulation (PAM): A form of signal modulation in which the message information is encoded in the amplitude of a series of signal pulses.

Return to zero (RZ): A pulse format used in telecommunication signals in which the signal power drops (returns) to zero after each symbol that has a nonzero power.

Self-phase modulation (SPM): A nonlinear optical effect that imposes a change in optical phase on an optical signal by the signal itself via the optical Kerr effect.

Wavelength-division multiplexing (WDM): An optical communication technology that multiplexes multiple optical carrier signals on a single optical fiber by using different wavelengths (colors) of laser light to carry different signals.

INTRODUCTION

Discrete multitone (DMT) is a digital transmission scheme that belongs to the class of *multicarrier modulation* (MCM) schemes, the key function of which is to partition a high-rate data stream into a large number of low-rate streams and to transmit them in parallel over equidistantly spaced subchannels. As the occupied bandwidth of a signal is reciprocal to its symbol rate, the sum of all low-rate bit streams occupies the same bandwidth as the high-rate signal. The main feature of MCM is that the low-rate (and hence narrowband) signals are much less susceptible to channel impairments; thus, reconstruction of the subchannel signals at the receiver side is simplified to a great extent. However, all subchannels have to be received in parallel and must be processed simultaneously, a requirement that can only be met in an economic way with digital signal processing. Because of the usually large number of carriers, the subchannel signals can be well adapted to the channel characteristics. As a consequence, multicarrier systems such as DMT offer the ability to maximize the data throughput over frequency-selective channels such as telephone subscriber lines. Thus, it does not come as a surprise that the main application of DMT is the transmission of broadband data over such lines, which are known as *asymmetric digital subscriber lines* (ADSLs) and *very high data rate digital subscriber lines* (VDSLs) (Bingham 2000).

The earliest ideas for MCM date back to the late 1950s when the first multicarrier systems were developed for military high-frequency transmission. The idea of synchronously modulating several narrowband signals onto equidistant carriers with overlapping spectra was realized as early as 1957 in the Collins Kineplex system (Doelz, Heald, and Martin 1957), which used *phase shift keying* (PSK) modulation to transmit 3000 bits/sec over twenty

subcarriers with overlapping spectra. This early system already made use of a guard time to prevent *intersymbol interference* (ISI). In the 1960s, this was followed by other high-frequency military systems.

The groundbreaking idea of using the *discrete Fourier transform* (DFT) instead of oscillator banks for modulation became widely known with the classical paper of Weinstein and Ebert (1971). Cimini (1985) investigated and suggested the use of MCM over mobile channels. Multicarrier systems had still not found their way into applications, but with the ascent of digital signal processing and the substantial progress in semiconductor technology in the early 1990s, Bingham (1990) concluded that the time had come for MCM. Kalet (1989) and Kasturia, Aslanis, and Cioffi (1990) provided in-depth investigations of the potential of MCM, and the race was on. Nowadays, MCM is being applied in many digital transmission systems, and it is still the preferred option for new developments such as fourth-generation cellular systems.

Apart from DMT, another well-known multicarrier scheme is *orthogonal frequency division multiplex* (OFDM), with which DMT has many basic principles in common. OFDM is a passband modulation scheme that is applied for wireless communication, while DMT is a baseband system and is normally used in wireline applications. Moreover, DMT offers the possibility of adjusting the modulation and transmit power in each subchannel (bit loading) and can thus be well adapted to frequency-selective channels.

Because MCM can be interpreted as a further development of *frequency division multiplexing* (FDM), in the next section we explain classical FDM principles and then derive the basics of multicarrier modulation such as the orthogonality criterion and show the need for the guard interval. In the third section, we turn our attention to the digital system model and develop the probably most

important characteristic of DMT, which is the decomposition of a frequency-selective broadband channel into parallel nonselective narrowband channels. The fourth section then goes into some implementation details such as equalization strategies, considering also an insufficient guard interval, and outlines the problem of the peak-to-average power ratio. Implementation alternatives with filter banks and variants of the guard interval are given. In the fifth section, we describe how adaptive bit loading can be used to maximize the transmission rate by making use of fundamental principles from information theory. Finally, the last section portrays the main applications of DMT and looks at recent advances with multi-user DMT.

BASICS OF MULTICARRIER MODULATION

Frequency Division Multiplexing

With FDM, the available bandwidth of the transmission medium is partitioned into a number of nonoverlapping frequency bands in order to transmit various signals simultaneously on the same medium. The basic block diagram is depicted in Figure 1. Each band-limited baseband signal $x_v(t)$ is modulated onto a complex carrier $\exp(j\omega_v t)$ with carrier frequencies $\omega_0, \dots, \omega_{N-1}$. The received FDM signal is demodulated with the complex conjugate carrier $\exp(-j\omega_v t)$ and then *low-pass* (LP) filtered to obtain the baseband signal $y_v(t)$. The FDM signal at the transmitter output is given by

$$s(t) = \sum_{v=0}^{N-1} x_v(t) e^{j\omega_v t} \quad (1)$$

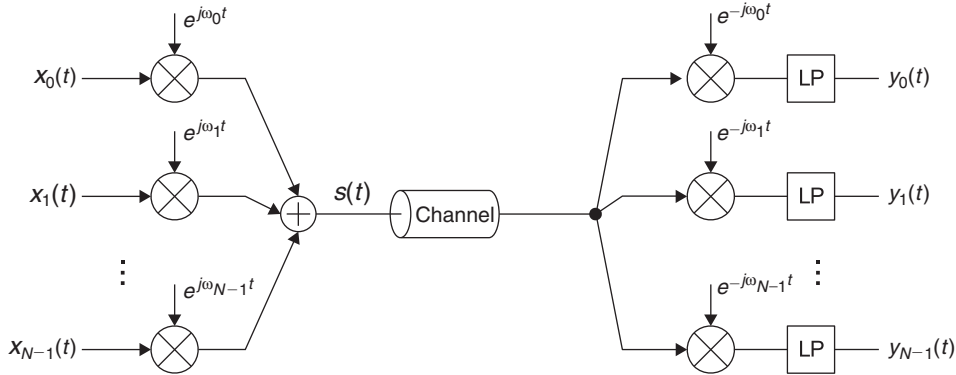

Figure 1: Analog frequency division multiplexing. The baseband signals $x_0(t), \dots, x_{N-1}(t)$ are modulated on different carriers and are transmitted over a common channel

Figure 2: Exemplary spectrum $S(\omega)$ of the FDM signal $s(t)$

Here and in the following we use the equivalent baseband notation for the output signal—that is, $s(t)$ is the complex envelope of the transmit signal, and the channel in Figure 1 is the equivalent baseband channel (for details, see, e.g., Haykin 2001).

Considering the spectra of the signals $x_v(t)$ on the v th branch, denoted by $x_v(t) \leftrightarrow X_v(\omega)$, we have

$$x_v(t) e^{j\omega_v t} \leftrightarrow X_v(\omega - \omega_v) \quad (2)$$

and hence the spectrum of the transmitter output signal

$$s(t) \leftrightarrow S(\omega) = \sum_{v=0}^{N-1} X_v(\omega - \omega_v) \quad (3)$$

The spectrum $S(\omega)$ is shown for an exemplary case in Figure 2. In classical FDM systems, the frequencies ω_v have to be chosen in such a way that the spectra of the modulated signals do not overlap. If all baseband signals $x_v(t)$ have the same bandwidth, then the carrier frequencies are chosen to be equidistant. However, the described FDM system wastes valuable bandwidth because some space is needed in the form of a guard band to accommodate the transition between the pass- and the stopband of each branch's signal.

This drawback of wasted spectrum can be overcome by multicarrier modulation such as DMT, which allows for a certain overlap between the spectra of the subchannel signals. Because spectral overlap in general could lead to signal distortions and cross talk, conditions to ensure the possibility of signal reconstruction have to be elaborated. This is addressed in the next section.

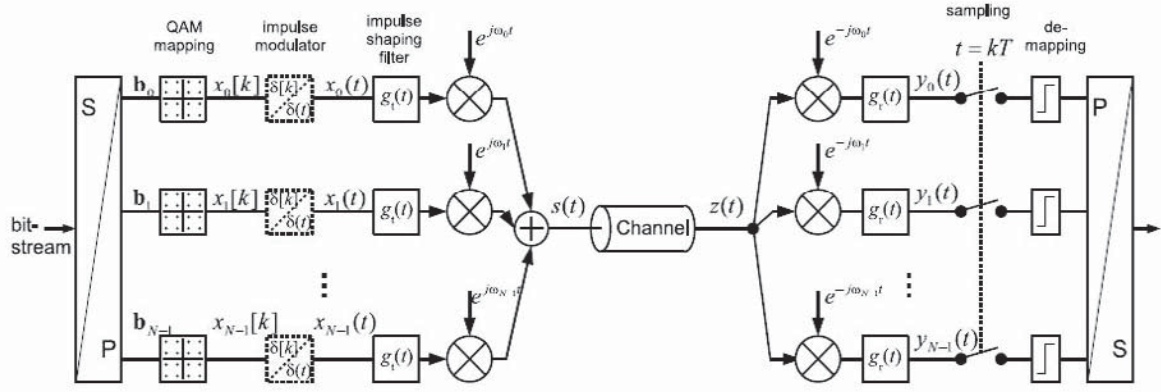

Figure 3: Block diagram of a general multicarrier system

Orthogonality Criterion

In a multicarrier system as depicted in Figure 3, the incoming bit stream is divided into N bit streams of lower rate and then mapped to *quadrature amplitude modulation* (QAM) symbols $X_v[k]$, $v = 0, 1, \dots, N-1$. The QAM symbols are taken out of a discrete alphabet—that is, $X_v[k] \in A_x$. In a multiple-access system, these sequences stem from different sources, which does not affect the following treatment as long as the sequences are synchronized. The QAM symbols $X_v[k]$ with $k \in \mathbb{Z}$ constitute a discrete time sequence $\{\dots, X_v[0], X_v[1], \dots\}$, which is translated by the impulse modulator into a continuous time function

$$x_v(t) = T \sum_{k=-\infty}^{\infty} X_v[k] \cdot \delta(t - kT) \quad (4)$$

Here $\delta(t)$ is the Dirac delta function, which is defined by $\delta(t) = 0$ for $t \neq 0$ and $\int_{-\infty}^{\infty} \delta(t) dt = 1$. Note that the impulse modulator is a theoretical concept that provides a mathematically rigorous transition from discrete time to continuous time signals but does not correspond to any identifiable circuit in a practical implementation. In the following, we write continuous time signals with parentheses, such as $s(t)$, and discrete time signals with brackets such as $s[n]$.

The signal after the impulse-shaping filter is $T \sum_k X_v[k] \cdot g_v(t - kT)$, where $g_v(t)$ denotes the impulse response of the impulse-shaping filter. These signals are modulated onto the subcarrier frequencies ω_v , and together they form the output signal

$$s(t) = T \sum_{v=0}^{N-1} e^{j\omega_v t} \sum_{k=-\infty}^{\infty} X_v[k] \cdot g_v(t - kT) \quad (5)$$

The carrier frequencies ω_v are equidistant and thus integer multiples of the subcarrier spacing $\Delta\omega$:

$$\omega_v = v \cdot \Delta\omega, \quad v = 0, 1, \dots, N-1 \quad (6)$$

Although all practical multicarrier systems are realized with digital signal processing, we will use the analog model

of Figure 3 in this section because the analysis can be done more conveniently and the basic principles of MCM can be visualized more clearly with this model. In the following sections, we will continue with a digital system model.

The output signal $s(t)$ can be either real or complex-valued. If complex-valued, $s(t)$ is considered as the complex envelope, and the channel is the equivalent baseband channel.

The receiver input signal $z(t)$ is demodulated and filtered by the receiver filters with impulse response $g_r(t)$, resulting in the signal

$$y_\mu(t) = \left(z(t) e^{-j\omega_\mu t} \right) * g_r(t) = \int_{-\infty}^{+\infty} z(\tau) e^{-j\omega_\mu \tau} g_r(t - \tau) d\tau, \quad \mu = 0, 1, \dots, N-1 \quad (7)$$

where $*$ denotes convolution. For the moment, we assume an ideal channel—that is, $z(t) = s(t)$ —and obtain from Equation 7 with Equations 5 and 6

$$y_\mu(t) = T \int_{-\infty}^{\infty} \sum_{v=0}^{N-1} e^{j(v-\mu)\Delta\omega\tau} \sum_k X_v[k] g_v(\tau - kT) g_r(t - \tau) d\tau \quad (8)$$

To obtain a discrete time sequence again, this signal is sampled at $t = kT$:

$$Y_\mu[k] = y_\mu(kT) = T \int_{-\infty}^{\infty} \sum_{v=0}^{N-1} e^{j(v-\mu)\Delta\omega\tau} \sum_\ell X_v[\ell] g_v(\tau - \ell T) g_r(kT - \tau) d\tau \quad (9)$$

From this expression for the received signal after sampling, we can observe two types of interference.

1. *Intersymbol interference* (ISI), a transmit symbol $X_v[k]$ which is sent at time k on subcarrier v influences previous and subsequent received samples $Y_v[\ell]$, $\ell \neq k$ on the same subcarrier.

2. *Inter-carrier interference (ICI)*, a transmit symbol $X_v[k]$ on subcarrier v has an impact on received symbols $Y_\mu[\ell]$, $\mu \neq v$ on other subcarriers—that is, cross talking occurs between adjacent subcarriers.

Now the objective is to recover the transmit sequences at the receiver without distortion. Because our system is linear and time-invariant, we can restrict the analysis to the evaluation of the response to a single transmit symbol on one subcarrier. We can then make use of the superposition theorem for the general case of arbitrary input sequences, which can be written as a linear combination of time-shifted unit impulses.

Without loss of generality, we assume that the system model in Figure 3 has zero delay—that is, the filters $g_t(t)$ and $g_r(t)$ are noncausal. We assume that one unit impulse $\delta[k]$ is transmitted at time $k = 0$ on subcarrier v :

$$X_i[k] = \delta[v - i] \cdot \delta[k], \quad i = 0, \dots, N - 1. \quad (10)$$

Here

$$\delta[k] = \begin{cases} 1 & \text{for } k = 0 \\ 0 & \text{for } k \neq 0 \end{cases} \quad (11)$$

is the discrete time equivalent of the Dirac delta function. The desired received signal is

$$Y_\mu[k] = \delta[v - \mu] \cdot \delta[k] \quad (12)$$

In this case, the received signal is free of interference at the sampling instants. This does not put any condition on the signal $y_\mu(t)$ between the sampling instants. However, to gain further insight into the nature of ISI and ICI, we take a step back and consider the signals before they are sampled at the receiver. The transmitter output signal for the sequence in Equation 10 is

$$s(t) = T g_t(t) e^{jv\Delta\omega t} \quad (13)$$

which is also the receiver input signal $z(t)$ because we assume an ideal channel. The *elementary impulse* $r_{v-\mu}(t)$ is defined as the response $y_\mu(t)$ to the transmitter input in Equation 10:

$$r_d(t) = T \int_{-\infty}^{\infty} e^{jd\Delta\omega\tau} g_t(\tau) g_r(t - \tau) d\tau \quad (14)$$

Here we set $d = v - \mu$ because the elementary impulse depends only on the difference of the subcarrier indices. The condition for no interference can now be formulated as

$$r_d(kT) = \delta[d] \cdot \delta[k] \quad (15)$$

This can be interpreted as the multicarrier version of the Nyquist criterion because it forces not only the absence of

ISI but also zero ICI. If we set $d = 0$, then Equation 15 simplifies to the Nyquist criterion for single-carrier systems. In the context of general multicarrier systems and filter banks, Equation 15 is often called the *orthogonality criterion* or the criterion for *perfect reconstruction*.

For standard multicarrier systems without guard interval, $g_t(t)$ and $g_r(t)$ are both rectangular with duration T . With the subcarrier spacing $\Delta\omega = 2\pi/T$, we obtain the elementary impulses

$$r_0(t) = \begin{cases} 1 - |t|/T & \text{for } |t| \leq T \\ 0 & \text{elsewhere} \end{cases}$$

$$r_d(t) = \begin{cases} \frac{\text{sgn}(t)(-1)^d}{j2\pi d} \left(1 - \exp\left(jd\frac{2\pi}{T}t\right) \right) & \text{for } |t| \leq T, \quad d \neq 0 \\ 0 & \text{elsewhere} \end{cases} \quad (16)$$

These functions are shown in the top left section of Figure 4 and help us understand the characteristics of ISI and ICI. We clearly see that at the sampling instants $t = kT$ no interference is present. This is not the case between the sampling instants where significant cross talk comes from the adjacent subchannels. The oscillation frequency of the cross talk increases with the distance d between transmitter and receiver subchannel index, whereas the amplitude decreases proportionally to $1/d$. Because of this slow decline, many adjacent subchannels contribute to the cross talk between the sampling instants. As long as this cross talk is zero at the sampling instants, no interference occurs there. However, it cannot be ignored for other time instants, as becomes clear from the eye diagram at the top right of Figure 4, which corresponds to the real part of $y_\mu(t)$ when the transmit symbols are 16-QAM modulated. Although the orthogonality condition of Equation 15 is fulfilled, the horizontal eye opening tends to zero, producing decision errors even for tiny sampling jitter or channel influences.

Introduction of the Guard Interval

An effective solution to increase the horizontal eye opening is the introduction of a *guard interval*. It is introduced by choosing different impulse responses $g_t(t) \neq g_r(t)$ at transmitter and receiver. The duration of the guard interval is

$$T_G = T - T_u \quad (17)$$

where T and T_u denote the length of the impulse response of the transmitter and receiver filter $g_t(t)$ and $g_r(t)$, respectively. Both impulse responses are rectangular and symmetric to $t = 0$. The subcarrier spacing is now given by

$$\Delta\omega = \frac{2\pi}{T_u} \quad (18)$$

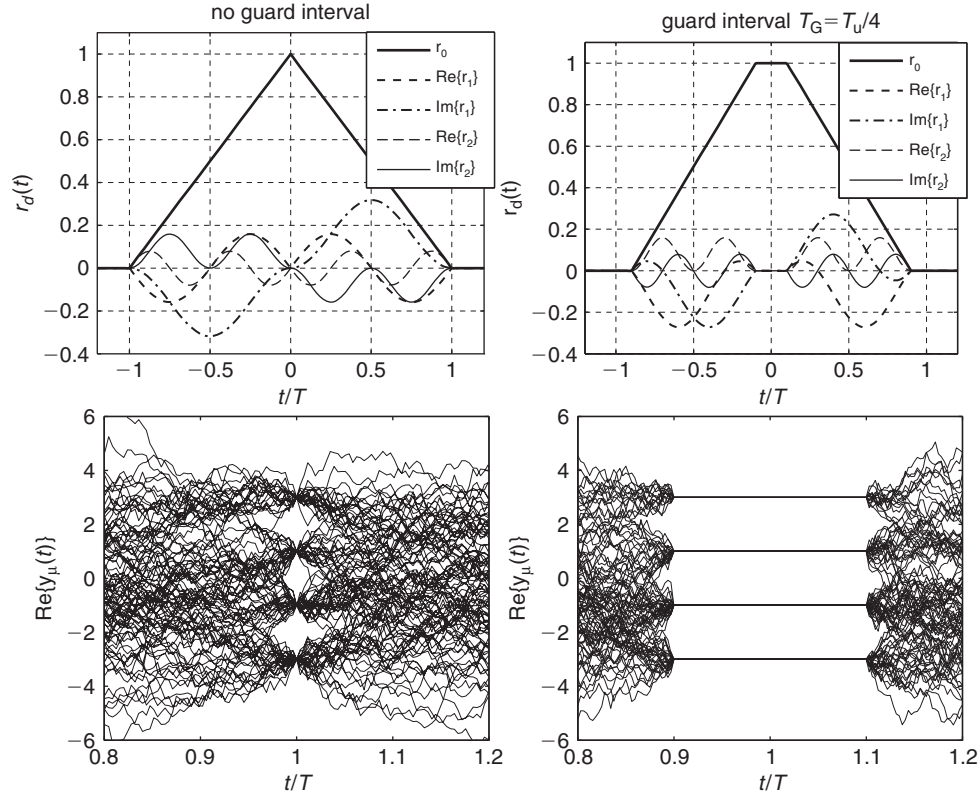

Figure 4: Elementary impulses (above) and eye diagrams (below) of a multicarrier system with rectangular impulse shapes, 16-QAM modulation, and $N = 256$ subcarriers. Left: Without guard interval. Right: Guard interval $T_G = T_u/4$

For the elementary impulses follows

$$r_0(t) = \begin{cases} \frac{-|t| + T - T_G/2}{T - T_G} & \text{for } \frac{T_G}{2} \leq |t| \leq T - \frac{T_G}{2} \\ 1 & \text{for } |t| < \frac{T_G}{2} \\ 0 & \text{for } |t| > T - \frac{T_G}{2} \end{cases} \quad (19)$$

$$r_d(t) = \begin{cases} \frac{\text{sgn}(t)(-1)^d}{j2\pi d} \left(\exp\left(j\pi \text{sgn}(t)d \frac{T_G}{T_u}\right) - \exp\left(jd \frac{2\pi}{T_u} t\right) \right) & \text{for } \frac{T_G}{2} \leq |t| \leq T - \frac{T_G}{2}, \quad d \neq 0 \\ 0 & \text{elsewhere} \end{cases} \quad (20)$$

As can be observed from the bottom of Figure 4, there are now flat regions around the sampling instants $t = kT$ that prevent any interference. This holds also for a channel

with an impulse response shorter than T_G . The horizontal eye opening is now as long as the guard interval. During this period, no information is transmitted and thus the spectral efficiency is reduced by the factor T_G/T .

PRINCIPLES OF DMT Implementation with Digital Signal Processing

Although the continuous time model we treated in the previous section is valuable for the theoretical system analysis, the implementation of MCM systems has been exclusively realized with digital signal processing ever since the technique became available. We obtain the discrete time system model depicted in Figure 5 by sampling the continuous time model in Figure 3 with the sampling period T_A . The impulse modulators are replaced by upsamplers that insert $N_s - 1$ zero samples after each incoming symbol $X_s[k]$. The basic time intervals are hence given by

$$\begin{aligned} T &= N_s \cdot T_A && \text{duration of DMT symbol,} \\ T_u &= N \cdot T_A && \text{"useful" time interval,} \\ T_G &= G \cdot T_A && \text{duration of guard interval.} \end{aligned} \quad (21)$$

Figure 5: Transmitter and receiver for digital multicarrier transmission

In the following, we will use the discrete time index k for the “slow” sampling time T or T_u and the index n for the “fast” time T_A . In accordance with Equation 17, one DMT symbol contains $N_S = N + G$ samples.

For the complex carriers in Figure 3, we obtain with Equations 6 and 18 and $t = n T_A$

$$\exp(j\omega_v n T_A) = \exp\left(j \frac{2\pi}{N} v n\right) = W_N^{-v \cdot n} \quad (22)$$

where we define the *twiddle factor*, W_N , which is also the N th root of unity:

$$W_N = \exp\left(-j \frac{2\pi}{N}\right) \quad (23)$$

Because we have made no assumptions about the filters $g_t(t)$ and $g_r(t)$, the sampling theorem is in general not fulfilled and thus the discrete time system model does *not exactly* represent the analog model. This explains the difficulties that arise when trying to derive the discrete time model from its continuous time counterpart. Nevertheless, it is a reasonable approximation, and the presented concepts such as the elementary impulses and the orthogonality criterion can be applied in the same way.

We now adopt *causal* discrete time filters:

$$g_t[n] = \begin{cases} 1/\sqrt{N} & \text{for } n = 0, 1, \dots, N_S - 1 \\ 0 & \text{elsewhere} \end{cases} \quad (24)$$

With this transmit filter, we can write for the output signal of the transmitter in Figure 5:

$$\begin{aligned} s[n] &= \sum_{v=0}^{N-1} W_N^{-v n} \sum_{k=-\infty}^{\infty} X_v[k] g_t[n - k N_S] \\ &= \frac{1}{\sqrt{N}} \sum_{v=0}^{N-1} X_v[\lfloor n/N_S \rfloor] W_N^{-v n} \end{aligned} \quad (25)$$

The rectangular pulse shape lets the sum over k disappear and allows us to write the output signal as a single sum using the integer division $\lfloor n/N_S \rfloor = n \operatorname{div} N_S$. Note that

the periodicity of the twiddle factor, W_N , is not identical to the filter length N_S . This is due to the guard interval and creates some subtle effects, as we will observe in the following.

In Equation 25, we recognize one expression of the discrete Fourier transform pair:

$$\text{DFT: } X_\mu = \frac{1}{\sqrt{N}} \sum_{v=0}^{N-1} x_v W_N^{v\mu}, \quad \text{IDFT: } x_v = \frac{1}{\sqrt{N}} \sum_{\mu=0}^{N-1} X_\mu W_N^{-v\mu} \quad (26)$$

We can thus identify the input signals $\{X_0[k], \dots, X_{N-1}[k]\}$ as a block with index k and consider the blockwise *inverse discrete Fourier transform* (IDFT):

$$x_i[k] = \frac{1}{\sqrt{N}} \sum_{v=0}^{N-1} X_v[k] W_N^{-vi}, \quad i = 0, 1, \dots, N-1 \quad (27)$$

The double-indexed sequence $x_i[k]$ contains the inverse discrete Fourier transformed input signals $X_v[k]$, which allows us to express the transmitter output signal of Equation 25 as

$$s[n] = x_{\operatorname{mod}_N(n)}[\lfloor n/N_S \rfloor] \quad (28)$$

where we introduced the modulus operator to keep the index in the specified range. Note that because of the periodicity of W_N , this is not strictly necessary here but will prove useful later.

For each block of N input samples, $N_S = N + G$ output samples are produced. The first block with $k = 0$ yields the output sequence

$$\{s[0], \dots, s[N_S - 1]\} = \{x_0[0], \dots, x_{N-1}[0], x_0[0], \dots, x_{G-1}[0]\}$$

while the second block ($k = 1$) gives the output

$$\begin{aligned} \{s[N_S], \dots, s[2N_S - 1]\} = \\ \{x_G[1], \dots, x_{N-1}[1], x_0[1], \dots, x_{2G-1}[1]\} \end{aligned}$$

Figure 6: Inverse discrete Fourier transform with parallel-serial conversion

We observe that each output block contains the symbols $x_0[k], \dots, x_{N-1}[k]$ plus G additional samples taken out of the same set. The calculation of $s[n]$ applying a block-wise IDFT is illustrated in Figure 6: A block of N input symbols is first IDFT-transformed and then parallel-serial converted. The commutator puts out N_s symbols for each block by turning more than one revolution, resting after each block in a different position. Thus, although each block contains all transformed symbols, the ordering and the subset of doubled samples vary. To overcome this inconvenience and to facilitate the block processing at the receiver side, practically all DMT systems compute a block of N samples by inverse DFT processing and insert the additional samples at the beginning of the block. Therefore, this common form of the guard interval is also called *cyclic prefix* (CP). Hence, a DMT block with index k will be ordered as follows:

$$\underbrace{x_{N-G}[k], x_{N-G+1}[k], \dots, x_{N-1}[k]}_{G \text{ guard samples}}, \underbrace{x_0[k], x_1[k], \dots, x_{N-1}[k]}_{N \text{ data samples}}$$

For this ordering, we can define the double-indexed output signal

$$s_v[k] = x_{\text{mod}_N(v-G)}[k] = \frac{1}{\sqrt{N}} \sum_{i=0}^{N-1} X_i[k] W_N^{-(v-G)i} \quad (29)$$

From this, the output signal $s[n]$ is given as

$$s[n] = s_{\text{mod}_{N_s}(n)} \left[\lfloor n / N_s \rfloor \right] \quad (30)$$

This operation ensures that each transmitted block is independent of the previous one, which simplifies the signal processing significantly. We will later see that—by an appropriately chosen guard time—this will hold also at the receiver side.

Baseband Transmission with Multicarrier Modulation

Because the DMT signal is transmitted over baseband channels, it has to be ensured that the output signal $s[n]$ is real-valued. In the following, we will derive the conditions that allow us to use the usual complex-valued QAM modulation on the subcarriers but nevertheless obtain a real-valued output signal.

To obtain a real-valued output, the samples $x_i[k]$ according to Equation 27 also have to be real. By decomposing $x_i[k]$ into real and imaginary parts and after some simple calculations, we obtain the conditions for the input sequences:

$$\begin{aligned} X_0[k], X_{N/2}[k] &\in \mathbb{R} \\ X_v &= X_{N-v}^* \quad \text{for } v = 1, 2, \dots, \frac{N}{2} - 1 \end{aligned} \quad (31)$$

To simplify the transmitter scheme, we can choose X_0 and $X_{N/2}$ as the real and imaginary part of one QAM symbol as indicated in Figure 7. For practical implementations, this is of minor importance because X_0 and $X_{N/2}$ are usually set to zero anyway. The reason for this will become clear when we look at the spectral properties of the DMT signal.

System Description with Matrix Notation

We have seen that the transmitter processes the data blockwise, resulting in a simple implementation without the need to store data from previous blocks. We now describe how this block independence can be extended to the receiver when including the influence of the channel. Figure 8 shows a block diagram for the complete DMT transmission system. For the moment, we focus on the signal only and consider the influence of the noise later. The receiver input signal is then given by

$$z[n] = s[n] * h[n] = \sum_m s[m] h[n - m] \quad (32)$$

where the discrete time *channel impulse response* (CIR), $h[n]$, includes the influence of the digital-analog and analog-digital conversion as well as any analog filters in the transmission chain. We assume that the CIR has finite length—that is, $h[n]$ has nonzero values only for $n = 0, 1, \dots, G$:

$$h[n] = 0 \quad \text{for } n < 0 \text{ or } n > G \quad (33)$$

As depicted in Figure 8, we define the vectors

$$\begin{aligned} \mathbf{x} &= (x_0, x_1, \dots, x_{N-1})^T, \quad \mathbf{s} = (s_0, s_1, \dots, s_{N+G-1})^T \\ &= (x_{N-G}, \dots, x_{N-1}, x_0, \dots, x_{N-1})^T \\ \mathbf{z} &= (z_0, z_1, \dots, z_{N+G-1})^T, \quad \mathbf{y} = (y_0, y_1, \dots, y_{N-1})^T \\ &= (z_G, z_{G+1}, \dots, z_{N+G-1})^T \end{aligned} \quad (34)$$

After the removal of the guard interval, we obtain for the components of the receive vector \mathbf{y}

$$y[n] = z[n + G] \quad \text{for } n = 0, 1, \dots, N - 1 \quad (35)$$

Using Equations 32 through 34, we can write

$$\begin{aligned} y[n] &= \sum_{m=0}^{G-1} x[m - G + N] h[n + G - m] \\ &\quad + \sum_{m=G}^{N+G-1} x[m - G] h[n + G - m] \end{aligned} \quad (36)$$

Figure 7: DMT transmitter. The bit sequence is first mapped to QAM symbols, which together with their complex conjugates form the input of the inverse DFT processor. Finally, the cyclic prefix is inserted and the symbols are converted to a serial data stream

Figure 8: DMT receiver. After serial-parallel conversion, the input symbols are DFT processed. The receiver discards the symbols corresponding to the cyclic prefix

which can be expressed in matrix notation as follows

$$\mathbf{y} = \begin{bmatrix} y_0 \\ y_1 \\ \vdots \\ y_{G-1} \\ y_G \\ y_{G+1} \\ \vdots \\ y_{N-1} \end{bmatrix} = \begin{bmatrix} h_0 & 0 & \cdots & 0 & h_G & \cdots & h_2 & h_1 \\ h_1 & h_0 & 0 & \cdots & 0 & h_G & \cdots & h_2 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ h_{G-1} & h_{G-2} & \cdots & h_0 & 0 & \cdots & 0 & h_G \\ h_G & h_{G-1} & h_{G-2} & \cdots & h_0 & 0 & \cdots & 0 \\ 0 & h_G & h_{G-1} & \cdots & h_1 & h_0 & 0 & \cdots \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & 0 & h_G & h_{G-1} & \cdots & h_1 & h_0 \end{bmatrix} \begin{bmatrix} x_0 \\ x_1 \\ \vdots \\ x_{G-1} \\ x_G \\ x_{G+1} \\ \vdots \\ x_{N-1} \end{bmatrix} = \mathbf{H}\mathbf{x} \quad (37)$$

This Equation with the *circular* matrix

$$(\mathbf{H})_{nm} = h[\text{mod}_N(n - m)] \text{ with } n, m = 0, 1, \dots, N - 1 \quad (38)$$

expresses the *circular convolution* (Oppenheim and Schaffer 1989), which corresponds to a multiplication in the frequency domain, and which can also be written as

$$y[n] = x[n] \otimes h[n] = \sum_{m=0}^{N-1} x[m] h[\text{mod}_N(n - m)] \quad (39)$$

From this point of view, the cyclic prefix transforms the linear convolution of Equation 32 into a circular convolution. Because the matrix \mathbf{H} is circular, its eigenvalues λ_μ and eigenvectors $\mathbf{\vartheta}_\mu$ are given by

$$\lambda_\mu = \sum_{i=0}^{N-1} h[i] W_N^{\mu i}, \quad \mathbf{\vartheta}_\mu = \frac{1}{\sqrt{N}} \begin{bmatrix} W_N^{-0} \\ W_N^{-\mu} \\ \vdots \\ W_N^{-(N-1)\mu} \end{bmatrix}, \quad \mu = 0, 1, \dots, N - 1 \quad (40)$$

This can be easily verified by checking the characteristic Equation $\mathbf{H}\mathbf{\vartheta}_\mu = \lambda_\mu \mathbf{\vartheta}_\mu$. We recognize the eigenvectors $\mathbf{\vartheta}_\mu$ as the columns of the inverse DFT matrix:

$$\mathbf{F}^{-1} = (\mathbf{\vartheta}_0, \mathbf{\vartheta}_1, \dots, \mathbf{\vartheta}_{N-1}) \quad (41)$$

The DFT matrix is unitary—that is, its inverse is identical to its conjugate transpose: $\mathbf{F}^{-1} = \mathbf{F}^H$. As a consequence of these special eigenvectors and eigenvalues, we can diagonalize the channel matrix with the DFT matrix:

$$\mathbf{F}\mathbf{H}\mathbf{F}^H = \mathbf{D} = \text{diag}(\lambda_0, \dots, \lambda_{N-1}) \quad (42)$$

with $\mathbf{X} = (X_0[k], \dots, X_{N-1}[k])^T$ and $\mathbf{Y} = (Y_0[k], \dots, Y_{N-1}[k])^T$, so we can write

$$\mathbf{Y} = \mathbf{F}\mathbf{y} = \mathbf{F}\mathbf{H}\mathbf{x} = \mathbf{F}\mathbf{H}\mathbf{F}^H \mathbf{X} = \mathbf{D}\mathbf{X} \quad (43)$$

or

$$Y_\mu[k] = \lambda_\mu \cdot X_\mu[k] \quad (44)$$

We can now describe the input-output relationship of the whole transmission system in Figure 8 with a single diagonal matrix. The result shows that because of the cyclic prefix, the parallel subchannels are independent and perfect reconstruction can be realized by a simple one-tap equalizer per subchannel at the output of the receiver DFT. As equalization is done after the DFT, this equalizer is often referred to as *frequency domain equalizer* (FEQ).

Following from Equation 40, we can interpret the eigenvalues λ_μ of the channel matrix as the DFT of the CIR. If we define the discrete time Fourier transform of the CIR as

$$H(\omega) = \sum_{n=0}^{N-1} h[n] e^{-j\omega n T_A} \quad (45)$$

we see that the eigenvalues in Equation 40 are nothing else than the values of the channel transfer function at the frequencies $\omega_\mu = \mu \cdot \Delta\omega$:

$$\lambda_\mu = H(\omega_\mu) \quad (46)$$

Because DMT is a baseband transmission scheme, the impulse response $h[n]$ is real-valued and therefore its spectrum shows hermitian symmetry:

$$\lambda_0, \lambda_{N/2} \in \mathbb{R}; \quad \lambda_\mu = \lambda_{N-\mu}^* \quad \mu = 1, \dots, N/2 - 1 \quad (47)$$

Let us now summarize the results, which highlight some of the main features of DMT. We have seen that the insertion of the cyclic prefix translates the linear convolution of Equation 32 into the circular convolution of Equation 39, which corresponds to a simple multiplication in the frequency domain as long as the impulse response of the channel is not longer than the guard interval. In this case, no interblock and intercarrier interference occur, and each subchannel signal is only weighted by the channel transfer function at the subcarrier frequency. It is this remarkable property that made multicarrier schemes such as DMT and OFDM so popular.

If the CIR exceeds the guard interval, then the described features are not valid anymore. To overcome this problem, which might appear in ADSL for especially long

lines, an additional equalizer has to be introduced as outlined later (in the section titled “Equalization for Insufficient Guard Interval Length”).

Spectral Properties of DMT Signals

For the calculation of the spectrum of the output signal, we consider the system model in Figure 5, which leads to a straightforward and comprehensible calculation. First we consider one modulated subchannel with the input signal given in Equation 10. This leads to the output signal and the corresponding spectrum:

$$\begin{aligned} s[n] &= g_t[n] \cdot W_N^{-vn} \leftrightarrow S(\omega) \\ &= \sum_{n=-\infty}^{\infty} g_t[n] W_N^{-vn} e^{-j\omega n T_A} = \sum_n g_t[n] W_N^{\left(\frac{\omega}{\Delta\omega} - v\right)n} \end{aligned} \quad (48)$$

where for the last expression we made use of Equations 18 and 21. For the rectangular pulse-shaping filter of Equation 24, we obtain for the output spectrum:

$$S(\omega) = \frac{1}{\sqrt{N}} \begin{cases} \frac{1 - W_N^{\left(\frac{\omega}{\Delta\omega} - v\right)N_s}}{1 - W_N^{\left(\frac{\omega}{\Delta\omega} - v\right)}} & \text{for } \omega \neq v \cdot \Delta\omega \\ N_s & \text{for } \omega = v \cdot \Delta\omega \end{cases} \quad (49)$$

In Figure 9a, the magnitude of the spectrum is depicted for the case that subcarrier $v \in \{10, 11, 12\}$ is modulated. The spectrum is quite similar to a $\sin(\omega)/\omega$ function but not identical because the system model in Figure 5 is discrete time. Another consequence is that $S(\omega)$ is periodic with $\omega_A = 2\pi/T_A = N \cdot \Delta\omega$. Note that the spectrum of a single subcarrier with carrier frequency $v\Delta\omega$ does *not* have zero crossings at the adjacent subcarrier frequencies $(v \pm m)\Delta\omega$ unless the guard interval is zero. Although in the literature it is often suggested that spectral nulls at adjacent subcarrier frequencies is tantamount to orthogonality, it is clear from Figure 9 that this condition is not necessary. Note also that to obtain a real-valued output signal, according to Equation 31, we also must send a unit impulse on subchannel $N - v$.

Figure 9: (a) Spectrum of the transmitter signal if subcarrier n is modulated with a unit impulse, guard interval $G = N/8$. (b) Power spectral density for $N = 32$, $G = 4$. The ripple increases with the duration of the guard interval

To calculate the *power spectral density* (PSD) of a DMT signal, we now consider stochastic input sequences $X_v[k]$, which are uncorrelated with zero mean and unit variance. Then the PSD of the output signal $s_v[n]$ corresponding to one subcarrier is given by

$$\Phi_v(\omega) = \frac{1}{N_S} |G(\omega)|^2 \quad (50)$$

where

$$G(\omega) = \sum_n g_t[n] e^{-j\omega n T_A} = \frac{1}{\sqrt{N}} \begin{cases} 1 - W_N^{\omega N_S / \Delta\omega} & \text{for } \omega \neq 0 \\ N_S & \text{for } \omega = 0 \end{cases} \quad (51)$$

From this we obtain the PSD of the output signal $s[n]$ as

$$\Phi_s(\omega) = \frac{1}{N_S} \sum_{\substack{v=-(N/2-1) \\ v \neq 0}}^{N/2-1} |G(\omega - v \cdot \Delta\omega)|^2 \quad (52)$$

which is depicted in Figure 9b for a system with $N = 32$. All subcarriers are modulated with unit power, except for carriers $v = 0$ and $v = N/2$. As the anti-aliasing low pass in the digital-analog converter has a cutoff frequency of $\omega_A/2 = N \cdot \Delta\omega/2$, the carriers in this frequency region cannot be modulated. Therefore, at least the carrier at $v = N/2$ remains unused. Because the anti-aliasing filter is not arbitrarily selective, usually many more subcarriers are left unmodulated. The carrier at $v = 0$ is normally not used either because most channels do not support a DC component.

IMPLEMENTATION ASPECTS

Having established the basic principles of DMT, in this section we specify further details that are important for implementation, starting with the one-tap equalizer made possible by the cyclic prefix. Because for especially long channels this simple and elegant method is not sufficient, we give a sketch of equalization strategies for the case of an insufficient guard interval. One major drawback of MCM is the problem of high peak power, which we outline and briefly sketch possible solutions. Finally, we describe implementation alternatives such as MCM with filter banks and some variants of the guard interval.

Frequency Domain Equalization

The signal after DFT processing at the receiver is given by

$$Y_\mu[k] = \lambda_\mu \cdot X_\mu[k] + w_\mu[k] \quad (53)$$

where $w_\mu[k]$ represents the noise on subchannel μ . In many practical cases, the noise on the channel can be modeled as *additive white Gaussian noise* (AWGN). After DFT processing, the noise is still white and Gaussian. In the

following, we assume that the post-DFT noise is Gaussian but not necessarily white—that is, the variance $\sigma_\mu^2 = E[|w_\mu[k]|^2]$ may vary from subchannel to subchannel.

Because the parallel subchannels are only affected by the constant eigenvalues of the channel matrix according to Equation 53, a simple one-tap equalizer with coefficient ψ_μ per subchannel is sufficient to recover the transmit signal:

$$\hat{X}_\mu[k] = \psi_\mu \cdot Y_\mu[k] = \psi_\mu \lambda_\mu X_\mu[k] + \psi_\mu w_\mu[k] \quad (54)$$

The simplest equalization strategy disregards the noise and simply recovers the transmit symbol by dividing through the channel transfer coefficient:

$$\psi_\mu = \frac{1}{\lambda_\mu} \Rightarrow \hat{X}_\mu[k] = X_\mu[k] + \frac{1}{\lambda_\mu} w_\mu[k] \quad (55)$$

Although this strategy is easy to implement, it has the drawback of noise amplification, which is especially severe for strongly attenuated subchannels. If we denote by $p_\mu = E[|X_\mu[k]|^2]$ the signal power on subchannel μ , then we can write for the SNR after equalization:

$$\gamma_\mu = \left| \lambda_\mu \right|^2 \cdot \frac{p_\mu}{\sigma_\mu^2} \quad (56)$$

From this expression, it is obvious that the SNR can be severely degraded if the channel is strongly attenuated.

This equalization strategy can be significantly improved by taking into account the noise power: the *minimum mean square error* (MMSE) equalizer minimizes the quadratic error $E[|\hat{X}_\mu - X_\mu|^2]$. This is achieved by the MMSE equalizer coefficients

$$\psi_\mu = \frac{\lambda_\mu^*}{\left| \lambda_\mu \right|^2 + \frac{\sigma_\mu^2}{p_\mu}} \quad (57)$$

and leads to the postequalization SNR

$$\gamma_\mu = \left| \lambda_\mu \right|^2 \frac{p_\mu}{\sigma_\mu^2} + 1 \quad (58)$$

which gives a significantly better performance than in the first case, especially for strongly attenuated subchannels with $\lambda_\mu < 1$.

Although the objective of the above equalizers is to recover the symbol $X_\mu[k]$, this is only an intermediate step in the reception. Each transmit symbol $X_\mu[k]$ corresponds to a number of bits, and the objective is to recover as much information as possible about the transmitted bits. In nearly all modern communication systems, channel coding is applied and the decoder at the receiver will work most efficiently if provided with *reliability information* about each bit. Each transmit symbol is taken out of a finite symbol alphabet—that is, $X_\mu[k] \in A_X$ —and corresponds to a bit vector $\mathbf{b}_\mu = (b_{\mu,1}, \dots, b_{\mu,Q})^T$, where $b_{\mu,q} \in \{0,1\}$.

Because, according to Equation 53, the subchannels are parallel and independent, in the following we focus solely on subcarrier μ .

On each subcarrier, a bit vector is mapped to a QAM symbol—that is,

$$X_\mu[k] = \text{map}(\mathbf{b}_\mu) \quad (59)$$

Whereas a hard demapper first equalizes the symbols and then calculates the corresponding bit sequence, a *soft demapper* computes for each detected bit a soft value that contains information about the reliability of this bit. A common measure is the *a posteriori probability* (APP) *log-likelihood value* (L value) of $b_{\mu,q}$, which is defined as

$$L_D(b_{\mu,q} | Y_\mu) = L_A(b_{\mu,q}) + L_E(b_{\mu,q} | Y_\mu) = \ln \frac{P[b_{\mu,q} = 1 | Y_\mu]}{P[b_{\mu,q} = 0 | Y_\mu]} \quad (60)$$

where

$$L_A(b_{\mu,q}) = \frac{P[b_{\mu,q} = 1]}{P[b_{\mu,q} = 0]} \quad (61)$$

is the *a priori* L value of $b_{\mu,q}$ and $L_E(b_{\mu,q} | Y)$ is the *extrinsic information*. The *a priori* knowledge may stem from a channel decoder if iterative decoding is applied. If no such knowledge is available, then the L-value $L_A(b_{\mu,q})$ is simply set to zero. The extrinsic information is given by

$$L_E(b_{\mu,q} | Y_\mu) = \ln \frac{\sum_{\mathbf{b} \in \mathbf{B}_{q,1}} p(Y_\mu | \mathbf{b}) \exp(\mathbf{b}_q^T \mathbf{A}_{\bar{q}})}{\sum_{\mathbf{b} \in \mathbf{B}_{q,0}} p(Y_\mu | \mathbf{b}) \exp(\mathbf{b}_q^T \mathbf{A}_{\bar{q}})} \quad (62)$$

where

$$p(Y_\mu | \mathbf{b}_\mu) = p(Y_\mu | X_\mu) = \frac{1}{\pi \sigma_\mu^2} \exp \left(-\frac{|Y_\mu - \lambda_\mu X_\mu|^2}{\sigma_\mu^2} \right) \quad (63)$$

is the conditional probability distribution function of the received noisy signal, $\mathbf{A} = (A_{\mu,1}, \dots, A_{\mu,Q})^T$ is the vector of *a priori* values corresponding to the bit vector \mathbf{b}_μ , and $\mathbf{A}_{\bar{q}}$ denotes this vector without its q th component. The sums are taken over all bit vectors that have a 1 or 0 in the q th position—that is, $\mathbf{B}_{q,j} = \{\mathbf{b} : b_q = j\}$.

The extrinsic L value is finally given as

$$L_E(b_{\mu,q} | Y_\mu) = \ln \frac{\sum_{\mathbf{b} \in \mathbf{B}_{q,1}} \exp \left(-\frac{|Y_\mu - \lambda_\mu X_\mu|^2}{\sigma_\mu^2} + \mathbf{b}_q^T \mathbf{A}_{\bar{q}} \right)}{\sum_{\mathbf{b} \in \mathbf{B}_{q,0}} \exp \left(-\frac{|Y_\mu - \lambda_\mu X_\mu|^2}{\sigma_\mu^2} + \mathbf{b}_q^T \mathbf{A}_{\bar{q}} \right)} \quad (64)$$

This value is passed to the channel decoder, which performs the inverse operation to the encoder in the transmitter. This calculation of soft bits as input to a channel decoder corresponds to a fundamental principle in digital communications that says no information should be discarded until a final decision is taken.

Equalization for Insufficient Guard Interval Length

As we have seen in the previous sections, one main feature of DMT is the low complexity of the single-tap equalization that is achieved by the insertion of the guard interval. However, if the CIR length occupies a significant fraction of the symbol time T , and if the number of subcarriers cannot be increased, then the necessary guard interval length would lead to a significant reduction in useful transmission time T_u and therefore decrease the spectral efficiency. This situation might occur in applications such as ADSL over long telephone lines, but alternative solutions have been investigated in order to cope with impulse responses that exceed the guard interval length. Basically, two methods as illustrated in Figure 10 can be distinguished:

1. In *time domain equalization* (TEQ), the received signal is equalized before being transformed by the DFT. Loosely speaking, the objective of this equalizer is to “shorten” the CIR.
2. In *frequency domain equalization* (FEQ), the equalizer is placed after the DFT which—in contrast to the simple one-tap equalizer described in the previous section—and generally considers several subcarriers and DMT symbols jointly.

Good overviews about equalization strategies for DMT can be found in Pollet et al. (2000) and Arslan, Evans, and Kiaei (2001). The final objective of the equalizer is usually to maximize the transmission rate, which has to be translated into a criterion for the equalizer coefficients.

Time Domain Equalization

It has been shown by al-Dhahir and Cioffi (1996) that the computation of the TEQ coefficients for rate maximization leads to a highly nonlinear optimization problem with several local minima. Because the equalizer coefficients must be initialized during the training phase in real time, modem designers resort to simpler criteria that depend more directly on the equalizer coefficients. A natural choice for the TEQ objective function is to “shorten” the CIR. The equalizer produces an “effective” CIR— $h_{\text{eff}}[n] = h[n] * a[n]$ —that is shorter than the guard interval. Several criteria for this “channel shortening,” such

Figure 10: Receiver with time- and frequency-domain equalizers

as the *mean square error* (MSE) with respect to a target impulse response or the signal energy within a window of length G , can be applied (Schur, Speidel, and Angerbauer 2000).

Frequency Domain Equalization

A rather natural choice to combat the effects of an insufficient guard interval is to use an equalizer after the receiver DFT that spans several subcarriers and DMT symbols. This can be seen as an extension of the simple one-tap equalizer described in the previous section. Karp, Trautmann, and Fliege (2004) showed that ISI and ICI can be completely removed by a block equalizer based on the zero-forcing criterion, as long as there are some unused subcarriers, which is the normal case in practical DMT systems. The resulting equalizer matrix is sparse, which means that the implementation cost of this block equalizer is rather low.

The Peak-to-Average Power Ratio Problem

One of the major difficulties of multicarrier systems when it comes to practical implementation is related to its high *peak-to-average power ratio* (PAPR). In multicarrier systems, the peak power of the output signal is significantly higher than its average power, leading to high linearity requirements for the power amplifier and requiring a huge range and high resolution for the digital-to-analog and analog-to-digital converter.

Based on the system model in Figure 3, we can define the PAPR as

$$\eta = \frac{\max \{|s(t)|^2\}}{E[|s(t)|^2]} \quad (65)$$

We assume that all subchannels use the same QAM constellation and that the sequences $X_\mu[k]$ are uncorrelated. Then for 2^Q -QAM with square constellations—that is, Q is even—the average signal power of $X_\mu[k]$ is given by

$$E_S = \frac{2^Q - 1}{6} d^2 \quad (66)$$

where d is the distance between two adjacent signal points. The signal power of the output signal $s(t)$ is

$$E[|s(t)|^2] = N \cdot E[|s_0(t)|^2] = NT E_S \int_{-\infty}^{+\infty} |g_t(t)|^2 dt \quad (67)$$

The output signal $s(t) = T \sum_k \sum_{v=0}^{N-1} e^{j\omega_v t} X_v[k] g(t - kT)$ takes on its maximum when all terms $e^{j\omega_v t} X_v[k]$ have the same phase. Denoting by $A = \max\{|X_v[k]|\}$ the maximum value of the signal constellation, the maximum output signal power is

$$\max\{|s(t)|^2\} = \left(ANT \sum_k |g(kT)|^2 \right)^2 \quad (68)$$

For square constellations, it holds that $A = \frac{\sqrt{2}}{2} (2^{Q/2} - 1) d$. We further assume normalized transmitter filters—that is, $\int |g(t)|^2 dt = 1$ —which finally yields the PAPR:

$$\eta = N \cdot \frac{3(2^{Q/2} - 1)^2}{2^Q - 1} \cdot T \cdot \left(\sum_k |g(kT)|^2 \right)^2 \quad (69)$$

From this expression, we see that the transmit filter has a minor influence on the PAPR, which is dominated by the number of subcarriers N . This is intuitive, because amplitude peaks occur when all subcarriers are in phase and the amplitudes simply add up.

Another explanation for the high PAPR when the number of subcarriers is large comes from the central limit theorem. When N becomes large, the amplitude distribution of the output signal, which is the sum of N independent subcarrier signals, tends to a Gaussian distribution, which has infinite PAPR. From an information theory perspective, this is an advantage of multicarrier systems: To achieve the Shannon capacity of a Gaussian channel, the transmitter signal has to be Gaussian distributed, too.

The PAPR problem has been recognized by the scientific community and a great number of partial solutions exist. Van Nee and Prasad (2000) classify the PAPR reduction techniques into the following three groups.

1. *Distortion of the transmit signal before the power amplifier.* This includes clipping and nonlinear companding, which indeed reduces the PAPR but on the other hand originates additional out-of-band emissions and in-band distortions (see e.g. O'Neill and Lopes 1995).
2. *Coding techniques to exclude sequences with a high peak power.* Because there are few sequences with a high power, not much overhead is required. However, the computational complexity of this approach can be significant (Van Nee 1996; Tarokh and Jafarkhani 2000).
3. *Probabilistic methods* that, for example, modify the phases of the QAM constellations by pseudorandom sequences or methods that make use of spreading (Müller-Weinfurter 2000).

These methods allow us to reduce the PAPR, but they come at the price of increased complexity and signaling overhead. There seems to be no unique and optimal solution to this problem, hence research is still active in this field. A comprehensive description of state-of-the-art methods to achieve a low PAPR can be found in the book by J. Tellado (2000).

Implementation as Filter Bank

So far, we only considered implementations with rectangular pulse shape. In fact, this is by far the most common option for practical systems, and from Figure 7 it is not obvious how to realize nonrectangular pulse shapes. For this purpose, the more general scheme in Figure 5 is much better suited. As long as the condition for perfect reconstruction is satisfied, the transmit and receive filters may

be chosen to fulfill any optimization criterion. A common objective for the design of the pulse-shaping filter is to reduce the spectral side lobes of the transmit signal (see e.g. Cherubini, Eleftheriou, and Ölçer 2002).

Although the filter bank implementation in Figure 5 is well suited for system analysis and for getting a good understanding of the system, it is not efficient for implementation. Similar to rectangular pulse shaping, which can be realized with a simple IDFT, MCM systems with pulse shaping can be implemented more efficiently with DFT processing. In addition to the IDFT processor, a polyphase filter bank is required as depicted in Figure 11.

We assume that the impulse response $g[n]$ has length $KN_s + 1$ and is symmetrical to $KN_s/2$, where K is the filter lengths in multiples of DMT symbols:

$$\begin{aligned} g[n] &= 0, \quad \text{for } n < 0, n > KN_s \\ g[n] &= g[KN_s - n] \end{aligned} \quad (70)$$

Note that this allows us to define filters of nearly arbitrary length that can be used to impose stringent conditions on the spectral properties of the output signal. The polyphase filter bank in Figure 11 consists of N_s filters with impulse responses:

$$g_i[k] = g[kN_s + i], \quad i = 0, 1, \dots, N_s - 1, k \in \mathbb{Z} \quad (71)$$

This decomposition of $g[n]$ into N_s filters of lower sampling rate is called *polyphase decomposition of type 1* (Vaidyanathan 1990 and 1993; Fliege 2000) and reads in the other direction:

$$g[n] = g_{\text{mod}_{N_s}(n)} \left[\left\lfloor n/N_s \right\rfloor \right] \quad (72)$$

It can be shown easily that the implementation in Figure 11 is equivalent to the MCM system in Figure 5. Because the polyphase filter bank operates at a fraction of the sampling rate of the direct implementation in Figure 5, the first variant is preferred for practical implementation.

Variants of the Guard Interval

Besides the most commonly applied cyclic prefix, there are other alternatives for the implementation of the guard interval. In this section, we briefly outline these alternatives, starting with a compact matrix notation of the cyclic prefix.

Figure 11: Transmitter with IDFT and polyphase filter bank

Cyclic Prefix

As we saw earlier, after the inverse Fourier transform, the last G samples of each DMT block are copied and inserted at the beginning of the block. We can thus write the output of the transmitter as

$$\mathbf{s}[k] = [\mathbf{F}_{\text{cp}} \mathbf{F}]^H \mathbf{X}[k] \quad (73)$$

where \mathbf{F} is the DFT matrix and \mathbf{F}_{cp} is the $N \times G$ matrix that is formed by the last G columns of \mathbf{F} . The received signal after the DFT is given by

$$\mathbf{Y}[k] = \mathbf{D} \mathbf{X}[k] + [\mathbf{0}_{N \times G} \mathbf{F}] \mathbf{w}[k] \quad (74)$$

where \mathbf{D} is a diagonal matrix as we saw in the previous section.

Zero Padding

Multicarrier modulation with zero padding has been proposed relatively recently by Scaglione, Giannakis, and Barbarossa (1999) and has been considered for wireless transmission by Muquet et al. (2002). It has been shown that in the noiseless case, zero padding allows us to recover the transmit symbol regardless of the channel zero locations—that is, the transmit symbol can even be recomputed at the receiver if the matrix \mathbf{H} according to Equation 37 has zero eigenvalues. This is not possible with a cyclic prefix where a channel zero at a subcarrier frequency will inevitably destroy that subchannel's symbol. However, it has to be noted that this argumentation is rather academic because it only holds for noiseless channels that, in reality, never occur.

With zero padding, the transmitter output is given by

$$\mathbf{s}[k] = [\mathbf{F} \mathbf{0}_{N \times G}]^H \mathbf{X}[k] \quad (75)$$

The receiver input signal is now

$$\begin{aligned} \mathbf{z}[k] &= \tilde{\mathbf{H}} \mathbf{F}_{\text{zp}} \mathbf{X}[k] + \mathbf{w}[k] \\ &= [\tilde{\mathbf{H}}_0 \tilde{\mathbf{H}}_{\text{zp}}] \mathbf{F}_{\text{zp}}^H \mathbf{X}[k] + \mathbf{w}[k] \\ &= \tilde{\mathbf{H}}_0 \mathbf{F}^H \mathbf{X}[k] + \mathbf{w}[k], \end{aligned} \quad (76)$$

where $\tilde{\mathbf{H}}$ is the $N_s \times N_s$ lower triangular Toeplitz matrix whose first column is $(h_0 \dots h_G \ 0 \dots 0)^T$, and $\tilde{\mathbf{H}} = [\tilde{\mathbf{H}}_0 \ \tilde{\mathbf{H}}_{\text{zp}}]$ is its partition into the first N and the last G columns. $\tilde{\mathbf{H}}_0$ is also Toeplitz and nonsingular—that is, it is always invertible. For zero padding, a slightly more complex receiver is in order because the Toeplitz matrix $\tilde{\mathbf{H}}$ cannot be diagonalized by the Fourier matrix as was the case with the circular matrix \mathbf{H} in Equation 37. If we adopt the MMSE criterion for the equalization of the input signal in Equation 76, then we obtain the equalization matrix

$$\mathbf{G} = \mathbf{F} \tilde{\mathbf{H}}_0^H \left(\frac{N_0}{E_s} \mathbf{I}_{N_s} + \tilde{\mathbf{H}}_0 \tilde{\mathbf{H}}_0^H \right)^{-1} \quad (77)$$

Thus, the signal after equalization is given by

$$\mathbf{Y}[k] = \mathbf{G} \mathbf{z}[k] = \mathbf{G} \mathbf{H}_0 \mathbf{F}^H \mathbf{X}[k] + \mathbf{G} \mathbf{w}[k] \quad (78)$$

The matrix $\mathbf{G} \mathbf{H}_0 \mathbf{F}^H$ is approximately diagonal; based on this observation, further receiver processing can be implemented based on soft demapping as outlined in the section on frequency domain equalization. For further details, see also Pfletschinger and Sanzi (2004).

Pseudorandom Postfix

The idea of the pseudorandom postfix is partially inspired by the zero-padding guard interval and shares some of its advantages (Muck et al. 2003). However, instead of appending G zero samples to each DMT symbol, a pseudorandom sequence is inserted. Because this sequence is known beforehand, the receiver can use this knowledge for channel estimation.

Similar to zero padding, the transmitted signal is given by

$$\mathbf{s}[k] = [\mathbf{F} \mathbf{0}_{G \times N}]^H \mathbf{X}[k] + [\mathbf{0}_{1 \times N} \mathbf{c}]^T \quad (79)$$

where $\mathbf{c} = (c_0, c_1, \dots, c_{G-1})^T$ is the pseudorandom postfix. Muck et al. (2003) propose several equalization schemes with different performance and complexity trade-offs for this multicarrier scheme. The basic advantage of this scheme is its ability to facilitate channel estimation in the receiver, especially if the Doppler spread is large.

CAPACITY AND ADAPTIVE BIT LOADING

Capacity of Frequency-Selective Channels

Shannon (1948) showed in his seminal work that the maximum bit rate for reliable communication over a noisy channel is given by the *channel capacity*. For an AWGN channel with complex-valued transmit signals, transmit power E_s , and noise power N_0 , this capacity is given by

$$R = \log_2 \left(1 + \frac{E_s}{N_0} \right) \quad (80)$$

The maximum achievable rate R is measured in bits per channel use, which is equivalent to bps/Hz when applied to a discrete time channel model. Because DMT decomposes the broadband channel into parallel independent subchannels, according to Equation 53 we can use this expression to compute the capacity per subchannel. The transmit and noise power on subchannel μ are given by $p_\mu = E[|X_\mu[k]|^2]$ and $\sigma_\mu^2 = E[|w_\mu[k]|^2]$, respectively. This gives the subchannel capacity

$$R_\mu = \log_2 \left(1 + \frac{|\lambda_\mu|^2 p_\mu}{\sigma_\mu^2} \right) = \log_2 (1 + T_\mu p_\mu) \quad (81)$$

where we defined the *channel gain-to-noise ratio* (CNR):

$$T_\mu = \frac{|\lambda_\mu|^2}{\Gamma \cdot \sigma_\mu^2} \quad (82)$$

For the following considerations on channel capacity and transmit power, it is sufficient to describe the channel by its CNR. The factor Γ denotes the SNR gap, which for the moment is set to unity. If the channel is frequency-selective, which is the usual case for DMT, then the simple AWGN formula of Equation 80 cannot be applied. However, because DMT decomposes the broadband channel into parallel, frequency nonselective subchannels, we can compute the capacity of the subchannel and obtain the capacity of the broadband channel as the sum of all subchannel capacities.

This sum capacity depends on the distribution of the total transmit power on the subchannels; thus, a natural question to ask is: How should the transmit power \bar{P} be allocated in order to maximize the channel capacity $R = \sum_\mu R_\mu$? This can be formulated rigorously as the following optimization problem:

$$\begin{aligned} \max. \quad & \sum_{\mu=1}^M R_\mu \\ \text{s.t.} \quad & \sum_{\mu=1}^M p_\mu \leq \bar{P}, \quad p_\mu \geq 0 \end{aligned} \quad (83)$$

where $\mu = 1, 2, \dots, M$ denotes the available subcarriers, and \bar{P} is the available transmit power. The solution to this problem is the famous *water-filling* solution (Gallager 1968):

$$p_\mu = \max \left\{ 0, P_0 - \frac{1}{T_\mu} \right\}, \quad \text{with } P_0 \text{ such that } \sum_\mu p_\mu = \bar{P} \quad (84)$$

The name of this solution comes from the nice graphical representation of the formula, which is depicted in Figure 12. We can interpret the inverse CNR $1/T_\mu$ as the bottom of a bowl, into which we fill an amount of water that corresponds to \bar{P} . The water will distribute itself such that the depth corresponds to the wanted function p_μ .

The water-filling solution finds the optimum power allocation to maximize the channel capacity. In a practical system, we need to consider implementable *modulation and coding schemes* (MCS) that operate at a rate below capacity. Moreover, only a small number of eligible MCS, each corresponding to a given code rate, is usually available.

To make use of the water-filling solution for practically implementable MCS, we can introduce the SNR gap, which provides a link between the information-theoretic channel capacity and the bit rate for (coded) QAM. The SNR gap Γ is the additionally required SNR in QAM modulation with a given target *bit error ratio* (BER) to achieve the bit rate R . In other words, if for the SNR γ the channel

Figure 12: Water-filling diagram. The inverse CNR $1/T_\mu$ can be interpreted as the bottom of a bowl. If this bowl is filled with an amount of water that corresponds to the available transmit power, then the depth corresponds to the optimum power allocation per subchannel

capacity is R , then with QAM we need an SNR of $\Gamma\gamma$ to achieve the same rate R .

Algorithms for Bit and Power Loading

For practical QAM modulation, the optimization problem of Equation 83 must be formulated in a slightly different way. Instead of the channel capacities, we have to consider bit rates b_μ , which are taken out of a discrete set $B = \{r_1, r_2, \dots, r_Q\}$. An associated set, $\gamma = \{\gamma_1, \gamma_2, \dots, \gamma_Q\}$, denotes the required SNRs to achieve these rates at a given BER. The modulation and coding scheme is sufficiently described by these two sets for a given target BER.

Apart from maximizing the bit rate, another common criterion is the minimization of the transmit power for a given target bit rate.

Maximum bit rate:

$$\begin{aligned} \max \quad & \sum_{\mu} b_{\mu} \\ \text{s.t.} \quad & \sum_{\mu} p_{\mu} \leq \bar{P}, \quad p_{\mu} \geq 0, \quad b_{\mu} \in B \end{aligned} \quad (85)$$

Minimum transmit power:

$$\begin{aligned} \min \quad & \sum_{\mu} p_{\mu} \\ \text{s.t.} \quad & \sum_{\mu} b_{\mu} \geq b_{\min}, \quad p_{\mu} \geq 0, \quad b_{\mu} \in B \end{aligned} \quad (86)$$

An algorithm that can be applied to both criteria is the *Hughes-Hartogs algorithm* (Hughes-Hartogs 1987). This is the optimal algorithm for the discrete optimization problems of Equations 85 and 86 and can be considered as the discrete version of the water-filling solution.

The Hughes-Hartogs algorithm is relatively simple and can be described in a few lines:

$$p_{\text{tot}} = 0, \quad b_m = i_m = 0 \quad \forall m = 1, \dots, M$$

$$\Delta p_m = \gamma_1 / T_m \quad \forall m = 1, \dots, M$$

while $\sum_m b_m < b_{\min}$ and $p_{\text{tot}} < \bar{P}$

$$\hat{m} = \arg \min_m \{\Delta p_m\} \quad // \text{ find subcarrier with smallest power increment}$$

$$p_{\text{tot}} = p_{\text{tot}} + \Delta p_{\hat{m}} \quad // \text{ increment total transmit power}$$

$$\text{if } p_{\text{tot}} < \bar{P}$$

$$i_{\hat{m}} = i_{\hat{m}} + 1, \quad b_{\hat{m}} = r_{i_{\hat{m}}} \quad // \text{ increment rate on chosen subcarrier}$$

$$\text{if } i_{\hat{m}} < Q \quad // \text{ rate increment still possible on chosen subcarrier?}$$

$$\Delta p_{\hat{m}} = (\gamma_{i_{\hat{m}+1}} - \gamma_{i_{\hat{m}}}) / T_{\hat{m}}$$

else

$$\Delta p_{\hat{m}} = \infty \quad // \text{ subcarrier fully loaded}$$

end if

end if

end while

The basic idea of this algorithm is to increase the rate of the subchannel that requires the least power for this rate increment. The algorithm first calculates the power increment for transmitting the next higher rate on each subcarrier. Then the subchannel with the lowest power increment is selected and—if neither the power nor the bit rate constraint is exceeded—the next higher bit rate is allocated to this subchannel. This process is repeated until the power or rate constraint is about to be exceeded. The algorithm can be used for both rate maximization or power minimization by simply setting the other constraint to infinity. It was originally formulated for uncoded QAM, but by defining the set B with noninteger rates, it can also be applied to coded QAM. The mapping between transmit power and rate, which substitutes Equation 81, is implicitly given by the set of minimum SNRs γ .

Although the Hughes-Hartogs algorithm provides the best solution, it is not the most efficient one from an implementation point of view. This issue has been addressed by various authors who have presented suboptimal but computationally more efficient solutions. These are too numerous to be listed, so we mention as an example the solution of Sonalkar (2002) and the references therein.

Significant contributions in this area have been provided first by Chow (1993) and later by Yu and Cioffi (2001), who formalized the observation that the capacity is reduced only to a small extent by constant power allocation. They describe a solution that allocates constant transmit power to a subset of the available subcarriers and illustrate a low-complexity algorithm that finds this subset. Moreover, they provide a bound on the rate loss with respect to the optimum water-filling solution.

The Hughes-Hartogs and the constant power algorithm are illustrated in the water-filling diagram in Figure 13.

APPLICATIONS AND EXTENSIONS OF DMT

The First Main Application: ADSL

The DMT modulation scheme has been selected as standard for asymmetric digital subscriber lines, a technique

Figure 13: (a) Bit allocation with the Hughes-Hartogs algorithm. Bits are allocated to the subchannel with the smallest power increment. (b) Constant power water filling. Constant power is allocated to a properly chosen subset of all subchannels

for providing high-speed data services over the existing copper-based telephone subscriber line infrastructure. Typically, these phone lines are unshielded twisted pairs that share the same cable with multiple other pairs. Hence, the performance of ADSL depends on the noise environment and cable loss. When lines are bound together in a cable, they produce cross talk from one pair to another at levels that increase with frequency and the number of cross-talking pairs or disturbers. For this reason, cross talk is one major noise source. Additional disturbances stem from impulse noise and possibly from radio frequency interferers. Beside that, line attenuation increases with frequency and distance. DMT is well suited for the wide variations in the ADSL channel characteristics. In particular, rate adaptation on a subchannel basis is quite straightforward for DMT in order to optimize the ADSL transmission system. In the sequel, certain aspects of an ADSL system are regarded.

The parameters of the DMT modulation scheme for downstream transmission are determined by the ADSL standard (ITU-T 1999) as follows:

- FFT size of $N = 512$. Excluding the two subcarriers at $\nu = 0$ and $\nu = N/2$, at most 255 usable parallel subchannels result.
- sampling rate $f_A = 1/T_A = 2.208 \cdot 10^6$ samples/s
- guard interval length $G = N/16 = 32$ samples
- adaptive bit loading with a maximum number of 15 bits per subcarrier (this corresponds to QAM with $2^{15} = 32768$ constellation points)
- a flat transmit power spectral density of approximately -40 dBm/Hz. As the spectrum ranges up to $f_A/2 = 1.104$ MHz, the transmit power is approximately 20 dBm.

Because ADSL services share the same line with the plain old telephone service (POTS), a set of service filters (POTS-splitter) at the customer premises and the network node separate the two frequency bands. Usually, POTS signals occupy a bandwidth up to 4 kHz. To allow a smooth and inexpensive analog filter for signal separation, ADSL services can use a frequency range from 25 kHz to as high as 1.1 MHz.

For a comprehensive overview of xDSL technology, see the books of Bingham (2000) and Starr, Cioffi, and Silverman (1999), as well as the June 2002 issue of the *IEEE Journal of Selected Areas in Communications* (vol. 20, no. 5).

DMT for Power Line Communications

Power line communication (PLC) systems aim at using the ubiquitous power line grid as a medium for last-mile access networks. As with ADSL, the key idea for economic feasibility is to use an advanced transmission scheme over an existing medium. One of the principal differences between the telephone subscriber line and the power line grid is that in the first system each user has a dedicated line while the latter is a shared medium; hence for PLC a multiple-access scheme is required. DMT can be extended straightforwardly to a multi-user scheme by allocating to each user a subset of the available subcarriers.

Another variant of PLC uses the power line for in-home communication, making use of the existing infrastructure of wires and wall outlets to provide a broadband LAN and thus constitute an alternative to WLAN for in-home use.

The major impairments of the power line channel are the frequency-dependent attenuation and considerable noise, which is typically far from the typical AWGN model. It is strongly colored and has multiple impulse components. In addition, narrowband interference from external radio sources is coupled into the network. DMT with adaptive bit loading can cope well with frequency-selective channels, colored noise, and narrowband interference by allocating more bits to subchannels with high SNR and apply lower rates on noisier subchannels.

A good high-level overview of PLC can be found in Majumder and Caffery (2004), while details on coding and modulation for PLC are given by Biglieri (2003). Up-to-date information can also be found in the July 2006 special issue of the *IEEE Journal on Selected Areas in Communications* (vol. 24, no. 7).

Advanced DMT Techniques

The prime application of DMT is ADSL, which connects individual users over the existing telephone subscriber line to a central office, which is connected to a backbone

network such as the Internet. These subscriber lines consist usually of twisted pairs that form part of a bigger cable bundle. Because the individual pairs are not shielded, electromagnetic coupling results in significant cross talk between the twisted pairs of different users. This creates a multi-user environment, which gives the opportunity for significant performance gains by treating the individual DMT systems jointly—that is, as a multi-user system. The main degrees of freedom for multi-user optimization come from the possibility for frequency-selective power allocation and from the possibility of coordinating transmission or reception of different users' signals. These techniques are known as *dynamic spectrum management* (see Cioffi 2005; Song and Chung 2002) and the following two main methods can be identified.

Multi-User Power Allocation with Iterative Water Filling

In this approach, all users optimize their own transmit PSD by considering the cross talk of all other users. This method is computationally inexpensive but nevertheless powerful and can be applied in a distributed or centralized version. If applied to an *interference channel*, the distributed algorithm converges to a Nash equilibrium (Yu, Ginis, and Cioffi 2002), while the centralized version converges to the maximum sum rate for a *multiple-access channel* (Yu et al. 2004).

Vectored DMT

In the downstream, the signals for all users in the same cable binder can be transmitted *cooperatively* by applying predistortion techniques. Ideally, these predistortions are designed such that, after passing through the channel, the received signals at the customers' modems are free of interference.

Both techniques have the potential to significantly increase the throughput on digital subscriber lines at a more than reasonable implementation cost.

CONCLUSION

The features and the underlying principles of DMT modulation have been explained. The criterion for orthogonality has been described, and the relationship between analog and digital system models have been illustrated. It has been shown how a broadband channel is divided into parallel frequency nonselective subchannels. This partitioning paves the way for DMT to adapt easily to frequency-selective channels and to approach the limits set by the channel capacity. For the main application of DMT—the transmission over digital subscriber lines—substantial performance gains can be achieved by considering the multi-user nature of the transmission environment.

GLOSSARY

Channel capacity: This fundamental figure of merit for a given channel model determines the maximum rate at which information can be reliably transmitted. This concept was developed by Shannon in his groundbreaking work and is therefore also called *Shannon*

capacity. The channel capacity can be seen as the upper bound of the bit rate for any realizable modulation and coding scheme.

Convolution: Describes a mathematical operation to compute the output signal of a linear system. The output signal is given as the convolution of the input signal with the impulse response. In frequency domain, the corresponding operation is the multiplication with the frequency response.

Digital subscriber line (DSL): Comprises all techniques for digital transmission over existing telephone subscriber lines. The most famous variant is *asymmetric digital subscriber line* (ADSL).

Discrete Fourier transform (DFT): Discrete variant of the Fourier transform that can be implemented very efficiently with digital signal processing if the number of input and output elements is a power of 2. In this case, it is also called *fast Fourier transform* (FFT).

Eye diagram: A plot of the signals after the receiver filter during the interval of the sampling period. This diagram gives a visualization of the expected intersymbol interference and the vulnerability of the system to phase jitter.

Log-likelihood value (L-value): Gives information about the reliability of a detected bit. A large positive L-value signifies that the bit is surely a 1, while a large negative value corresponds to a probable 0. If no information about the bit is available, then the L-value is zero.

Nyquist criterion: This criterion defines the condition on the transmit and receive filters to ensure that at the sampling instants the received signal is not influenced by preceding or successive samples—that is, that the received signal is free of intersymbol interference.

Phase shift keying (PSK): Digital modulation format that modulates only the phase of the carrier frequency while the amplitude is kept constant.

Quadrature amplitude modulation (QAM): Digital modulation format that modulates the phase and the amplitude of the carrier frequency. This can be considered as the concurrent modulation of two sinusoidal carriers that are shifted in phase by 90 degrees.

Water filling: The term used to describe the method for optimal power allocation in a frequency-selective channel. The name comes from the visualization of a water basin into which a certain amount of water is poured. The wanted function corresponds to the water depth.

INTRODUCTION

Pulse position modulation (PPM) is a signaling format in which the temporal positions of pulses are modulated by a message. In this chapter, we explore the history, fundamentals, and modern design principles of PPM. As we shall see, the PPM signal format has a long history and a bright future.

History

Early references to PPM in the electrical engineering literature use the term *pulse position modulation* unevenly to refer to any one of a multitude of transmission schemes in which pulse positions are modulated by a message. In several early descriptions of PPM (Lacy 1947; McAulay 1968; Riter, Boatright, and Shay 1971), the frequency of the pulses was held fixed and information was contained in the continuous variation of a pulse from its nominal position. This has been referred to as *PPM with a fixed reference* (Ross 1949); in today's terminology, it would be referred to as *analog PPM*. When the pulse positions can take on only discrete values, as is the case in modern designs, the early literature referred to the modulation as *quantized PPM* (QPPM) (Pettit 1965).

In another early scheme, the frequency of pulses was held fixed, with the center of each pulse not varying at all from the nominal frequency. The information was contained in the variation in the position of the rising (and symmetrically falling) edge of the pulse. To maintain a constant energy per pulse, the amplitude was varied inversely to the pulse width. In today's terminology, this is more properly termed *return-to-zero pulse width modulation* and *pulse amplitude modulation*.

These and other types of pulsed transmissions have been in use since at least World War II ("Pulse position" 1945) and expressed in early *private branch exchange* (PBX) implementations by AT&T (Meiseand and DeStefano 1966). Indeed, the concept of pulsed transmission is much older than that: Native Americans used it in their smoke signals, with one puff meaning "Attention," two in rapid succession meaning "All is well," and three in rapid succession meaning "Danger" or "Help" (Tomkins 2002). Several decades ago, the optical communications literature came on what is now the standard definition of PPM (Gagliardi and Karp 1976), which is a specific form of QPPM. In this chapter, to avoid confusion, we shall define and analyze PPM in only this standard way.

Applications

PPM has a rich history of applications in optical, radio frequency, and acoustical communications.

Optical Communications Links

In recent years, the dominant application of PPM has been optical communications. PPM has long been suggested for use in optical systems because its potential for a high peak-to-average power ratio naturally fits the physical properties of lasers, which may emit a pulse of light with a high peak power but which output a much lower average power. Such a property has been shown to be an efficient means of transmitting at high data rates, even when background light interferes.

Using PPM, a laser sends a pulse of light delayed in proportion to the value of the message being transmitted. The light pulses can be either transmitted through free space, including to and from outer space (Wilson and

Lesh 1993; Wilson et al. 1997; Townes et al. 2004), or coupled to an optical fiber (Palais 2004; Ohtsuki and Kahn 2000). The receiver detects the delay of the light pulse to decipher the intended message. [In the case of earlier demonstrations (Wilson and Lesh 1993; Wilson et al. 1997) pulse lasers were used, but not PPM specifically.]

In one impressive PPM application, NASA developed technology for high-speed optical transmission from a Mars orbiter, originally set to launch in 2009, to Earth (Townes et al. 2004). The system supports data rates as high as 50 Mbps over a distance of 150 million kilometers using a laser with an average output power of 5 W, which is one hundred times faster than Mars–Earth data rates achieved as of this writing. The link design uses 32-ary and 64-ary PPM (Moision and Hamkins 2003), depending on link conditions, highly accurate pointing algorithms (Lee, Ortiz, and Alexander 2005), reception with either the 5-meter Hale telescope on Palomar Mountain or an array of smaller telescopes (Candell 2005), efficient photodetectors (Biswas and Farr 2004), and a specially developed *error-correction code* (ECC) that operates within 1 decibel (dB) of the Shannon limit (Moision and Hamkins 2005, “Coded”). Laboratory demonstrations showed the proper operation of a multi-Mbps end-to-end system under expected link conditions, but a new emphasis on human flight missions within NASA has forced the cancellation of this robotic mission.

Another free space optical application that uses PPM is the infrared links for the consumer mobile electronics devices that are becoming ubiquitous. The Infrared Data Association has developed the IrDa standard (Knutson and Brown 2004) which includes, among other modes, a “fast infrared” mode that operates at 4 Mbps using 4-ary PPM. Laptop computers, cell phones, personal information managers, cameras, printers, and many other consumer devices now have IrDa-compliant transceivers. Infrared television remote controls do not typically use the IrDa standard, but they often operate with a type of PPM as well (Casier, De Man, and Matthijs 1976). For example, JVC, Mitsubishi, NEC, Philips, Sanyo, Sharp, and Toshiba manufacture televisions that use PPM as the format for infrared remote control. An NEC data sheet (NEC Corporation 1994) contains a description of a representative signaling format.

Remotely Controlled Vehicles

Remotely controlled aircraft, watercraft, vehicles, and robots routinely use PPM as a method of accurately obtaining controlling information from the operator. Signals transmitted with radio frequency pulses have time delays that are proportional to several controls (e.g., the angles of ailerons, elevators, and rudder and steering and throttles) that the operator desires to set.* PPM is chosen for this application because the vehicles and vessels require low-complexity receivers (especially aircraft), and the

electronics needed to convert a pulse to a motor position are simple.

Medical Sensors

A sensor may be implanted in or attached externally to medical patients who require close monitoring of blood pressure, blood flow, temperature, the presence of certain chemicals, and the vital signs of a baby during birth. The sensor can transmit radio waves to a remote receiver that displays or records the data. PPM is an efficient transmission for this application, particularly for analog data such as these, thereby providing the longest possible battery life before inconvenient sensor replacement (Bornhofs et al. 2001).

Oil and Coal Drilling

Drilling is necessary in both the oil and coal industries for both exploration and methane drainage. Automatic monitoring of the borehole trajectory, bit thrust, and torque during drilling assists greatly in drilling the longest, straightest, and most accurately aimed holes. To do this, so-called measure-while-drilling or logging-while-drilling techniques are used, by which pressure pulses in the drilling fluid are modulated with PPM at the end of the drill bit down the hole and detected at the surface (Marsh et al. 2002).

Underwater Acoustic Communications Links

PPM can also be used for acoustic underwater signaling. A short acoustical tone is transmitted with a delay that is a linear function of the value being sent (Riter, Boatright, and Shay 1971). In addition to ocean communication on Earth, this technique has been considered for the exploration of Europa, a moon of Jupiter with a thin layer of ice and liquid water beneath. In this mission scenario, a probe would penetrate the surface and communicate with acoustic PPM back to a surface spacecraft.

FUNDAMENTALS OF PPM

Definition of PPM

PPM is a modulation format that maps message bits to pulse positions. In the modern use of the term, a PPM *symbol* comprises M slots, exactly one of which contains a pulse. Input message bits determine which of the M positions is used. For the simplest mapping, M is typically taken to be a power of 2, in which case $\log_2 M$ message bits specify one of the M possible positions of the pulse, as shown in Figure 1. If the slots are numbered 0, 1, ..., $M - 1$, then in the mapping shown in Figure 1, the decimal representation of the bits is the number of the slot containing the pulse. As a shorthand, M -ary PPM is often referred to as M -PPM (not to be confused with *multipulse* PPM, or MPPM, discussed later in this chapter).

Mathematically, M -ary PPM may be described as the encoding of a k -bit source $\mathbf{U} = (U_1, \dots, U_k) \in \{0,1\}^k$ to yield a signal $\mathbf{X} = (0, \dots, 0, 1, 0, \dots, 0) \in \{0,1\}^M$, $M = 2^k$, which contains a single one in the position indicated by the decimal representation of \mathbf{U} .

*In 1898, Nikola Tesla was issued the first patent (U.S. patent 613, 809) for remote-controlled vessels. The patent, however, primarily concerns the mechanical positions of brushes and contact plates and does not propose PPM. The controlling actions are made by directly rendering a given circuit either active or inactive, according to the signal transmitted from a remote operator.

Figure 2: Block diagram of PPM modulator and memoryless channel

PPM Channel Model

To facilitate the analysis in this chapter, we now formalize a description of the channel model. The transmission channel for each slot, the *slot channel*, is a binary-input unconstrained-output channel, with input $X \in \{0,1\}$ and output $Y \in \mathbb{R}$. When no pulse is transmitted in a slot, $X = 0$; and when a pulse is transmitted in a slot, $X = 1$. We define $f_{Y|X}(y|x)$ as the *conditional probability density* (or mass) of receiving $Y = y$ in a slot, given $X = x$.

The PPM symbol $\mathbf{X} = (X_1, \dots, X_M)$ is transmitted via M uses of the slot channel and results in the received vector $\mathbf{Y} = (Y_1, \dots, Y_M) \in \mathbb{R}^M$. This is illustrated in Figure 2. We let $S = \{\mathbf{x}_1, \dots, \mathbf{x}_M\}$ be the set of M -PPM symbols. Each $\mathbf{x}_k = (x_{k,1}, \dots, x_{k,M})$ is a binary M -vector with one 1 in position k , and $M - 1$ zeros in all other positions. We define $f_{Y|X}(\mathbf{y}|\mathbf{x})$ as the conditional probability density of receiving $\mathbf{Y} = \mathbf{y}$ in the M slots, given $\mathbf{X} = \mathbf{x}$.

If the slot channel is memoryless, then every slot of the transmission is conditionally independent of every other slot, given the transmitted sequence. In other words, if PPM symbols $\mathbf{x} = (\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(N)})$ are transmitted, where each symbol $\mathbf{x}^{(i)} \in S$ is a binary M -vector as described above, then the conditional probability or probability density of receiving the real M -vector $\mathbf{y} = (\mathbf{y}^{(1)}, \dots, \mathbf{y}^{(N)})$ factors over the symbols and slots as

$$f_{\mathbf{Y}|\mathbf{X}}(\mathbf{y}|\mathbf{x}) = \prod_{i=1}^N \prod_{j=1}^M f_{Y_j^{(i)}|X_j^{(i)}}(y_j^{(i)}|x_j^{(i)}) \quad (1)$$

For this type of channel, there is no intersymbol interference and no interslot interference. If the slot channel is also stationary, then each factor in Equation 1 simplifies to $f_{Y|X}(y_j^{(i)}|x_j^{(i)})$.

The likelihood ratio of receiving value y in a slot is denoted by $L(y) \triangleq \frac{f_{Y|X}(y|1)}{f_{Y|X}(y|0)}$, which for algebraic convenience we assume to be finite for all y . We also assume that

$L(y)$ is monotonic in y , as is the case for many channels of practical interest (e.g., Poisson, Gaussian, and Webb-McIntyre-Conradi) (Vilnrotter, Simon, and Srinivasan 1999). The log-likelihood ratio is denoted $\Lambda(y) = \log L(y)$. $F_{Y|X}(y|1)$ ($F_{Y|X}(y|0)$) denotes the cumulative distribution—that is, the probability that a received signal (nonsignal) slot has value less than or equal to y .

Several common probability densities arise in PPM applications. Perhaps the most common is the Poisson distribution, which arises for optical communications:

$$f_{Y|X}(k|0) = \frac{K_b^k e^{-K_b}}{k!}, k \in \{0\} \cup \mathbb{N} \quad (2)$$

$$f_{Y|X}(k|1) = \frac{(K_s + K_b)^k e^{-(K_s + K_b)}}{k!}, k \in \{0\} \cup \mathbb{N} \quad (3)$$

where K_b is the average number of background photons detected when $X = 0$ and $K_s + K_b$ is the average number of signal and background photons detected when $X = 1$. Several other models for optical communications may arise, depending on whether the system is limited by shot noise or thermal noise; whether the photodetector is a PIN diode, a *photomultiplier tube* (PMT), or an *avalanche photodiode detector* (APD); and which of various approximations are used. The equations governing these models are discussed in depth in Dolinar et al. (2006) and Gagliardi and Karp (1995) and summarized here in Table 1. In each case, m_0 and σ_0^2 denote the mean and variance conditioned on $X = 0$, and m_1 and σ_1^2 denote the corresponding quantities conditioned on $X = 1$. We define the slot *signal-to-noise ratio* (SNR) as $\beta = (m_1 - m_0)^2 / \sigma_0^2$, the “excess SNR” as $\gamma = (m_1 - m_0)^2 / (\sigma_1^2 - \sigma_0^2)$, and the “bit SNR” as $\beta_b = \beta / (2R_c \log_2 M)$, where R_c is the ECC code rate ($R_c = 1$ if uncoded).

Bit-to-PPM Symbol Mappings

Figure 1 shows one mapping of user bits to pulse positions. We refer to this as a *bit-to-symbol* mapping. Each $\log_2 M$ bit corresponds to one PPM symbol. There are many choices—indeed, $M!$ choices—for the bit-to-symbol mapping. One question naturally arises: What is the best choice of the bit-to-symbol mapping?

If we suppose, as is consistent with typical applications, that the slot channel is either slowly varying or stationary, then we arrive at a convenient result: The performance of the system is equivalent under every bit-to-symbol mapping. To see this, we note that one bit-to-symbol mapping can be obtained from any other bit-to-symbol mapping by a suitable reordering of the coordinates of the transmitted slots. For example, if bits 11 are mapped to PPM symbol (0,0,0,1) in one bit-to-symbol mapping and to (0,1,0,0) in another, then we may transform the first mapping to the second, in part, by moving the fourth slot to the second position. Because the channel is stationary and the slots are conditionally independent, the reordering does not affect the statistics of the channel, and the performance will be the same.

In this situation, the choice of bit-to-symbol mapping is made for the convenience of the implementation.

Table 1: Probability mass functions probability density functions of several optical channel models*

Channel model	pmf or pdf
Poisson	$f_{Y X}(k x) = \frac{m_x^k e^{-m_x}}{k!}$, where $m_0 = K_b, m_1 = K_s + K_b, k \in \{0\} \cup \mathbb{N}$,
AWGN	$f_{Y X}(y x) = \frac{1}{\sigma_x} \phi\left(\frac{y - m_x}{\sigma_x}\right)$, $y \in \mathbb{R}$, where $\phi(x) = \frac{1}{\sqrt{2\pi}} e^{-x^2/2}$
McIntyre–Conradi**	$f_{Y X}(k x) = \sum_{n=1}^k \frac{n\Gamma\left(\frac{k}{1-k_{eff}} + 1\right) \left[\frac{1+k_{eff}(G-1)}{G}\right]^{n+k_{eff}k/(1-k_{eff})} \left[\frac{(1-k_{eff})(G-1)}{G}\right]^{k-n} K_x^n e^{-K_x}}{k(k-n)!\Gamma\left(\frac{k_{eff}k}{1-k_{eff}} + n + 1\right)n!}$
WMC**	$f_{Y X}(y x) = \frac{1}{\sqrt{2\pi\sigma_x^2}} \left(1 + \frac{y-m_x}{\sigma_x\delta_x}\right)^{-3/2} \exp\left[-\frac{(y-m_x)^2}{2\sigma_x^2\left(1 + \frac{y-m_x}{\sigma_x\delta_x}\right)}\right]$, $y \in \mathbb{R}$
WMC +Gaussian	$f_{Y X}(y x) = \int_{m_x - \delta_x\sigma_x}^{\infty} \frac{1}{\sqrt{2\pi\sigma_n^2}} \exp\left[-\frac{(y-t)^2}{2\sigma_n^2}\right] \cdot \frac{1}{\sqrt{2\pi\sigma_x^2}} \left(1 + \frac{t-m_x}{\sigma_x\delta_x}\right)^{-3/2} \exp\left[-\frac{(y-m_x)^2}{2\sigma_x^2\left(1 + \frac{t-m_x}{\sigma_x\delta_x}\right)}\right] dt$

*In each case, for $x \in [0,1]$, m_x and σ_x^2 are the mean and variance when $X = x$, respectively

**Webb, McIntyre, and Conradi 1974

Table 2: Common Bit-to-Symbol Mappings for 8-ary PPM

Natural	Gray	Anti-Gray	PPM pulse position
000	000	000	0
001	001	111	1
010	011	001	2
011	010	110	3
100	110	011	4
101	111	100	5
110	101	010	6
111	100	101	7

The typical mapping is the *natural* mapping, in which the decimal representation of the bits is equal to the slot position of the pulse in the PPM symbol. The natural mapping is shown in Figure 1 and in Table 2.

Many applications, especially high-speed applications, risk interslot interference. This occurs, for example, when a laser pulse width is wider than a slot epoch, or when the detector bandwidth is not sufficiently high to prevent the detected pulse from spreading across slot boundaries. This introduces memory into the channel, and equation 1 no longer holds. In addition, the choice of the symbol mapping affects performance.

For uncoded PPM on a channel with interslot interference, a PPM symbol with a pulse in the i th position is generally more likely to be incorrectly detected as having a pulse in the $(i - 1)$ th or $(i + 1)$ th position than in any other position. Thus, a *Gray code* mapping (Gray 1953) helps reduce the bit error rate. A Gray code has the property that adjacent PPM symbols correspond to input bits that

differ in at most one position, as seen in Table 2. For example 00,01,11,10 is a Gray code. PPM symbol errors that are off by only one slot result in only one bit error when a Gray code is used, instead of an average of $M(\log_2 M)/(2(M - 1))$ bit errors that would result from a symbol error in a system employing a random bit-to-symbol mapping.

There are many distinct Gray code labelings (Agrell et al. 2004), but, to good approximation, all Gray codes have the same performance. One common and easily constructed Gray code is the *binary-reflected Gray code*. This code of size n bits is built from the code of size $n - 1$ bits by appending a copy of the code in reverse order and prepending a 0 to the original code and a 1 to the new copy. For example, the Gray code 00,01,11,10 is copied in reverse order (10,11,01,00) and prepended with a 1, becoming the Gray code 000,001,011,010,110,111,101,100, as shown in Table 2.

Coded PPM refers to a system in which the input to the bit-to-symbol mapper has been previously encoded by an ECC. When coded PPM is used on a channel with interslot interference, often the opposite bit-to-symbol effect is needed, namely, the property that adjacent PPM symbols correspond to input bits that differ in as *many* positions as possible. Loosely speaking, the reason for this is that the ECC and PPM detectors work best when they complement each other, with the PPM detector determining roughly where the pulse is within a few slot positions and the structure of the ECC determining the specific slot position. If adjacent ECC code words correspond to slots that are in near proximity, neither the ECC nor the PPM detector can determine the correct slot exactly.

Therefore, a good bit-to-symbol mapping for coded PPM is often an *anti-Gray mapping*, in which adjacent M -ary PPM symbols correspond to input bits that differ in either $\log_2 M$ or $\log_2(M - 1)$ bit positions. An anti-Gray code may be constructed from the binary-reflected

Gray code using the following method. Beginning with the first half of the Gray code (the words beginning with a 0), insert after each word its 1's complement negation (bitwise exclusive OR with the all 1's). In the original Gray code, words are all distinct, and all have a zero in the first position; therefore, the words in the anti-Gray code are also distinct. This mapping is shown in Table 2.

System Design Considerations

The bandwidth, power, efficiency, and throughput of a PPM system are interrelated parameters. Proper design of a near-optimal PPM system requires a careful examination of these parameters (Moision and Hamkins 2003; Hamkins and Moision, 2005) and a well-defined system optimization metric.

A *bandwidth constraint* is a limitation on the minimum slot width, T , in order to eliminate, or allow only a given level of, *intersymbol interference* (ISI). A *peak power constraint* is a limitation on the power within slots containing a signal. For example, for the optical Poisson channel, the peak power is $K_s hc/(\lambda T)$ W, because there are an average of K_s photons in the signal slot of duration T seconds and each photon has energy hc/λ J, where λ m is the wavelength of the photon, $h = 6.626 \times 10^{-34}$ J · s is Planck's constant, and $c = 3 \times 10^8$ m/s is the speed of light. An average power constraint is a limitation on the average power over all slots, or, in this same example, $K_s hc/(\lambda MT)$. The photon efficiency of the system is the number of bits per photon that the system achieves, or $R_c \log_2 M/K_s$ bits/photon, where R_c is the code rate of the ECC ($R_c = 1$, if uncoded). The throughput of the system is $R_c \log_2 M/(MT)$ bits/s.

An example helps illustrate a potential pitfall of the PPM system design. Suppose photon efficiency were paramount in an optical PPM system. Then the design naturally leads one to using a very large PPM order M , because photon efficiency $R_c \log_2 M/K_s$ is increasing in M . Intuitively, this makes sense, because a pulse is rarely sent (only 1 out of M slots), but it represents many ($\log_2 M$) bits. However, if there is a limited bandwidth, then increasing M necessarily reduces the data rate. Furthermore, if the peak power is limited, then increasing M reduces the average power as well (because $\log_2 M/M$ is decreasing), which can increase the error rate of the system.

The example above shows one reason why a penchant for maximizing photon efficiency, or any other single system parameter, can be a mistake. A better question to ask is, Within the power and bandwidth constraints of a system, what is the highest throughput that can be reliably achieved with a coded PPM system of acceptable implementation complexity? The answer to this can be found by following a series of steps:

1. Determine the average power, peak power, bandwidth, and implementation complexity limitations of the system.
2. Set the slot width equal to the minimum allowed by the bandwidth and complexity constraints.
3. Compute the capacity of the PPM channel under these constraints, for various PPM orders M , and identify the PPM order M^* having the highest capacity, and the

corresponding data rate in bits per second or bits per slot.

4. Design an ECC, and associated encoder and decoder, with performance near the capacity of M^* -ary PPM.

In some applications, such as deep space communications where the received signal is especially weak, the use of ECC is essential, and the procedure above is necessary to arrive at a successful design. On the other hand, for other applications, such as remote-controlled aircraft, signaling on fiber-optic cabling, and the mining and medical applications, signal power may not be an issue, and instead simplicity considerations may dominate the link design.

DETECTION OF PPM SIGNALS

Maximum Likelihood Detection of Uncoded PPM

After observing $\mathbf{Y} = (Y_1, \dots, Y_M)$, the receiver must decide which PPM symbol $\mathbf{X} \in S$ was sent. The decision rule that minimizes the probability of error is the *maximum a posteriori* (MAP) rule, given by $\arg\max_{\mathbf{x}} f_{\mathbf{Y}|\mathbf{X}}(\mathbf{x}|\mathbf{y})$. When the symbols are sent with equal likelihood, an application of Bayes's rule implies that the MAP decision is equivalent to the *maximum likelihood* (ML) decision, given by

$$\hat{\mathbf{X}} = \arg\max_{\mathbf{x}} f_{\mathbf{Y}|\mathbf{X}}(\mathbf{y}|\mathbf{x}) \quad (4)$$

On a memoryless stationary channel, the conditional probability (or probability density) of receiving $\mathbf{Y} = \mathbf{y}$, given $\mathbf{X} = \mathbf{x}_k$, is

$$\begin{aligned} f_{\mathbf{Y}|\mathbf{X}}(\mathbf{y}|\mathbf{x}_k) &= f_{Y_1|X}(y_1|1) \left(\prod_{i \neq k} f_{Y_i|X}(y_i|0) \right) \\ &= \frac{f_{Y_1|X}(y_1|1)}{f_{Y_1|X}(y_1|0)} \left(\prod_{i=1}^M f_{Y_i|X}(y_i|0) \right) \end{aligned}$$

The ML symbol decision rule is $\hat{\mathbf{X}} = \mathbf{X}_{\hat{k}}$, where

$$\hat{k} = \arg\max_k f_{\mathbf{Y}|\mathbf{X}}(\mathbf{y}|\mathbf{x}_k) = \arg\max_k L(y_k) = \arg\max_k y_k \quad (5)$$

and where we made use of the monotonicity of the likelihood ratio. Equation 5 is maximized by the index k corresponding to the largest slot value—that is, the ML detection rule is to choose the symbol corresponding to the largest observed slot value. The rule has also been generalized to hold for multipulse PPM on a Poisson channel (Georgiades 1994) and arbitrary discrete memoryless channels (Hamkins and Moision 2005), as well as for even more general modulations (Hamkins et al. 2004).

Maximum Likelihood Detection of Coded PPM

A block of N PPM symbols (each a binary vector of length M) is an element of the Cartesian product $S^N = S \times \dots \times S$. A block code is a subset $C \subset S^N$. When codeword from

C are transmitted on the channel, the ML codeword decision is the codeword $\mathbf{x} \in C$ that maximizes Equation 1. Following the same method as in the uncoded case above, the ML decision is $\hat{\mathbf{x}} = (\hat{x}_1, \dots, \hat{x}_N)$ where \hat{k} is given by

$$\hat{k} = \underset{\underline{k}: (x_{k_1}, \dots, x_{k_N}) \in C}{\operatorname{argmax}} \prod_{i=1}^N f_{Y|X}(\mathbf{y}^{(i)} | \mathbf{x}_{k_i}) \quad (6)$$

$$= \underset{\underline{k}: (x_{k_1}, \dots, x_{k_N}) \in C}{\operatorname{argmax}} \prod_{i=1}^N L(y_{k_i}^{(i)}) \quad (7)$$

$$= \underset{\underline{k}: (x_{k_1}, \dots, x_{k_N}) \in C}{\operatorname{argmax}} \log \prod_{i=1}^N L(y_{k_i}^{(i)}) \quad (8)$$

$$= \underset{\underline{k}: (x_{k_1}, \dots, x_{k_N}) \in C}{\operatorname{argmax}} \sum_{i=1}^N \Lambda(y_{k_i}^{(i)}) \quad (9)$$

In other words, the ML rule chooses the PPM code word that maximizes the sum of the log-likelihood ratios of its pulsed slots. As can be seen from Equation 9, the ML decision requires storing all of the slot values from all of the symbols in the block. This is called a *soft decision decoder*. Maximum likelihood decoding of modern codes is usually too complex to be practical, and instead the codes are decoded using suboptimal methods. On the other hand, Equation 9 demonstrates that the set of slot likelihood ratios is a sufficient statistic for ML decoding. Turbo codes, turbo-like codes, and low-density parity check codes are each decoded using slot likelihood ratios (Benedetto et al. 1996) and an iterative algorithm that attempts to approximate the ML decoder, typically with good results.

A lower complexity decoder results when symbol decisions are made first and then fed into the decoder. In this *hard decision decoder*, an initial vector of k 's are made according to Equation 5—that is, using symbol-by-symbol decisions—and these are fed to the decoder, which attempts to correct the errors. This is the method used in a conventional decoder for a Reed-Solomon code, for example. An additional penalty, generally of approximately 2 dB, results from using a hard decision decoder compared to a soft decision decoder.

PERFORMANCE OF PPM

We now derive general formulas for the PPM *symbol error rate* (SER) and *bit error rate* (BER), as a function of the channel statistics $f_{Y|X}(y|x)$. The derivation assumes that the channel is memoryless and stationary, and that slot and symbol timing are perfectly known.

Symbol Error Rate and Bit Error Rate of Uncoded PPM

On a continuous-output memoryless channel, the PPM symbol error probability, P_s , is the well-known performance (Gallager 1968) of an ML detector for M -ary orthogonal signaling:

$$P_s = 1 - \Pr(Y_1 = \max\{Y_1, \dots, Y_M\} | X_1 = 1) \\ = 1 - \int_{-\infty}^{\infty} f_{Y|X}(y|1) \left[\int_{-\infty}^y f_{Y|X}(y'|0) dy' \right]^{M-1} dy \quad (10)$$

Equation 10 may be evaluated numerically by first producing a table lookup for the bracketed term and then computing the outer integral numerically in the usual way (Press et al. 1992).

When the channel outputs take on discrete values, there is a possibility of a tie for the maximum count. Suppose a value of k is detected in the slot containing the pulse, l nonsignal slots also have count k , and the remaining nonsignal slots have count strictly less than k . Then the correct decision is made with probability $1/(l+1)$. Otherwise, an error is made. By summing over all possible values of k and l , it follows that

$$P_s = 1 - \sum_{k=0}^{\infty} \sum_{l=0}^{M-1} \Pr \left[\begin{array}{l} \text{correct decision when } l \\ \text{nonsignal slots tie the sig-} \\ \text{nal slot for the maximum} \\ \text{count} \end{array} \right] \quad (11)$$

$$\times \Pr \left[\begin{array}{l} \text{exactly } l \text{ of } M-1 \\ \text{nonsignal slots have} \\ \text{value } k, \text{ all others} \\ \text{smaller} \end{array} \right] \times \Pr \left[\begin{array}{l} \text{signal slot} \\ \text{has value } k \end{array} \right]$$

$$= 1 - \sum_{k=0}^{\infty} \sum_{l=0}^{M-1} \frac{1}{l+1} \binom{M-1}{l} f_{Y|X}(k|0)^l F_{Y|X}(k|1) \\ \times (k-1|0)^{M-l-1} f_{Y|X}(k|1) \quad (12)$$

An extension of Equation 12 to n -pulse PPM, $n \geq 2$, is straightforward and involves a triple summation in place of the double summation (Hamkins and Moision 2005). After some algebraic manipulation, Equation 12 can be rewritten in a single summation as (Hamkins 2004)

$$P_s = 1 - \frac{1}{M} \sum_{k=0}^{\infty} L(k) (F_{Y|X}(k|0)^M - F_{Y|X}(k-1|0)^M) \quad (13)$$

where $L(k)$ is the likelihood ratio. On a noiseless channel, $f_{Y|X}(0|0) = 1$, and the erasure probability is $f_{Y|X}(0|1)$; thus, Equation 13 can be simplified to

$$P_s = \frac{(M-1)f_{Y|X}(0|1)}{M} \quad (14)$$

This is consistent with the fact that the symbol decision (guess) is wrong $M-1$ out of M times when no signal is received.

Once the PPM symbol is detected, it is mapped to a string of $\log_2(M)$ bits via the inverse of the encoding mapping (see Table 2). There are $M/2$ symbol errors that will produce an error in a given bit in the string, and there are $M-1$ unique symbol errors. Thus, assuming all symbol errors are equally likely, the resulting BER is

$$P_b = \frac{M}{2(M-1)} P_s \quad (15)$$

where P_s is given by Equation 10 or Equation 13.

We now proceed to evaluate the error-rate expressions above for a couple of specific channel models: the

Poisson channel and the *additive white Gaussian noise* (AWGN) channel. The reader is reminded that the error rates derived here assume perfect slot and symbol timing and a memoryless, stationary channel. If timing jitter or intersymbol interference were present, for example, then performance would degrade.

Poisson Channel

For $K_b > 0$, the SER in Equation 13 becomes

$$P_s = 1 - \sum_{k=0}^{\infty} \left(1 + \frac{K_s}{K_b}\right)^k \frac{e^{-K_s}}{M} (F_{Y|X}(k|0)^M - F_{Y|X}(k-1|0)^M) \quad (16)$$

where $F_{Y|X}(k|0) = \sum_{m=0}^k \frac{K_b^m e^{-K_b}}{m!}$. When $K_b = 0$, from Equation 14 we have

$$P_s = \frac{(M-1)e^{-K_s}}{M} \quad (17)$$

and from Equation 15 we see that $P_b = \frac{1}{2}e^{-K_s}$, which is independent of M and equal to that of on-off keying. This is shown in Figure 3a. As K_b increases, the dependence on M grows and the performance for each M degrades, as seen in Figure 3b and 3c. It is not appropriate to interpret performance versus K_s as a measure of power efficiency, however. K_s is proportional to the *peak* power. The average transmitter power is proportional to K_s/M photons per slot. Whereas low values of M in Figure 3a, 3b, and 3c produce a lower BER compared to high values of M , the situation is reversed in Figure 3d, 3e, and 3f, which plot versus K_s/M . The performance is also shown relative to the photon efficiency, $\log_2 M/K_s$ bits/photon, in Figure 3g, 3h, and 3i, where it is also seen that high values of M are more photon efficient. Note that there is an average

Figure 3: BER of uncoded M -PPM signaling on a Poisson channel versus quantities proportional to peak power (a, b, and c), average power (d, e, and f), and photon efficiency (g, h, and i) for $M = 2$ to 4096 and $K_b = 0, 0.01, 1$

power difference of approximately 30 dB between $M = 2$ and $M = 4096$ (Figure 3d, 3e, and 3f) and a photon-efficiency difference of approximately 10 dB (Figure 3g, 3h, and 3i). The performance is also shown in terms of the slot SNR $\beta = K_s^2/K_b$ in Figure 4a through 4d, where we see little dependence on M ; when plotted in terms of the bit SNR $\beta_b = K_s^2/(2K_b \log_2 M)$, the 30 dB gap manifests itself again.

AWGN Channel

The probability of symbol error is given by Equation 10, which becomes

$$P_s = 1 - \int_{-\infty}^{\infty} \frac{1}{\sigma_1} \phi\left(\frac{x - m_1}{\sigma_1}\right) \Phi\left(\frac{x - m_0}{\sigma_0}\right)^{M-1} dx \quad (18)$$

$$= 1 - \int_{-\infty}^{\infty} \sqrt{\frac{\gamma}{\beta + \gamma}} \phi\left(\sqrt{\frac{\gamma}{\beta + \gamma}}(v - \sqrt{\beta})\right) \Phi(v)^{M-1} dv \quad (19)$$

where $\phi(x) = \frac{1}{\sqrt{2\pi}} e^{-x^2/2}$ is the standard normalized Gaussian probability density function, $\Phi(x)$ is its cumulative distribution function, and, as defined earlier, $\beta = (m_1 - m_0)^2/\sigma_0^2$ and $\gamma = \frac{(m_1 - m_0)^2}{\sigma_1^2 - \sigma_0^2}$. If $\sigma_1 = \sigma_0$, then $\gamma = \infty$ and Equation 19 simplifies to

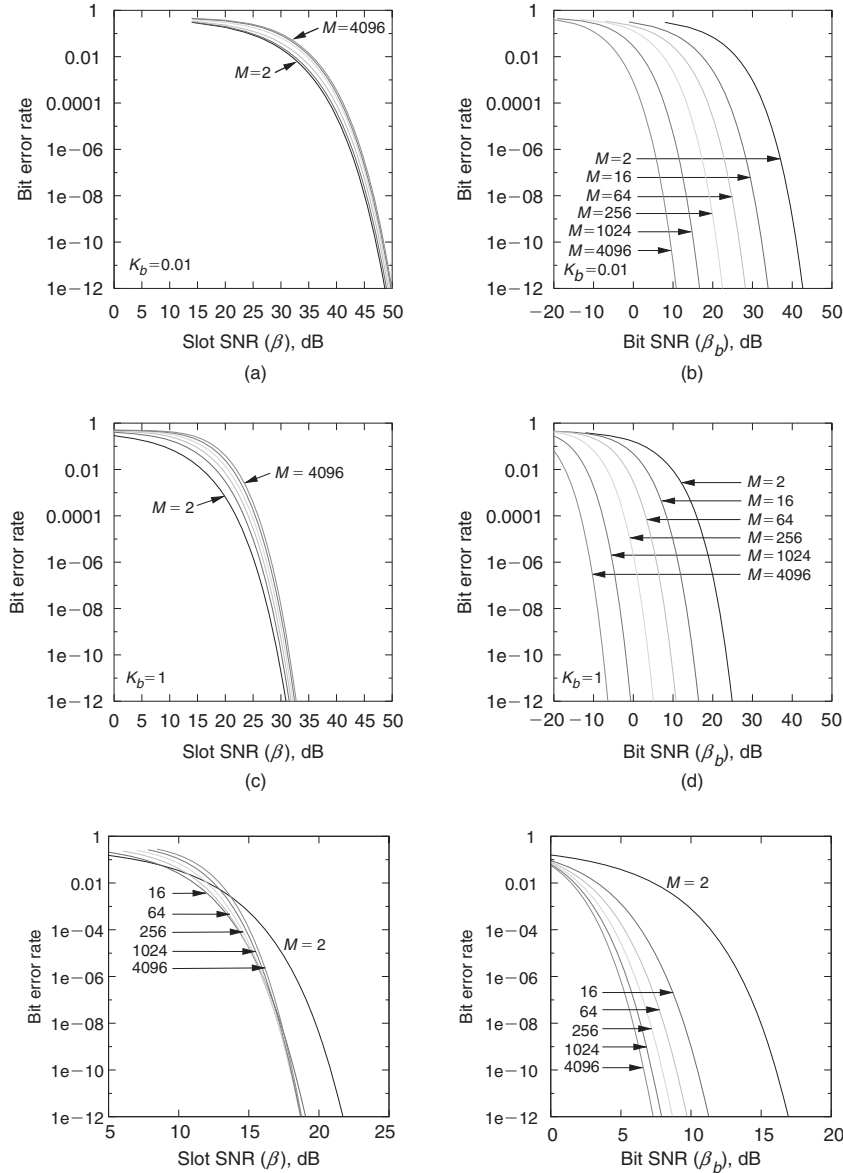

Figure 4: BER of uncoded M -PPM signaling—(a) Poisson channel versus slot SNR, (b) Poisson channel versus bit SNR, (c) Poisson channel versus slot SNR, (d) Poisson channel versus bit SNR, (e) AWGN channel versus slot SNR, and (f) AWGN channel versus bit SNR

$$P_s = 1 - \int_{-\infty}^{\infty} \phi\left(x - \sqrt{\beta}\right) \Phi(x)^{M-1} dx \quad (20)$$

The BER P_b is then given by Equation 15 and can be expressed in terms of the bit SNR $\beta_b = \beta/(2R_c \log_2 M)$. This is shown in Figure 4e and 4f.

Performance of Coded PPM

A full treatment of the subject of code design and performance is beyond the scope of this chapter. In lieu of the expanded discussion, we summarize the conventional approaches and recent advancements in the area and direct the reader to references where the complete details are contained.

Conventional Coded PPM Approaches

As mentioned earlier in this chapter, the initial PPM applications were analog in nature and, of course, did not use any coding. Shortly after quantized, now conventional, PPM became common in the literature, it was realized that an ECC could substantially improve performance.

Reed-Solomon (RS) codes (Lin and Costello 1983) were among the first codes proposed for use with PPM (McEliece 1981). An $RS(n, k)$ code is a linear block code that encodes every block of k data symbols into n code symbols, where each symbol is an element of the Galois field with $q = n + 1$ elements, denoted $GF(q)$ (Lin and Costello 1983). Most commonly, q is a power of 2, $q = 2^s$, in which case each symbol is conveniently represented by s bits. Thus, the code can also be viewed as a (sn, sk) binary code.

The beauty of RS-coded PPM is that the RS code symbols in $GF(q)$ are a natural fit with the nonbinary nature of PPM signaling. One can use $RS(n, k)$ with M -PPM, $M = n + 1$, by assigning each RS code symbol to one PPM symbol. On the other hand, if system constraints push one toward small M , this leads to small block-length codes that have limited coding gain. This problem can be overcome, in part, by using a longer RS code and splitting RS code symbols across multiple PPM symbols (Hamkins and Moision 2005).

Recent Advancements in Coded PPM: Serially Concatenated PPM

An ECC maps information bits to coded bits, whereas PPM maps these coded bits to PPM symbols. We may consider the combination of the code and modulation as a single large code that maps information bits directly to symbols transmitted on the channel. If the ECC is

conducive to iterative decoding (Benedetto et al. 1996), then one effective technique for decoding the large code is to iteratively decode the modulation and the ECC.

Following this approach, codes have been developed for the deep space optical PPM channel that operate within 1 dB of the capacity limit (Moision, Hamkins, and Cheng 2006), several dB better than RS-coded PPM, and more than 1 dB better than turbo-coded PPM which does not iteratively demodulate the signal (Hamkins and Srinivasan 1998). A representative example of the *serially concatenated PPM* (SCPPM) code is shown in Figure 5. The code is the serial concatenation of a convolutional code, a bit interleaver, an accumulator (differential encoder), and PPM. The specific design involves optimizing the PPM order, code rate, and convolutional code, given the design constraints (Moision and Hamkins 2003). The code is decoded iteratively (Moision and Hamkins 2005, "Coded"), using standard turbo-decoding principles. The complexity may be reduced by discarding most of the slot likelihood ratios without noticeably affecting performance (Moision and Hamkins 2005, "Reduced"), and other complexity-reducing implementation techniques (Cheng, Moision, and Hamkins 2006) make it possible to produce a 50 Mbps decoder on standard FPGA hardware that became available in 2006.

The performance of various rate 1/2 codes on a Poisson channel is illustrated in Figure 6, along with channel capacity. The channel was set to $K_b = 0.2$ background photons per slot, which is typical for the existing MLCD-class design for reception from Mars. The SCPPM code performs within approximately 0.75 dB of soft decision capacity and well beyond the performance of hard decision capacity. There is a gap of 1.5 dB between hard decision and soft decision capacity for this channel. Recall from earlier that an approximate 2 dB gap exists between hard and soft decision decoding. The 2-dB gap is a rule of thumb that applies to a wide range of coded communications systems, but it is not a theorem. For the optical application, the gap between hard and soft decision decoding for the optical channel is not actually fixed; instead, it varies with the channel model and operating conditions. In fact, the hard and soft capacity gap for the Poisson channel is zero when $K_b = 0$, because hard and soft decisions are equivalent in that case; the gap increases to several dB with increasing K_b .

Figure 6 also shows the performance of two RS codes. The RS (63,31) code has symbols that are matched to the PPM order; it operates at approximately 4.25 dB from soft decision capacity when the BER is 10^{-6} . The longer block length RS (4095,2047) code reduces this gap to 3.7 dB. The gap remains several dB away from soft decision

Figure 5: The SCPPM encoder

Figure 6: Performance of uncoded, RS-coded, and SCPPM-coded 64-PPM versus average power on a Poisson channel with $K_b = 0.2$

capacity, in part because of its use of hard decision decoding.

SYNCHRONIZATION

To detect symbols properly, a PPM receiver must acquire the PPM symbol timing—that is, identify the boundaries of the PPM symbols. The total timing may either be determined directly, or the problem may be partitioned into one of determining the slot timing and symbol timing sequentially. Figure 7 illustrates this for the case of 4-PPM. The transmitted PPM symbols in the upper part of the figure are misaligned by a slot offset and symbol offset at the receiver, shown in the lower part of the figure. The total timing error is the difference of the symbol offset and the slot offset.

Blind Synchronization

A *blind synchronizer* is one that operates without any knowledge of the PPM symbols being transmitted—that is, when no pilot or repetition signal is available. This is the case for any system in which transmitted PPM symbols consist solely of those that result from a modulation of coded or uncoded user data.

The PPM slot synchronization problem is closely related to the well-studied problem of symbol timing recovery of radio frequency *binary phase shift keying* (BPSK) signals. They both can be solved by arithmetically combining the energy detected in certain intervals of time in such a way that an error signal is generated that is proportional to the timing error. Two differences are that in PPM the signal energy is confined to a single slot among M slots instead of appearing in every slot, and the signal is on-off instead of antipodal.

For BPSK, timing recovery can be accomplished with a *digital transition tracking loop* (DTTL). For PPM, the analogue of the DTTL is a decision-directed slot recovery loop (Srinivasan, Vlnrotter, and Lee 2005), which is illustrated in Figure 8. As described in Srinivasan, Vlnrotter, and Lee (2005):

A PPM signal delayed by the timing error $\Delta > 0$ is passed to the top branch that outputs the integrated slot values and selects the slot corresponding to the maximum value over an arbitrarily defined “pseudo-symbol.” In the lower branch, the signal is further delayed by one symbol duration and passed to the error detector, which multiplies it by a “chopping function”—a square

Figure 7: The transmitted symbols (top) result in a slot offset and symbol off set at the receiver (bottom)

Figure 8: Decision-directed slot synchronization of PPM

wave at the slot frequency—and integrates over the duration of a slot, each slot. The signal is then gated by the slot selector from the upper branch in order to create the timing error signal, which is filtered and then passed to the numerically controlled oscillator ..., which outputs the slot clock. Note that symbol synchronization need not be assumed for this algorithm to work. If the initial pseudo-symbol interval contains two signal pulses, there will simply be two main contenders for the maximum slot to be picked by the slot selector, only one of which can be picked to contribute to the error detector. On the other hand, if the pseudo-symbol interval contains no signal pulse, a noise slot will be picked as the maximum, effectively increasing the symbol-error rate ... in the PPM decision process.

Following slot synchronization, symbol synchronization is performed. If aligned, each PPM symbol will contain exactly one pulse. The number of signal pulses per (potentially misaligned) PPM symbol may be estimated by comparing slot values to a threshold. PPM symbol synchronization can be accomplished by, for example, comparing the slot offset that maximizes the number of PPM symbols having exactly one pulse exceeding the threshold.

In some designs, *dead time* is inserted between every PPM symbol. This can aid in symbol synchronization, because a correlation against the channel output will reveal no signal energy during the dead time. Dead time is sometimes needed in Q-switched laser communications, for example, to allow sufficient time for the laser to recharge before the next pulse is transmitted. Dead time does not cost the transmitter any power, but because it lowers the data rate it is usually avoided when possible.

Synchronization Using Pilot Tones

In some PPM applications (Lacy 1947), a *pilot tone* was transmitted along with the modulated pulses to simplify the synchronization process. A pilot tone is a series of reference pulses, perhaps even full PPM symbols, inserted throughout the PPM symbol stream.

For example, a single known PPM symbol (e.g., \mathbf{x}_1) may be inserted after every n th PPM symbol. If there are s samples per slot, then M -PPM symbol synchronization is achieved by forming a length- sM vector sum of channel outputs over many blocks of sM samples. If the user data are random—that is, independent and equally likely a priori to take on any PPM value—then the samples in the slot corresponding to the pilot tone slot will have a disproportionately large correlation compared to the other slots. This accomplishes both slot and symbol synchronization in a low-complexity fashion.

Because a pilot tone is an unmodulated signal not representing any user information, its use reduces the efficiency of the transmission in terms of both bits per joule and bits per second. Therefore, the pilot tone is generally used as infrequently as the successful operation of the synchronization system allows. Also, care must be taken for uncoded PPM systems because the pilot signal might not be discernible in the presence of a string of all zeros in the user data—for example, as might occur in a raster scan of a dark area of an image.

CAPACITY OF PPM ON AN OPTICAL CHANNEL

Shannon (1948) demonstrated that for any communications channel, as long as the rate of transmitting information is less than some constant, C , it is possible to make the average error probability arbitrarily small by coding messages into a large enough class of signals. The constant C is called the *capacity* of the channel. Characterizing the capacity of the optical channel provides a useful bound on the data rates achievable with any coding scheme, serving as a benchmark for assessing the performance of a particular design.

The capacity will be a function of the received optical signal and noise powers, the modulation, and the detection method. The loss in capacity by restricting the modulation to PPM is small in the low average power regime where the deep space optical channel currently operates (Hamkins and Moision 2005; Wyner 1988; Boroson 2006).

We divide the capacity into two categories depending on the type of information provided to the decoder by the

receiver. In one case, the receiver passes hard PPM decisions on to the decoder. The hard decision capacity may be expressed as a function of the probability of uncoded PPM symbol error, P_s , derived for several channel models presented earlier. In the second case, the receiver passes soft log-likelihood ratios to the decoder. In this case, the soft decision capacity may be expressed as a function of the channel statistic $f_{Y|X}$. The soft decision capacity is at least as large as the hard decision capacity, as the slot counts provide additional information to the decoder.

General Capacity Formulas

The hard decision PPM channel is an M -ary input, M -ary output, symmetric channel with capacity given by (Gallager 1968):

$$C = \log_2 M + (1 - P_s) \log_2 (1 - P_s) + P_s \log_2 \left(\frac{P_s}{M - 1} \right) \text{ bits per PPM symbol} \quad (21)$$

where P_s is the probability of incorrect PPM symbol detection, given by Equation 10 or Equation 13.

The soft decision capacity is given by (Moision and Hamkins 2003):

$$C = E_{\mathbf{Y}} \log_2 \left[\frac{ML(Y_1)}{\sum_{j=1}^M L(Y_j)} \right] \text{ bits per PPM symbol} \quad (22)$$

an expectation over \mathbf{Y} , where $L(y) = f_{Y|X}(y|1)/f_{Y|X}(y|0)$ is the channel likelihood ratio, the Y_j have density $f_{Y|X}(y|1)$ for $j = 1$ and density $f_{Y|X}(y|0)$ otherwise.

The M -fold integration in Equation 22 is often intractable. However, it is straightforward to approximate the expectation by a sample mean. A quick approximation follows from the lower bound

$$C \geq E \log_2 \left[\frac{M}{1 + \frac{M-1}{L(Y_1)}} \right] \text{ bits per PPM symbol} \quad (23)$$

which is a good approximation for large M , reducing the M -fold integration (or set of M -dimensional vector samples) needed to evaluate Equation 22 to a one-dimensional integral (or set of scalar samples).

Capacity of PPM on Specific Channels

Poisson Channel

We consider first the Poisson channel. The behavior of the case $K_b = 0$ has a particularly simple form. When $K_b = 0$, we have

$$L(k) = \begin{cases} e^{-K_s} & k = 0 \\ \infty & k > 0 \end{cases}$$

and Equation 22 reduces to

$$C = (\log_2 M)(1 - e^{-K_s}) \text{ bits/PPM symbol}$$

When $K_b = 0$, only signal photons are detected. If any signal photons are detected, then the signal is known exactly. If no photons are detected, then all M candidate symbols are equally likely. Because the received statistic takes binary values, the soft and hard decision capacities are equal.

When $K_b > 0$, we have $e^{-K_s} \left(1 + \frac{K_s}{K_b}\right)^k$, and Equation 22 becomes

$$C = (\log_2 M) \left(1 - \frac{1}{\log_2 M} E_{Y_1, \dots, Y_M} \log_2 \left[\sum_{i=1}^M \left(1 + \frac{K_s}{K_b} \right)^{(Y_i - Y_1)} \right] \right)$$

The case $K_b = 1$ is illustrated in Figure 9 as a function of average power (to within a constant factor) K_s/M for a range of M . In the plot, an average power constraint would be represented by a vertical line. A peak constraint can be shown (Moision and Hamkins 2003) to result in an upper limit on the PPM order. Hence, the maximum data rate subject to both peak and average power constraints can be identified using Figure 9.

AWGN Channel

For the AWGN channel, the likelihood ratio reduces to

$$L(y) = \sqrt{\frac{\gamma}{\beta + \gamma}} \exp \left[\frac{\beta \mathbf{v}^2 + 2\gamma \sqrt{\beta} \mathbf{v} - \gamma \beta}{2(\beta + \gamma)} \right]$$

where $\mathbf{v} = (y - m_0)/\sigma_0$ (recall that β and γ were defined earlier). The capacity reduces to

$$C = \log_2 M - E \log_2 \sum_{j=1}^M \exp \left[\frac{(V_j - V_1)\beta(V_j + V_1) + 2\gamma\sqrt{\beta}}{2(\beta + \gamma)} \right]$$

bits per PPM symbol, where $V_j = (V_j - m_0)/\sigma_0$ for $j = 1, \dots, M$, or, when $\sigma_1 = \sigma_0$,

$$C = \log_2 M - E \log_2 \left[\sum_{j=1}^M e^{\sqrt{\beta}(V_j - V_1)} \right] \text{ bits per PPM symbol} \quad (24)$$

RELATED MODULATIONS

On-Off Keying

On-off keying (OOK) is another slotted modulation in which each slot contains either a pulse (1) or no pulse (0). In general, OOK allows any pattern of zeros and ones, and thus it is a generalization of several other modulation types. As such, the capacity of a channel using OOK is an upper bound on the capacity of a channel using one of its special case modulations. PPM is a special case of OOK, with the constraint that there is exactly one pulse

Figure 9: Capacity of M-PPM on a Poisson channel when $K_b = 1$

per M slots. Duty-cycle constrained OOK is another special case of OOK in which the fraction of slots with pulses is constrained to a specific number (Borson 2006; Barron 2004). Duty-cycle constrained OOK is closely related to PPM, because each can have a duty cycle of $1/M$; it is also a generalization of PPM, because it does not require a frame of M slots to contain exactly one pulse.

Multipulse PPM

Multipulse PPM (MPPM), first proposed in Herro and Hu (1988), is a generalization of PPM that allows more than one pulse per symbol. In n -pulse M -slot MPPM there are n unique symbols that correspond to the possible ways to populate M slots with n pulses. This is illustrated in Figure 10 when $n = 2$ and $M = 8$. When $n > 1$, the mapping from message bits to MPPM symbols becomes more

complicated, as $\binom{M}{n}$ is not a power of 2—that is, each multipulse symbol corresponds to a noninteger number of bits. This complication can be avoided by using a MPPM subset of size $2^{\lfloor \log_2 \binom{M}{n} \rfloor}$ (Sato, Ohtsuki, and Sasase 1994), which reduces throughput.

A recent result (Hamkins and Moision 2005) shows that in many cases of practical interest, the capacity of MPPM is not substantially greater than that of conventional PPM. The added complexity of implementing MPPM would not be justified in those cases. When the average power is sufficiently high, corresponding to an optimum PPM size of approximately 16 or less, then MPPM or more general modulations (e.g., Barron 2004) can begin to show power-saving gains of 1 dB or more over conventional PPM.

Overlapping PPM

Overlapping PPM (OPPM) is a generalization of PPM proposed in Lee and Schroeder (1977). In OPPM, each symbol interval of length T is divided into NM chips of duration $T_c = T/(NM)$. A pulse occupies N chips and is constrained to be entirely contained within the symbol epoch. This is shown in Figure 11 with $N = 3$ and $M = 4$. When $N = 1$, we have ordinary PPM as discussed above in which $\log_2 M$ bits are transmitted per T seconds. When $N > 1$, the pulse can be in one of $NM - N + 1$ positions (the last $N - 1$ positions are disallowed because the pulse must be completed contained within the symbol boundary), and we have $\log_2 [NM - N + 1]$ bits per T seconds—that is, nearly an additional $\log_2 N$ bits per T seconds for large M . OPPM imposes more stringent synchronization requirements, and special synchronizable codes may be used to aid in this (Calderbank and Georgiades 1994).

Note that OPPM may result from a PPM modulation in which the slot width is accidentally or intentionally set too small. This can happen when the slot widths are defined too narrowly for the pulse width being transmitted or when the bandwidth of the detectors does not support the full resolution of the slot. Whatever the cause, the result is intersymbol interference. Even with perfect synchronization, the modulation set is not orthogonal, and

Figure 10: Two-pulse 8-ary PPM has $\binom{8}{2} = 28$ symbols

Figure 11: Each OPPM symbol with $N = 3$ and $M = 4$ has twelve chips. The pulse may begin in any of ten positions

Figure 12: A 4-ary PPM message (top) and the corresponding 4-ary DPPM message (bottom)

thus the raw SER performance will be degraded compared to PPM.

The intersymbol interference degradation may be mitigated with an ECC. This was recognized by Georgiades (1989), who proposed a trellis-coded modulation in conjunction with PPM and OPPM. The optimal receiver structure for this coded modulation involves a Viterbi decoder, and performance of this receiver for the AWGN and Webb channel models has been determined (Srinivasan 1998; Kiasaleh and Yan 1998).

Analog PPM

Analog PPM (Lacy 1947; McAulay 1968; Riter, Boatright, and Shay 1971; Ross 1949) may be viewed as the asymptotic limit of OPPM, in which the discrete chips that mark the permissible times at which a pulse may become infinitesimally narrow. In this way, the concepts of a slot and chip disappear entirely, and the pulse delay from the beginning of the symbol is simply an analog value. The position of a pulse is linearly related to the value of the analog message intended to be transmitted. For this modulation format, unless another synchronization method is provided, it may be necessary to transmit an auxiliary pulse to identify the beginning of each symbol.

The performance of such systems, in terms of the power efficiency or the effective information throughput achieved, is generally not comparable to conventional PPM with discrete slots, especially because an ECC is conceptually difficult to apply to an analog modulation format. However, this is compensated by the remarkable simplicity of the analog circuit that can measure the delay of the pulse. For the remote-controlled aircraft application mentioned early in the chapter, these lightweight receiver electronics are critical to a successful design, and analog PPM is often used. Several parameters—such as the position of the rudder, aileron, and elevators—can be independently controlled, and each parameter may take on infinitely many values.

Differential PPM

In *differential PPM* (DPPM) (Zwillinger 1988), also called *truncated PPM* (TPPM) and *digital pulse interval modulation* (DPIM), throughput is increased by beginning a new PPM symbol immediately following the slot containing

the pulse. In other words, nonpulsed slots of a PPM symbol that follow a pulsed slot are flushed. This is shown in Figure 12. Information is conveyed in DPPM by the amount of separation between pulses. In one sense, this means that symbol synchronization is easier than in PPM: In PPM, the detection of a pulse does not assist much in determining the boundary of the PPM symbol, whereas in DPPM the symbol always sends with a pulse. On the other hand, the variable length of the symbols imposes a significantly more challenging synchronization problem than PPM because a missed pulse detection would lead to a *deletion* of a symbol from the symbol stream. Symbol deletions are generally fatal in both uncoded transmission (which is typically validated by a cyclic redundancy check) and to decoding algorithms. There may be methods of averting the synchronization problems with DPPM by buffering data and performing an appropriate sequence-detection algorithm. DPPM increases the throughput per unit time by almost a factor of two because symbols are on average only half as long as they would be with ordinary PPM.

Wavelength Shift Keying

From the viewpoint of communication theory, *wavelength shift keying* (WSK) (Dolinar et al. 2006), is similar to PPM of the same dimension. Instead of placing a single pulse of laser light of a given wavelength into one of M time-disjoint time slots, WSK places a single laser pulse of one of M disjoint wavelengths. This is shown in Figure 13. At the receiver, a filter bank completely separates the wavelengths before detection. Like PPM, this modulation is orthogonal. Therefore, if the channel is statistically

Figure 13: 4-ary WSK uses four frequencies in one time slot for each two bits

Figure 14: 4-ary WSK with 4-PPM uses four frequencies (in rows) and four times slots (in columns) for each four bits per symbol

identical at the various wavelengths, the maximum likelihood rules presented in the earlier section “Detection of PPM Signals” and the performance presented in the section “Performance of PPM” carry over to WSK as well.

Combined PPM and Wave Shift Keying

WSK transmits a pulse during every time slot. One way to reduce the required average laser power is to use a combination of PPM and WSK (Dolinar et al. 2006): By restricting the laser pulse to one of M time-slots, but allowing the laser pulse to take on any of N wavelengths, the low average laser power of conventional PPM can be maintained with the added advantage of increased data rate. This can be demonstrated by observing that the dimensionality of the signal space has been increased from M dimensions (PPM) to NM dimensions.

Combined PPM and WSK is an orthogonal signaling scheme. Therefore, if the channel is statistically identical at the various wavelengths, then the maximum likelihood rules presented in “Detection of PPM Signals” and the performance presented in “Performance of PPM” carry over to combined PPM and WSK as well (see Figure 14). The performance is the same as PPM, but with NM dimensions instead of M . The probability of correct detection is given by Equations 10 and 13, but with M replaced by NM .

The information throughput of this combined modulation scheme is $\log_2 NM = \log_2 N + \log_2 M$ bits per symbol period, or $\log_2 N$ more than M -PPM alone. For a given bandwidth, the throughput of combined PPM and WSK is higher than PPM alone. However, this modulation scheme requires N detectors, one for each wavelength, instead of just one. In addition, a method (e.g., high-dispersion grating) is needed to direct each distinct wavelength to a different detector.

CONCLUSION

Pulse position modulation is a modulation format with a rich set of applications in optical, radio frequency, and acoustical communications. The modern usage of PPM refers to a modulation format in which a binary input of $\log_2 M$ bits determines which of M slots is to have a pulse in it. This modulation has a high peak-to-average power ratio. The precise mapping of bits to PPM symbols may or may not affect performance, depending on the system; under typical circumstances, the maximum likelihood detection of a PPM symbol corresponds to the slot with the largest received value. A general formula for the capacity of PPM is known; thus, given bandwidth and power

constraints, an appropriate near-capacity error-correcting code can be designed for many typical applications.

GLOSSARY

Channel capacity: The maximum mutual information between the input and output of a channel among all possible inputs to the channel. This determines the maximum data rate that is supportable by a given stochastic channel.

Gray code: An ordered set of binary vectors in which adjacent vectors differ in exactly one bit. An *anti-Gray code* is an ordered set of binary vectors in which adjacent vectors differ in either all positions or all but one position.

Maximum likelihood (ML) detection: The ML detection of a signal received from a channel is the value of the channel input that, among all possible channel inputs, maximizes the conditional probability density function of the observed channel output given the channel input.

Pulse position modulation (PPM): A signaling format in which the temporal positions of pulses are modulated by a message.

Reed-Solomon code: An error-correcting code popularly used with PPM signaling.

Serially concatenated PPM: An error-correcting code comprising the serial concatenation of a convolutional code, interleaver, and PPM.

Slot: An interval of time during which a 1 or a 0 is transmitted. In an optical communications application, a laser pulse would either be present or absent during this time interval.

Symbol error rate (SER): The probability that a symbol is detected in error, typically under the assumption of ML detection.

Symbol synchronization: The temporal alignment of a received stream of slots with the true symbol boundaries of the transmitted signal.

INTRODUCTION

In computer and communication networks, where different layers communicate at the peer level, a study of physical layer is necessary to understand the concept of information communication at the most fundamental level and how information is physically communicated from one point to another. Communication at the physical layer is the most fundamental way of providing connectivity to numerous hosts in a computer network such as the Internet. The physical layer provides connectivity between two directly connected nodes whether they are connected through a wire as in the IEEE 802.3 standard or through a wireless link as in the IEEE 802.11 standards.

In a computer network such as the Internet, end systems communicate with each other through a network that is largely a collection of communication links connected through packet switches. In almost all cases, the communication between end systems will be in the form of packets. At times, a circuit switch is used to provide an interface to end users, as in the case of users communicating through dialup connections. In a layered architecture, the network layer and the layers above it provide end-to-end connectivity between the end systems. The data-link layer, however, provides connectivity between two directly connected nodes, where a node can be an end system or an intermediate switch. The data-link layer is responsible for transporting physical frames between two directly connected or adjacent nodes. A frame is nothing more than a sequence of bits; for transporting a frame between two adjacent nodes, the data-link layer uses the services of a physical layer that is responsible for physically transporting individual bits.

In this chapter, we will consider communication of digital data only at the physical layer. This can be accomplished by various methods, one of which is *digital phase modulation* (DPM). Sometimes, digital phase modulation is used synonymously with *phase shift keying* (PSK), which is only a special case of DPM. Our focus will be on the generation and detection of digital phase modulated signals and their various properties. In the next section,

we provide background for understanding communications at the physical layer, eventually leading to a definition of digital phase modulation.

BACKGROUND

At the physical layer, the communication of digital data between two directly connected nodes is carried out in one of the two fundamental ways. The first way is by using baseband communication whereby the digital data are transmitted without altering the frequency spectrum of the digital message signal or the digital baseband signal. The baseband digital communication (also known as *baseband pulse transmission*) is, therefore, a direct transportation of a digital baseband signal that is generated by directly representing digital symbols in one of the various electrical pulse shapes. Baseband digital transmission is carried over baseband channels, which are usually low-pass in nature. The second way of transporting digital data is by means of passband communication whereby the digital data to be transported are used to generate a passband digital signal that is then transmitted to the receiver.

A passband digital signal is generated by using the digital data symbols to alter some characteristics of a carrier, which is usually sinusoidal. The characteristics of a sinusoidal carrier that may be modified by the digital data include the amplitude, phase, and frequency, resulting in digital amplitude, digital phase, and digital frequency modulation, respectively. Thus, we define *modulation* as the process in which a message signal alters the properties of a carrier signal (Wikipedia 2007, "Modulation"). As a result of modulation, the frequency spectrum of the modulated signal is usually quite different from that of the baseband signal or message signal. The spectrum of the modulated signal may be obtained from the spectrum of the baseband signal in a way that depends on the type of modulation and the carrier frequency.

The message signal or the modulating signal can either be analog or digital. However, in computer networks, the message signal is almost always digital: Symbols are

selected from a discrete set and sent one after the other every symbol period (or signaling period). The modulation in which the modulating signal is digital is called *digital modulation*. Because a digital signal is obtained by choosing one symbol from a discrete set, a simple way of performing digital modulation is to switch the amplitude, frequency, or phase of the carrier based on the symbol selected from that discrete set. In this form, digital modulation is also termed as *keying*. In *amplitude shift keying*, for example, the amplitude of the carrier wave is switched every symbol period from one value to another based on a symbol selected from the discrete set, which includes all possible digital symbol values.

We may now define a special form of digital phase modulation called *phase shift keying* (PSK). In PSK, the phase of a carrier—usually sinusoidal—is shifted at the start of each symbol interval directly in accordance with the digital data that need to be communicated from transmitter to the receiver in that interval (Wikipedia 2007, “Phase-shift keying”). If the digital data are binary, there are only two possible symbol values (typically, 0 and 1), and the simplest way to achieve PSK is to transmit one of the two possible sinusoidal waves phase shifted by 180 degrees with respect to each other when one of the two possible symbols is to be sent. In PSK, the information to be communicated is exclusively encoded in the phase of the carrier at the beginning of every symbol interval. The envelope remains constant in a PSK signal, while the frequency also remains constant throughout a given symbol. However, an abrupt phase transition happens at symbol boundaries, causing frequency impulses.

Other modulation methods exist, in addition to PSK, in which the information can be exclusively sent in the phase of the carrier. All such digital modulation methods in which the phase of the carrier contains the information to be transferred are classified as *digital phase modulation*. By this definition, the amplitude of a DPM signal should remain constant. Because phase and frequency are related to each other, a generic digital phase modulation may also be viewed as a digital frequency modulation scheme. In particular, *continuous phase modulation* (CPM) is a nonlinear modulation scheme that falls under phase as well as frequency modulation.

Digital phase modulation can either be linear or nonlinear. Linear DPM can further be *without* memory (also known as *coherent PSK* with *binary phase shift keying*, *quadrature phase shift keying*, and *offset quadrature phase shift keying* as examples) or *with* memory (such as differential PSK). In nonlinear digital phase modulation with memory, the modulated signal is constrained to maintain a constant envelope and continuous phase, avoiding abrupt changes in phase. CPM is an example of nonlinear digital phase modulation with memory. A special case of CPM is *continuous phase frequency shift keying* (CPFSK). A famous modulation scheme called *minimum shift keying* is a further special case of CPFSK.

Coherent PSK is the simplest form of digital phase modulation and is used whenever the receiver is able to locally generate the carrier with correct frequency and phase; otherwise, the differential form is preferred. If the coherent form is used, then the demodulator must track the carrier by using a carrier recovery circuit. Any errors

in tracking lead to performance degradation of the overall communication, resulting in higher bit error rates. Demodulation of CPM signals is usually accomplished by using coherent demodulators followed by sequence detectors.

A description of DPM requires understanding the terminology used in a digital communication system. We therefore first consider a baseband communication system to introduce the terminology before we set out to describe the DPM techniques in more detail.

DIGITAL COMMUNICATION SYSTEMS

In a digital communication system, the information to be sent from transmitter to receiver is always encoded in the form of digital data. If the information to be sent is already in the digital format, then the sender is not required to take any extra effort when using the digital communication system. If, however, the information to be sent is analog, such as the voice in a *voice over Internet protocol* (or VoIP) call between two end users, it is the responsibility of the sender to convert the analog information (voice) into digital format by employing analog-to-digital conversion. Obviously, the receiver will need to reverse the process by constructing an analog signal from the received digital signal.

Baseband Signal Representation

To become familiar with the terminology of digital communication systems, we start by defining a baseband digital signal as follows:

$$x(t) = \sum_{n=-\infty}^{\infty} a_n p(t - nD)$$

Usually, this signal will be available at the output of an analog-to-digital converter. This signal is also known as a digital *pulse amplitude modulation* (PAM) signal and is transmitted as is in a baseband digital system. However, in passband digital systems such as PSK, the signal $x(t)$ is fed to a modulator before subsequent transmission. In the above expression, $x(t)$ is the baseband digital signal, $p(t)$ is the pulse shape, and a_n is the n th digital symbol that needs to be sent from the transmitter to the receiver. For a binary digital system, the symbol a_n represents one single bit and will take one of the two possible values—that is, a_n will belong to a set whose cardinality is 2. In many cases, a_n will be a symbol representing more than a single bit; in such cases, a_n will belong to a set with higher cardinality. Note that D is the duration of one symbol in the above expression, and its inverse is called the *symbol rate*. For binary digital systems, each symbol will represent a single bit, and the symbol rate will be equal to the *bit rate*. However, if a_n belongs to a set with cardinality 4, then each symbol a_n will represent two binary digits (bits), and the bit rate will be twice the symbol rate. In general, if a_n belongs to a set with cardinality M , then the bit rate is $\log_2 M$ times the symbol rate. We usually use T_b for bit duration, where T_b is related to D for an M -ary digital signal

as $D = T_b \log_2 M$. Obviously, for binary signals, $M = 2$ and $D = T_b$.

Line Codes

It is important to understand the baseband digital formats (also referred to as *line codes*) because the passband digital signals (including digital phase modulation or PSK) are generated by modulating a carrier according to the baseband digital signal. Line codes or baseband digital formats are defined by selecting the parameters a_n and $p(t)$ in the expression for a baseband digital signal. Spectral properties of line codes depend on the pulse shape $p(t)$, the symbol values a_n , and the symbol rate $1/D$, and they play an important role in signal transmission. In this chapter, we only describe line codes that are of relevance to the material presented here. For a complete reference of line codes, see Barry, Lee, and Messerschmitt (2003).

The *non-return-to-zero* (NRZ) or *unipolar NRZ* or *nonpolar NRZ* format is characterized by $a_n \in \{0, 1\}$ and $p(t) = A \Pi(t/D)$ or any time-shifted version, where $\Pi(t)$ is defined as:

$$\Pi(t) = \begin{cases} 1 & |t| \leq \frac{1}{2} \\ 0 & \text{otherwise} \end{cases}$$

The NRZ format corresponding to the binary sequence 101101 is shown in Figure 1, along with other baseband digital formats.

The *return-to-zero* (RZ) format is characterized by an $a_n \in \{0, 1\}$ and $p(t) = A \Pi(t + D/4)$ or any shifted version. Because the signal level returns to zero in the middle of the bit value, we should expect relatively higher frequency components in RZ compared with NRZ format, an undesirable effect. However, the RZ format aids the

receiver in synchronization by guaranteeing a return to zero in the middle of the bit.

The polar NRZ format has the same pulse shape as the unipolar NRZ counterpart, but it uses an alphabet $a_n \in \{-1, +1\}$. Similarly, polar RZ is similar to unipolar RZ except that $a_n \in \{-1, +1\}$ for the polar case. These formats are shown in Figure 1 for the binary sequence 101101. Note that for the RZ and NRZ formats, for either polar or unipolar case, the signal has a nonzero DC value that is usually an undesirable characteristic. A popular digital baseband signal format is *Manchester encoding*, which guarantees zero DC value irrespective of the proportions of 1's and 0's in the digital signal. Manchester encoding format is also shown in Figure 1 along with other binary formats. All of these baseband digital signal formats are for the binary case where $D = T_b$ —that is, the symbol period is the same as the bit period. In general, the symbol period will be greater than or equal to the bit period.

Passband Signal Representation

The passband digital signal is obtained by modulating a carrier with a baseband digital signal. This process is referred to as *passband modulation*, and the carrier wave used is usually a sinusoidal wave. For communication over wireless channels and for longer distances, passband communication is used whereby passband signals are transmitted over the communication channel. Passband modulation is also employed whenever the communication medium is to be shared for multiple simultaneous communications over different frequency bands, as in standard commercial AM and FM radio. A large number of digital modulation schemes are used in practice (see section 1.5 of Xiong 2000). One of the most basic schemes for passband digital transmission is digital phase modulation in which the phase of the carrier is modified according to the digital baseband signal. In the rest of the chapter, we describe and analyze various DPM schemes with a particular focus on PSK. The reader is referred to Proakis (2000) and Anderson and Sundberg (1991) for details of more advanced DPM techniques. Phase shift keying is a special case of DPM in which the phase of the carrier is selected, in accordance with the digital symbol, at the beginning of the symbol interval. Thus, in PSK, phase discontinuities are observed at the start of *symbol intervals* (or *symbol boundaries*). In another type of DPM, continuous phase modulation, there are no phase discontinuities but the phase is allowed to vary throughout the symbol interval in a continuous manner.

Let us first introduce the mathematical representation of a passband digital signal. Any passband digital signal $x_c(t)$ is completely described by its in-phase and quadrature components and a carrier frequency. Mathematically, we write

$$x_c(t) = x_I(t) \cos 2\pi f_c t - x_Q(t) \sin 2\pi f_c t$$

where $x_c(t)$ is the modulated signal or passband signal, $x_I(t)$ is the in-phase component of the passband signal, $x_Q(t)$ is the quadrature component of the passband signal, and f_c is the frequency of the sinusoidal carrier.

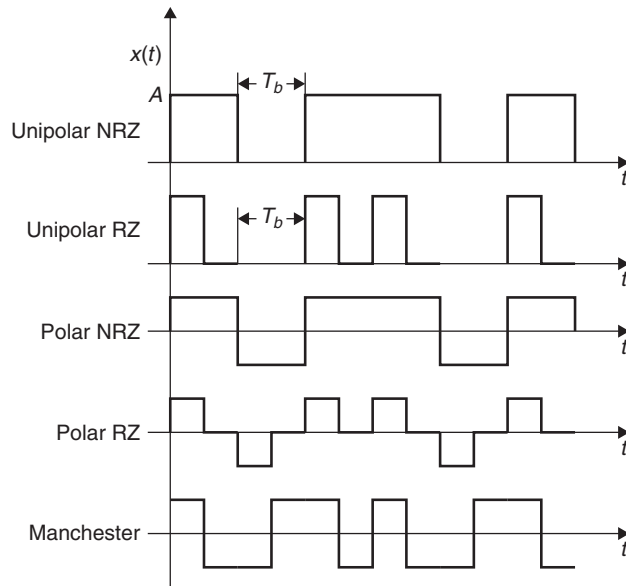

Figure 1: Digital PAM formats for unipolar NRZ, unipolar RZ, bipolar NRZ, bipolar RZ, and split-phase Manchester encoding for binary data 101101

Using the famous Euler's equation $e^{j\theta} = \cos \theta + j \sin \theta$, we can write the above expression as

$$x_c(t) = \Re[x_B(t)e^{j2\pi f_c t}]$$

where $x_B(t)$ is called the baseband equivalent signal or the complex envelope of the passband signal and is given by

$$x_B(t) = x_I(t) + jx_Q(t)$$

The in-phase and quadrature components and the complex envelope are all low-pass signals. The passband signal can be completely described by knowing the carrier frequency and the complex envelope. We may further note that the power spectral density of the passband signal is completely obtained from the power spectral density of the complex envelope by knowing the carrier frequency (Carlson, Crilly, and Rutledge 2002).

Constellation Diagrams

In passband digital systems, such as those that use digital phase modulation or PSK, a symbol is sent as a digital signal from the transmitter to the receiver during every symbol interval. The signal sent in each interval is chosen from a set whose cardinality depends on the level of modulation. For binary modulation, for example, the signal sent in each interval is chosen from one of the two possible signals and represents a single bit of information. For quaternary modulation, the signal sent in each symbol interval represents two binary bits and is chosen from a set of four signals.

For passband digital modulation, the signal sent in each symbol is represented by the expression for $x_c(t)$ given in the preceding section on passband signal representation and can be considered as a weighted combination of two orthogonal basis functions $\phi_1(t)$ and $\phi_2(t)$. For phase shift keying, a possible set of such basis functions is:

$$\begin{aligned}\phi_1(t) &= \sqrt{\frac{2}{T}} \cos 2\pi f_c t \\ \phi_2(t) &= -\sqrt{\frac{2}{T}} \sin 2\pi f_c t\end{aligned}$$

where f_c is the frequency of each of the basis functions, and T is its reciprocal.

The digital passband signal transmitted in each interval is obtained by taking the weighted sum of $\phi_1(t)$ and $\phi_2(t)$, where the weights are obtained by selecting some appropriate values for $x_I(t)$ and $x_Q(t)$. Note that the basis functions $\phi_1(t)$ and $\phi_2(t)$ chosen above are not only orthogonal to each other—that is, $\int_T \phi_1(t) \phi_2(t) dt = 0$ —but also have unit energy—that is, $\int_T \phi_1^2(t) dt = \int_T \phi_2^2(t) dt = 1$. To find the projection of a signal point along the basis function $\phi_1(t)$, we may simply use

$$x_{c1,\phi_1} = \int_T x_{c1}(t) \phi_1(t) dt$$

where $x_{c1}(t)$ is one of the two possible signals that can be transmitted within a symbol interval, and x_{c1}, ϕ_1 is the projection of $x_{c1}(t)$ along the basis function $\phi_1(t)$.

We usually show the projections along the basis functions as a point in a plane where the axes represent the basis functions. Each point in such a two-dimensional plane refers to a signal in one symbol interval. The figure obtained by displaying all possible points is called a *constellation diagram*. Thus, a binary digital system has a constellation diagram with only two points, while the constellation diagram of a quaternary signal contains four points in the plane of basis functions (Wikipedia 2007, “Constellation diagram”). Example constellation diagram for commonly used PSK schemes are given in subsequent sections.

GENERATION OF COHERENT PSK SIGNALS

In this section, we introduce the process of generating a coherent PSK signal. To this end, we first provide a mathematical representation of the PSK signals. To develop an understanding of PSK signals, we start with the simplest of the PSK signals: the *binary phase shift keying* (BPSK) signal, which is also known as a *binary antipodal signal*. Any reference to PSK would implicitly mean coherent PSK, unless stated otherwise.

Representation of BPSK

The BPSK signal is represented by two points on the constellation diagram. Corresponding to each constellation point, the two possible digital passband signals, one of which is selected for transmission in each symbol interval, are given by:

$$\begin{aligned}x_{c1}(t) &= A \cos 2\pi f_c t \\ x_{c2}(t) &= -A \cos 2\pi f_c t\end{aligned}$$

In terms of the basis functions given in the preceding section on constellation diagrams, these two passband signals are

$$\begin{aligned}x_{c1}(t) &= A \sqrt{\frac{T}{2}} \phi_1(t) \\ x_{c2}(t) &= -A \sqrt{\frac{T}{2}} \phi_1(t)\end{aligned}$$

The projection of $x_{c1}(t)$ along the two axes in the constellation diagram is

$$\begin{aligned}x_{c1,\phi_1} &= \int_T x_{c1}(t) \phi_1(t) dt = A \sqrt{\frac{T}{2}} \\ x_{c1,\phi_2} &= \int_T x_{c1}(t) \phi_2(t) dt = 0\end{aligned}$$

Similarly, the projection of $x_{c2}(t)$ along the two axes in the constellation diagram is

Figure 2: Constellation diagram for BPSK

$$\begin{aligned} x_{c2,\phi_1} &= \int_T x_{c2}(t)\phi_1(t)dt = -A\sqrt{\frac{T}{2}} \\ x_{c2,\phi_2} &= \int_T x_{c2}(t)\phi_2(t)dt = 0 \end{aligned}$$

The constellation diagram in Figure 2 shows $x_{c1}(t)$ and $x_{c2}(t)$ as points on the plane of basis functions. Both constellation points lie along the $\phi_1(t)$ axis with no component along $\phi_2(t)$. Furthermore, the two constellation points are 180 degrees from each other. The total number of constellation points (i.e., two in this case) indicate that the constellation diagram belongs to a binary digital system. For a quaternary system, the constellation diagram would contain four constellation points, as will be explained in later sections.

Every signal has an associated energy; therefore, each point in a signal constellation diagram has an associated transmitted energy. The average energy of all of the signal points in a constellation diagram is referred to as *transmitted energy per symbol*. For a binary constellation (i.e., with two constellation points), the transmitted energy per symbol is equal to the *transmitted energy per bit*, usually denoted by E_b . Thus, for BPSK signals, the energy of signal $x_{c1}(t)$ within one symbol interval is

$$\begin{aligned} E_{x_{c1}} &= \langle x_{c1}(t)x_{c1}(t) \rangle \\ &= \int_T x_{c1}(t)c_{c1}(t)dt \\ &= \int_T \frac{A^2T}{2} \phi_1(t)\phi_1(t)dt \\ &= \frac{A^2T}{2} \end{aligned}$$

By symmetry, the energy of the signal $x_{c2}(t)$ within one symbol interval is $E_{x_{c2}} = \frac{A^2T}{2}$. In general, the energy of a signal point is given by the sum of squares of projections along each basis function. Thus, for BPSK, the energy for the first constellation point is given by

$$\begin{aligned} E_{x_{c1}} &= \sqrt{x_{c1,\phi_1}^2 + x_{c1,\phi_2}^2} \\ &= \frac{A^2T}{2} \end{aligned}$$

Finally, the transmitted energy per bit for BPSK is given by averaging the energy per bit corresponding to each signal point in the constellation:

$$\begin{aligned} E_b &= \frac{\langle x_{c1}(t)x_{c2}(t) \rangle + \langle x_{c2}(t)x_{c2}(t) \rangle}{2} \\ &= \frac{A^2T}{2} \end{aligned}$$

Generation of BPSK

In practice, a binary digital signal consists of bits, a sequence of 1's and 0's, and one of the two signals in BPSK constellation is assigned to each bit. For example, for the BPSK signals given in the preceding section, a 1 can be represented by $x_{c1}(t)$ while a 0 can be represented by $x_{c2}(t)$. Thus, the transmitted signals that correspond to each bit value will be as shown in Figure 3. The assignment of bit values to one of the constellation points is completely arbitrary, and the transmitter and receiver must use the same assignment. For example, for BPSK representation in the previous section, one could assign $x_{c1}(t)$ to bit value 0 and $x_{c2}(t)$ to bit value 1.

A simple method to generate the BPSK signal is to take the polar NRZ baseband signal and multiply it with the sinusoidal carrier at frequency f_c , as shown in Figure 4. The resulting product will be a BPSK signal and is shown in Figure 5 for an example binary sequence 101101. The carrier frequency is deliberately chosen to be an integer multiple of the inverse of symbol period. It will be shown in the section on demodulation that this is not a strict requirement on the carrier frequency as long as it is much larger than the inverse of the symbol period.

Representation and Generation of QPSK

The *quadrature phase shift keying* (QPSK) signal is represented by four points on the constellation diagram. As usual, for every symbol period, we select one from the four symbols for transmission during the same symbol period. However, in this case, each symbol represents two information bits and therefore the symbol period is twice the bit period. The four signals, each corresponding to one constellation point, are given by the generic expression for passband signals:

$$x_c(t) = x_I(t)\cos 2\pi f_c t - x_Q(t)\sin 2\pi f_c t$$

To generate the QPSK signal, we need to find the in-phase and quadrature components, $x_I(t)$ and $x_Q(t)$, for each of the four signal points. These components are listed in Table 1.

Thus, for example, the expression for the signal $x_{c1}(t)$ that corresponds to the first constellation point is

$$\begin{aligned} x_{c1}(t) &= \frac{A}{\sqrt{2}} \cos 2\pi f_c t - \frac{A}{\sqrt{2}} \sin 2\pi f_c t \\ &= \frac{A}{2} \sqrt{T} \phi_1(t) + \frac{A}{2} \sqrt{T} \phi_2(t) \end{aligned}$$

Figure 3: Signal set for BPSK with $A = 1$ 

Figure 4: Generation of BPSK signal from polar NRZ signals

Then the projections of $x_{c1}(t)$ on the axes representing the two basis functions are

$$x_{c1,\phi_1} = \int_T x_{c1}(t)\phi_1(t)dt = \frac{A}{2}\sqrt{T}$$

$$x_{c1,\phi_2} = \int_T x_{c1}(t)\phi_2(t)dt = \frac{A}{2}\sqrt{T}$$

The projections of other signal points on the basis functions can be similarly determined. The complete constellation diagram for the QPSK signal is shown in Figure 6.

For QPSK, one symbol represents two signal bits, which means that the energy per bit is one-half the energy per symbol. The energy per symbol can be determined by taking the average energy for each signal point in

the constellation. For the first constellation point, the corresponding energy, if that symbol is transmitted in one symbol period, is given by

$$E_{x_{c1}} = \langle x_{c1}(t)x_{c1}(t) \rangle$$

$$= \int_T x_{c1}(t)x_{c1}(t)dt$$

$$= \frac{A^2T}{2} \quad (\text{using orthonormality of basis functions})$$

This energy can also be determined by taking the sum of squares of projections along each basis function, as given below:

$$E_{x_{c1}} = \sqrt{x_{c1,\phi_1}^2 + x_{c1,\phi_2}^2}$$

$$= \frac{A^2T}{2}$$

By symmetry, the energy of other signal points within one symbol interval is $\frac{A^2T}{2}$, and thus the transmitted energy per symbol is $\frac{A^2T}{2}$. Finally, the energy per bit for QPSK is

Figure 5: BPSK-transmitted signal for bit sequence 101101

Table 1: In-Phase and Quadrature Components of a QPSK Signal

Constellation point signal	In-phase component, $x_I(t)$	Quadrature component, $x_Q(t)$
$x_{c1}(t)$	$\frac{A}{\sqrt{2}}$	$\frac{A}{\sqrt{2}}$
$x_{c2}(t)$	$-\frac{A}{\sqrt{2}}$	$\frac{A}{\sqrt{2}}$
$x_{c3}(t)$	$-\frac{A}{\sqrt{2}}$	$-\frac{A}{\sqrt{2}}$
$x_{c4}(t)$	$\frac{A}{\sqrt{2}}$	$-\frac{A}{\sqrt{2}}$

**Figure 6:** Constellation diagram for QPSK

$$E_b = \frac{1}{2} \frac{A^2 T}{2} = \frac{A^2 T}{4}$$

Now that we have expressions for each signal point in the QPSK constellation, the generation of the QPSK signal becomes straightforward. First, we emphasize that each constellation point represents two signal bits and, as in the case of BPSK, every possible pair of bits needs to be mapped onto one of the constellation points. Because there are four possible combinations a bit pair may take—00, 01, 10, and 11—we have just enough constellation points to map these bit pairs. Once again, the mapping is arbitrary as long as a single bit pair maps onto a single constellation point. Next, we note from Table 1 that in-phase and quadrature component pairs can be generated by mixing two polar NRZ BPSK signals. Thus, the QPSK signal can be generated by adding two BPSK signals that are generated using *quadrature carriers*. To generate the two BPSK signals, we split the polar NRZ encoded information bits into even and odd numbered bits using a demultiplexer and perform individual BPSK modulation as shown in Figure 7.

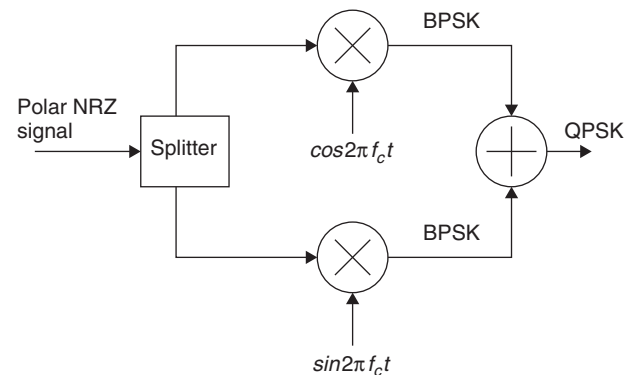

M-ary PSK

The constellation points in BPSK and QPSK signals may be considered as lying along a circle, where one

constellation point can be obtained by adding some phase shift to another constellation point. The two constellation points in BPSK are 180 degrees apart, at 0 degrees and 180 degrees, whereas the constellation points in QPSK lie at 45, 135, 225, and 315 degrees along a circle whose radius can be computed from the projections of any point along the two basis functions. In both cases, the circle along which the constellation points lie has a radius equal to the square root of the transmitted energy per symbol.

The idea of placing the constellation points along a circle in the basis functions plane can be extended to higher modulation levels. For example, in 8-PSK (or 8-ary PSK) eight points are spaced at 45 degrees from adjacent points along a circle in the plane formed by the two basis functions, as shown in Figure 8. This also means that the signal energy of each constellation point is the same and is equal to the transmitted energy per symbol. For M-ary PSK, there are M constellation points along a circle in the basis function plane and each constellation point represents $\log_2 M$ bits transmitted in each symbol.

M-ary PSK signals can be generated by generalizing the idea of generating the QPSK signal from two BPSK signals. Theoretically, one signal point on the M-ary constellation can be obtained from another by adding appropriate phase shift to the modulated signal. Practically, every possible $\log_2 M$ -bit sequence is mapped onto a constellation point. When a given bit sequence of length $\log_2 M$ bits occurs in the message stream, the signal corresponding to the mapped constellation point is transmitted

**Figure 7:** Generation of QPSK signal from polar NRZ signals

Figure 8: Constellation diagram for M-ary PSK

in the symbol interval. To generate the signal corresponding to a constellation point, the in-phase and quadrature components of the signal are summed after modulating with $\cos 2\pi f_c t$ and $\sin 2\pi f_c t$, respectively.

DEMODULATION OF COHERENT PSK SIGNALS

As mentioned in the early background section, coherent PSK is used when the receiver or the demodulator is able to locally generate the carrier with correct phase and frequency. To this end, the coherent receiver tracks the carrier by using a carrier recovery circuit. We will briefly describe the carrier recovery circuit in the later section on synchronization and carrier recovery while discussing synchronization and its effects on the performance of PSK signals. For this section, we assume that the demodulator has some mechanism to track the carrier and will somehow be able to generate the carrier with the correct frequency and phase. We will also assume that the transmitted signal does not encounter any imperfection or noise in the channel. In real communications, however, the received signal will not be an exact replica of the transmitted signal, only a noisy version of it. This will lead to occasional errors in making a decision at the demodulator about what was sent from the transmitter. For an understanding of the demodulation process, we may ignore the channel imperfections and later evaluate the effects of noise once the demodulation process is completely understood.

A simple construction of a coherent BPSK receiver is shown in Figure 9, where $r(t)$ is the received signal. Ignoring the noise, the received signal in each symbol interval

Figure 9: Demodulation of BPSK signals

is equal to the signal corresponding to one of the two constellation points in the BPSK constellation. Recall from the earlier section on BPSK that the two possible symbols in each symbol interval are:

$$\begin{aligned} x_{c1}(t) &= A \cos 2\pi f_c t \\ x_{c2}(t) &= -A \cos 2\pi f_c t \end{aligned}$$

For a single symbol period, the received signal will thus be equal to either $x_{c1}(t)$ or $x_{c2}(t)$. In general, for $-\infty < t < \infty$, the received signal $r(t)$ can be written in terms of a polar NRZ signal using the previously discussed mechanism for generating a BPSK. In other words,

$$r(t) = \sum_{n=-\infty}^{\infty} a_n p(t - nT) \cos 2\pi f_c t$$

where $a_n \in \{-1, +1\}$ and $p(t) = A\Pi(\frac{t}{T})$. Thus, the signal $\hat{r}(t)$ at the output of the integrator is given by

$$\begin{aligned} \hat{r}(t) &= \frac{1}{T} \int_{(k-\frac{1}{2})T}^{(k+\frac{1}{2})T} r(t)^2 \cos 2\pi f_c t dt \\ &= \frac{1}{T} \int_{(k-\frac{1}{2})T}^{(k+\frac{1}{2})T} \left(\sum_{n=-\infty}^{\infty} a_n A \Pi\left(\frac{t-nT}{T}\right) \cos 2\pi f_c t \right) 2 \cos 2\pi f_c t dt \\ &= \frac{1}{T} \int_{(k-\frac{1}{2})T}^{(k+\frac{1}{2})T} A a_k 2 \cos^2 2\pi f_c t dt \\ &= \frac{A a_k}{T} \int_{(k-\frac{1}{2})T}^{(k+\frac{1}{2})T} (1 + \cos 4\pi f_c t) dt \\ &= A a_k + \frac{A a_k}{4\pi T f_c} [\sin 4\pi f_c (k + \frac{1}{2})T - \sin 4\pi f_c (k - \frac{1}{2})T] \\ &= A a_k + \frac{A a_k}{4\pi T f_c} 2 \cos 4\pi f_c kT \sin 2\pi f_c T \end{aligned}$$

In the above expression, the second term is approximately equal to zero if $f_c T \gg 1$, and is exactly zero if f_c is an integer multiple of $1/T$. Thus, the input to the decision device, shown as the last box in Figure 9, is approximately (or exactly if f_c is an integer multiple of $1/T$ equal to $A a_k$). The decision device infers that a $+1$ was sent from the transmitter if the input to the decision device is greater than 0 and decides that a -1 was sent otherwise. Thus, in the absence of noise, one can completely and perfectly recover the transmitted signal using the above demodulation scheme. The presence of noise in the signal would cause the input to the decision device to be different from $A a_k$, depending on the magnitude of the noise, and may lead to occasional errors in inferring what was sent from the transmitter.

The demodulator for QPSK and M-ary PSK can be constructed on a similar principle, whereby the in-phase and quadrature components are demodulated separately and then combined to generate the transmitted signal (Xiong 2000).

SPECTRAL CHARACTERISTICS OF PSK SIGNALS

The *power spectral density* (PSD) of a modulated signal is a direct indication of the bandwidth efficiency of the modulation scheme. A modulated signal with *wider* PSD consumes more transmission bandwidth compared to a signal that has narrower PSD. We will provide expression for the power spectral density of M-ary PSK signals, which can be specialized for $M=2$ (BPSK) and $M=4$ (QPSK). To simplify things, we use the fact that for pass-band signals with certain properties, the PSD can be obtained by dividing by the symbol duration the power spectral density of the corresponding baseband signal. A BPSK signal generated from the polar NRZ signal in the previous section on BPSK possesses these properties and, therefore the PSD of the BPSK signal is simply $1/T$ times the PSD of the underlying polar NRZ signal shifted to baseband. Recall that the BPSK signal is given by

$$x_c(t) = \sum_{n=-\infty}^{\infty} a_n p(t - nT) \cos 2\pi f_c t$$

whose underlying baseband signal is the following polar NRZ signal:

$$\begin{aligned} x(t) &= \sum_{n=-\infty}^{\infty} a_n p(t - nT) \\ &= \sum_{n=-\infty}^{\infty} a_n \text{A}\Pi\left(\frac{t-nT}{T}\right) \end{aligned}$$

The energy spectral density of $x(t)$ in a single symbol period is given by the squared Fourier transform of $x(t)$ by considering just one symbol period. Thus, if $\tilde{x}(t)$ represents the single symbol of $x(t)$, then a possible value

of $\tilde{x}(t)$ is $a_n \text{A}\Pi(\frac{t}{T})$. The Fourier transform $\tilde{X}(f)$ of $\tilde{x}(t)$ is, therefore, $a_n A T \text{sinc } fT$. Thus, the *energy spectral density* (ESD) of the signal $x(t)$ is $a_n^2 A^2 T^2 (\text{sinc } fT)^2$; and because $a_n \in \{-1, +1\}$, the ESD of $x(t)$ is $A^2 T^2 (\text{sinc } fT)^2$. Then the PSD of the polar NRZ signal $x(t)$ is given by its ESD divided by the symbol period—that is,

$$\begin{aligned} \text{PSD of } x(t) &= S_x(f) = 1/T A^2 T^2 (\text{sinc } fT)^2 \\ &= A^2 T (\text{sinc } fT)^2 \end{aligned}$$

Finally, the baseband-shifted PSD of BPSK signal is given by the PSD of the baseband polar NRZ signal divided by the symbol period T . Thus,

$$\begin{aligned} \text{Shifted PSD of BPSK} &= S_{x_c}(f) = 1/T A^2 T (\text{sinc } fT)^2 \\ &= A^2 (\text{sinc } fT)^2 \end{aligned}$$

It can be seen that the PSD of a polar NRZ signal falls off with squared frequency and crosses the first null at $fT = 1$ or $f = 1/T$. Thus, the PSD of a BPSK signal will also fall off with squared frequency, will be centered at f_c , and will hit the first null at $f_c \pm 1/T$. The PSD of a BPSK signal for the positive frequencies is shown in Figure 10.

The PSD of a QPSK signal can be easily determined by considering the structure that was used earlier (in the section on the representation and generation of QPSK) for the generation of BPSK by taking the sum of two independently generated BPSK signals. In other words, in one symbol period, we generate two independent BPSK signals, each of which has a corresponding baseband polar NRZ signal given by $a_n \frac{A}{\sqrt{2}} \Pi(\frac{t}{T})$. Because this signal is $1/\sqrt{2}$ times the polar NRZ signal $\tilde{x}(t)$ considered above, its PSD is one-half of the PSD of the BPSK signal considered above. However, the QPSK is generated by summing up

Figure 10: Power spectral density of BPSK signals

two such independent BPSK signals; thus, the PSDs are also added, and the PSD of the QPSK signal has the same expression as in the case of BPSK and is given below:

$$\begin{aligned}\text{Shifted PSD of QPSK} &= 2 \times (A/\sqrt{2})^2 (\text{sinc } fT)^2 \\ &= A^2 (\text{sinc } fT)^2\end{aligned}$$

This expression for power spectral density is also correct for an M-ary PSK modulation with parameter $A = \sqrt{2E/T}$, where E and T are energy per symbol and symbol period, respectively.

ERROR PERFORMANCE OF PSK SIGNALS

An important performance parameter of any digital modulation scheme is the average number of bits that are inferred incorrectly at the receiver. In an ideal communication channel, no errors are observed, but practical channels are noisy, which means that the signals transmitted through the channel are contaminated by noise. We usually model the noise as additive white Gaussian noise (Wikipedia 2007, “Additive white Gaussian noise”) —that is, the probability density function of noise, which is assumed to be added to the transmitted signal, follows a Gaussian distribution, and individual noise samples are uncorrelated with each other, leading to flat power spectral density.

The effect of additive noise is to add an undesirable random parameter (voltage, phase, or frequency) to the actual signal. This results in a received signal that has moved away from the original constellation point used for that signal in that symbol period. For distinguishing the received signals corresponding to two neighboring constellation points, the receiver usually places the decision boundary midway between the two points. Thus, for the BPSK signal, where the two constellation points are at $\pm A\sqrt{T}/2$, the decision boundary is the vertical line midway between the two constellation points. Thus, received signals in the first and fourth quadrant are mapped to $\pm A\sqrt{T}/2$, while the signals in the second and third quadrant are mapped to $-A\sqrt{T}/2$. Similarly, for QPSK, the lines along the horizontal and vertical axes form the decision boundaries. An error results when the noise added to the signal is such that the contaminated signal crosses a decision boundary such that it is mistakenly regarded as belonging to a neighboring constellation point.

Although the effect of additive noise is simply to move the received signal away from its corresponding constellation point with the addition of an undesirable random parameter, the signals also undergo fading in wireless communication channels. Fading may increase the bit error rates by many times compared to those obtained in additive noise channels only (Rappaport 2001). In this chapter, we only include the bit error rates (or probability of bit errors) in *additive white Gaussian noise* while omitting the error rates for fading channels that can be found in more advanced texts (e.g., Proakis 2000; Barry, Lee, and Messerschmitt 2003).

To find the bit error rate (or error probability) of BPSK, we recall from the earlier section on the representation of BPSK that the BPSK transmitter sends one of the two

possible symbols, $xc_1(t)$ or $xc_2(t)$, in each symbol interval. There are two possible ways a receiver can make an error: (1) $xc_1(t)$ was transmitted, but the additive noise pushed the received signal into the region that corresponds to $xc_2(t)$; or (2) $xc_2(t)$ was transmitted, but the additive noise pushed the received signal into the region that corresponds to $xc_1(t)$. For obtaining a quantitative expression, we consider additive noise with a constant two-sided power spectral density of $N_0/2$ and Gaussian distribution after demodulation, which is given by:

$$f_N(n) = \frac{1}{\sqrt{\pi N_0}} e^{-\frac{n^2}{N_0}}$$

The probability of error in a single bit interval is given by the sum of probabilities of two mutually exclusive events (Couch 1995):

1. The transmitter sent $xc_1(t)$ and the receiver detected $xc_2(t)$, which happens when additive noise after demodulation is less than $xc_1\phi_1$.
2. xc_1 The transmitter sent $xc_2(t)$ and the receiver detected $xc_1(t)$, which happens when additive noise after demodulation is greater than $-xc_2\phi_1$.

If the probability of sending $xc_1(t)$ is the same as the probability of sending $xc_2(t)$, which is usually the case, then by symmetry the error probability is given by the probability that the demodulated noise is greater than $xc_1\phi_1 = A\sqrt{\frac{T}{2}} = \sqrt{E_b}$. Thus, the bit error probability $P_{b,\text{BPSK}}$ is given by

$$\begin{aligned}P_{b,\text{BPSK}} &= P\{\text{Additive Noise} > \sqrt{E_b}\} \\ &= \int_{\sqrt{E_b}}^{\infty} \frac{1}{\sqrt{\pi N_0}} e^{-\frac{n^2}{N_0}} dn \\ &= Q\left(\sqrt{\frac{2E_b}{N_0}}\right)\end{aligned}$$

where $Q(\cdot)$ is the tail of the standard Gaussian distribution (a Gaussian distribution with zero mean and unit variance).

A similar method of error probability analysis for QPSK can be carried out and is given in Haykin (2000). In summary, for QPSK, the symbol error probability is given by

$$P_{s,\text{QPSK}} = 2Q\left(\sqrt{\frac{E}{N_0}}\right)$$

where E is the symbol energy, and for QPSK the symbol energy is twice the bit energy as explained in the earlier section on BPSK representation—that is, $E = 2E_b$. With using a special encoding technique called *Gray encoding*, the probability of bit error in QPSK can be kept at one-half of the probability of symbol error. Thus, the bit error rate for QPSK is given by

$$\begin{aligned}
 P_{b,\text{QPSK}} &= \frac{1}{2} \times 2Q \left(\sqrt{\frac{E}{N_0}} \right) \\
 &= Q \left(\sqrt{\frac{E}{N_0}} \right) \\
 &= Q \left(\sqrt{\frac{2E_b}{N_0}} \right)
 \end{aligned}$$

which is the same as the bit error rate for BPSK. Thus, coherent QPSK delivers the same bit error rates as coherent BPSK but has the capability of transmitting data twice as fast, keeping other parameters constant. Thus, in practice, coherent QPSK is a preferred modulation scheme when compared with coherent BPSK (Simon, Hinedi, and Lindsey 1994).

SYNCHRONIZATION AND CARRIER RECOVERY

As we observed in the section “Demodulation of Coherent PSK Signals,” coherent demodulation of coherent PSK requires the availability of a correct carrier frequency and phase at the receiver. This can be accomplished by using a carrier recovery circuit that usually employs a *phase-locked loop* (Xiong 2000). In fact, if the transmitter chooses to include an extra *pilot* signal at the carrier frequency (at which the PSK signals have no spectral components), the receiver may use this pilot signal to acquire the synchronization. If the pilot signal is not included in the transmitted signal, then carrier recovery is accomplished by using a nonlinear circuit. A newer approach to carrier synchronization is by setting up a DSP algorithm that maximizes the likelihood estimate of the carrier phase in an iterative manner (Haykin 2000).

Differential PSK does not require carrier synchronization because it can use noncoherent detector. However, both coherent and differential modulation require another type of synchronization called *symbol synchronization*. Note from the BPSK demodulation discussed earlier that the integral operation in the demodulator is carried out over precisely one symbol time. Therefore, the receiver must somehow determine the start and end of each symbol. Symbol synchronization, also referred to as *clock recovery*, is extremely important for correct detection of symbols and is usually implemented in DSP before performing carrier synchronization.

From the demodulation process, we note that the accuracy of clock recovery (or symbol synchronization) and phase synchronization determines the accuracy of the decisions taken at the receiver. It is shown in Xiong (2000) that a phase synchronization error of ϕ will result in a reduction in the amplitude of the signal that is fed to the decision device by a factor $\cos \phi$. Thus, the bit error probability of the BPSK signal in the presence of a phase error ϕ will be given by

$$P_b = Q \left(\sqrt{\frac{2E}{N_0}} \cos \phi \right)$$

From this equation, we note that the argument of the Q function is directly affected by the phase error, and thus even small local carrier phase errors may significantly affect the bit error rates of coherent BPSK systems.

SPECTRUM CONTROL IN DIGITAL PHASE MODULATION

Coherent PSK signals undergo abrupt phase transitions at the beginning of symbol intervals, causing high-powered spectral side lobes that may interfere with adjacent channels. To illustrate the abrupt phase transitions, let us consider the example of QPSK signal described earlier in “Representation and Generation of QPSK.” The QPSK constellation shown in Figure 6 consists of four points, exactly one of which is transmitted in one symbol period, corresponding to a two-bit sequence that appears in the bit stream of message signal during that symbol period. The signal transmitted in one symbol interval does not depend on the signal transmitted in a previous or future symbol interval. Thus, the constellation point in each symbol interval is chosen independently. Because the constellation points represent signals with differing phases (at 45, 135, 225, and 315 degrees), phase change at each symbol boundary could be 0 degrees, ± 90 degrees, and ± 180 degrees.

Another issue related to abrupt phase transitions turns up when we consider the demodulator that invariably uses a bandpass filter before detection in order to limit the amount of additive white Gaussian noise. Some PSK transmitters will also include the bandpass filter to limit the side lobe power and consequent interference with adjacent frequency bands. Passing a PSK signal through a bandpass filter causes amplitude variation through a phenomenon called FM-to-AM conversion (Carlson, Crilly, and Rutledge 2002). This amplitude variation can deteriorate the error rate performance of the overall system.

To combat abrupt phase transitions at the beginning of symbol intervals, variations of PSK have been devised. One such variation for QPSK is called *staggered QPSK* or *offset-keyed* (or *offset*) *QPSK*, abbreviated *OQPSK*. Using *OQPSK*, constellation points chosen in any two consecutive symbol periods are not allowed to be diagonally opposite to each other, thus avoiding the ± 180 -degree phase transition at the beginning of the symbol period. Thus, the allowable phase transitions at the beginning of a symbol period are limited to 0 degrees and ± 90 degrees. *OQPSK* is generated by delaying the bit stream responsible for generating the quadrature component by half a symbol period. Although *OQPSK* exhibits the same bit error performance as exhibited by *QPSK*, it results in reduced amplitude fluctuations after bandpass filtering when compared with *QPSK*.

The use of *OQPSK* limits the phase transitions to at most ± 90 degrees at the beginning of a symbol interval. These phase transitions can be eliminated altogether by using *CPM*. In *CPM*, the phase transitions, which happen at the beginning of a symbol interval in case of *QPSK* and *OQPSK*, are spread over the whole symbol interval in such a way that a phase continuity is maintained throughout the symbol period, including the symbol boundaries. A generic continuous phase modulated signal is given by

$$x_c(t) = \sqrt{\frac{2E}{T}} \cos(2\pi f_c t + \phi_0 + \phi(t))$$

where the variable portion of phase $\phi(t)$ is given by

$$\phi(t) = 2\pi h \sum_{j=0}^n a_j q(t - jT)$$

and where $q(t)$ is called the phase-shaping pulse and h is the modulation index. The phase-shaping pulse $q(t)$ is related to the frequency-shaping pulse $g(t)$ as:

$$q(t) = \int_{-\infty}^t g(y) dy$$

Note that the expression of CPM signal $x_c(t)$ indicates that the CPM is a variation of frequency modulation; however, because of a direct relationship between frequency and phase (instantaneous frequency is the derivation of instantaneous phase), a CPM signal can either be viewed as a frequency-modulated or a phase-modulated signal. When $g(t)$ is a rectangular pulse of duration LT , we get a special family of CPM called L -REC CPM. For $L = 1$, we get 1-REC CPM, which is also known as *continuous phase frequency shift keying*. A further specialization of CPFSK with $h = 1/2$ yields the well-known *minimum shift keying* (MSK). For demodulation purposes, a usual way to interpret a CPM signal is to consider it as a concatenation of a trellis code followed by memoryless modulation (Wilson 1995). Thus, the demodulation of CPM signals may be carried out by a linear demodulator followed by a sequence detector.

CONCLUSION

Digital phase modulation is a widely used modulation technique in computer and communication networks. This type of modulation has an attractive property—it maintains a constant envelope—and is therefore suitable for communication in nonlinear channels. Many existing communication networks use phase shift keying or other digital phase modulation schemes for communication at the physical layer. Specifically, current wireless LAN standards such as IEEE 802.11b, IEEE 802.11g and others such as Bluetooth and GSM make use of digital phase modulation in various transmission modes.

We studied the methods for generating and demodulating the PSK signals and also learned PSK signal representation in the signal space. We evaluated the PSK schemes with respect to the error probabilities they offer and briefly described the two types of synchronization required in coherent systems. Expressions for bit error rates for BPSK and QPSK are provided in this chapter, and we learned that, keeping other parameters the same, QPSK delivers data at twice the rate of BPSK and therefore is a preferred modulation technique.

Phase shift keying is the simplest form of digital phase modulation. Constant envelope is the most notable and useful property of PSK signals. In general, all DPM schemes maintain a constant envelope. Furthermore, PSK

undergoes abrupt phase changes at symbol boundaries, resulting in relatively high energy at higher frequency side lobes. This abrupt phase change can be subsided by using techniques such as offset QPSK, which limits the phase jump at symbol boundaries. Furthermore, CPM allows a complete elimination of abrupt phase changes at symbol boundaries by allowing a continuous change of phase throughout the symbol. CPM signals may be viewed as coding followed by modulation and therefore may be demodulated by using a coherent demodulator followed by a sequence detector. By avoiding abrupt phase changes, CPM avoids high power in side lobes, resulting in spectrally efficient modulation.

GLOSSARY

Bit error rate: The average number of bits received in error when a digital signal is sent from one point to another.

Carrier signal: A signal or wave that is a relatively high-frequency signal, usually a sinusoidal. One property of a carrier signal—phase, frequency, or amplitude—is varied according to a message signal that needs to be transmitted from one point to another.

Constellation: The representation of signal points of a digital modulation scheme on a plane whose axes are represented by orthonormal basis functions.

Continuous phase frequency shift keying (CPFSK): A special case of CPM in which the frequency-shaping pulse is rectangular with a duration equal to the symbol interval.

Continuous phase modulation (CPM): A digital modulation in which the modulated signal is constrained to maintain a constant envelope and continuous phase, avoiding abrupt changes in phase.

Demodulation: The process of extracting the message signal from the modulated signal received at the receiving end of a communication system.

Message signal: An electrical signal, typically a representative of a physical quantity, that is usually transmitted from the source to the destination in a communication system.

Minimum Shift Keying (MSK): A special case of CPFSK. In particular, MSK is CPFSK with a minimum modulation index that results in orthogonal signaling.

Modulation: The process of varying some property (amplitude, phase, or frequency) of a carrier signal according to a message signal that needs to be conveyed to the receiver.

Phase shift keying (PSK): A modulation method in which the phase of a carrier signal is varied directly in accordance with a digital message signal.

Synchronization: The process in which two quantities are made to vary in unison. In PSK, two types of synchronization are needed: phase synchronization and symbol synchronization.

INTRODUCTION

Information is sent from one point in the network to another and can be converted to either a digital signal or an analog signal. This chapter deals with the shaping of digital data so that it is suitable for transmission over a channel. The digital messages can be stored in the memory of the computer and include data, text, numbers, graphical images, audio, and video. Passband systems have a relatively constant attenuation over the bandwidth because the carrier frequency is much larger compared to the signal bandwidth and the cross-talk coupling loss is also relatively frequency-independent. In baseband modulation, however, data are transmitted directly without resorting to frequency translation. A variety of waveforms have been studied, and the ones that have good power, spectral efficiency, and adequate timing information are used for converting the data, a sequence of bits, to a digital signal. These baseband modulation waveforms are called *line codes*, *baseband waveforms*, or *pulse-coded modulation* (PCM) codes. Line coding is an issue in baseband systems (compared to the passband systems) that operate over

cable because the channel exhibits a large variation in attenuation over the bandwidth of interest and also has a large variation in cross-talk coupling loss. However, improvement in performance of these systems is possible by controlling the power spectrum of the transmitted signal.

In the next section, we give an overview of the fundamentals of optimum detection of binary (and multiple-level) signals in *additive white Gaussian noise* (AWGN) and briefly describe how to calculate the *power spectral density* (PSD) of random digital signals. For more details, the interested reader is referred to Simon, Hinedi, and Lindsey (1995).

The rest of the chapter is broadly divided into two categories of line codes: those that are suitable for transmission over (1) wireline links and (2) optical fiber. Line codes that are appropriate over wireline systems are discussed in the third section and can be broadly divided into four subclasses: *non-return to zero* (NRZ), *return-to-zero* (RZ), *pseudoternary* (PT) and *biphase* (see Figure 1). These line codes will be compared based on their spectral characteristics, bandwidth, error performance, error-detection

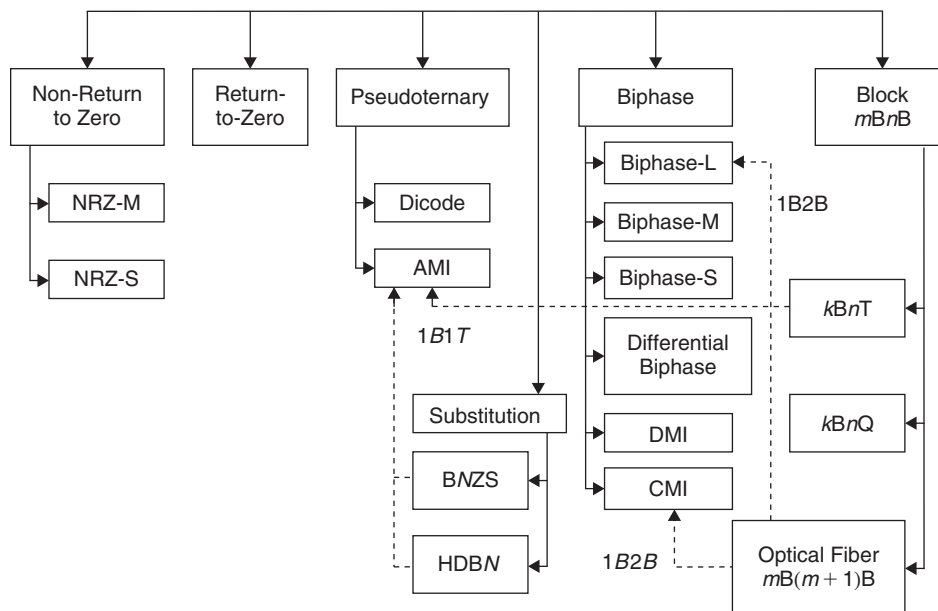

Figure 1: Line code tree

capability, self-synchronization ability, and bit sequence independence or transparency. Substitution codes overcome the shortcomings of the pseudoternary line codes—the most popular wireline line codes—by exchanging the consecutive zeros with various control signals that improve the timing information of the original codes. Block codes are not limited to binary and introduce redundancy through which the characteristics of the line code can be controlled. The nonbinary block codes (ternary and quaternary) are used in wireline systems where bandwidth is a premium. However, because the optical sources and detectors operate in the nonlinear mode, binary block codes are preferred in optical fiber transmission systems where abundant bandwidth is available. The block codes used for optical fiber are discussed in the last major section.

PROBABILITY OF BIT ERROR AND POWER SPECTRAL DENSITY

This section gives an overview of fundamentals of optimum detection of binary (and multilevel) signals in channels disturbed by AWGN and the basics of PSD calculations for digital random signals.

Probability of Bit Error

The probability of making a bit error after transmission through an AWGN channel is discussed in this section. The AWGN channel model implies that channel frequency response is flat and has infinite bandwidth. The only distortion introduced is by the additive white Gaussian noise. This is not an accurate model for practical channels except probably the satellite channel, but it is reasonably accurate as long as signal bandwidth is much narrower than that of the channel.

From the signal-detection viewpoint, binary line code (i.e., code that uses two signals to transmit information) presents one of two hypotheses:

$$\begin{aligned} H_1 : s_1(t) & \quad 0 \leq t \leq T_b & \text{a priori probability } p_1 \\ H_2 : s_2(t) & \quad 0 \leq t \leq T_b & \text{a priori probability } p_2 \end{aligned} \quad (1)$$

Signal energies are $E_1 = \int_0^{T_b} s_1^2(t) dt$, $E_2 = \int_0^{T_b} s_2^2(t) dt$, and the correlation coefficient⁰ between the two signals is $\rho_{12} = \frac{1}{\sqrt{E_1 E_2}} \int_0^{T_b} s_1(t) s_2(t) dt$ where $|\rho_{12}| \leq 1$. When a matched filter receiver is used, the bit error probability, P_b , of equally likely binary signals, in AWGN with zero mean and variance $N_0/2$, is given by Simon, Hinedi, and Lindsey (1995):

$$P_b = Q \left(\sqrt{\frac{E_1 + E_2 - 2\rho_{12}\sqrt{E_1 E_2}}{2N_0}} \right) \quad (2)$$

where $Q(x)$ represents the area under the tail of a unit normal variate—that is, the normal random variable has a zero mean and unit variance. The bit error probability

is minimum for antipodal signals—in other words, when $\rho_{12} = -1$ and 3 dB worse for equal energy binary orthogonal signals, or when $\rho_{12} = 0$.

For M-ary signals, the minimum error probability receiver computes (Simon, Hinedi, and Lindsey 1995)

$$l_j = \ln(p_j) - \frac{1}{N_0} \sum_{i=1}^N (r_i - s_{ij})^2 \quad j = 1, 2, \dots, M \quad (3)$$

and chooses the largest l_j . For equally likely signals, the decision rule reduces to calculating the distance between the signals and selects the signal that is at a minimum distance. The received signal is given by

$$r(t) = s_j(t) + n(t) \quad j = 1, 2, \dots, M \quad (4)$$

where $n(t)$ is AWGN with zero mean and variance $N_0/2$. Note also that r_i are statistically independent Gaussian random variables with variance $N_0/2$:

$$r_i = \int_0^{T_b} r(t) \Phi_i(t) dt \quad i = 1, 2, \dots, N \quad (5)$$

$\Phi_i(t)$ are N orthonormal basis functions. The projection of $s_j(t)$ onto $\Phi_i(t)$ is s_{ij} :

$$s_{ij} = \int_0^{T_b} s_j(t) \Phi_i(t) dt \quad \begin{matrix} i = 1, 2, \dots, N \\ j = 1, 2, \dots, M \end{matrix} \quad (6)$$

Power Spectral Density

A general formula for calculating the power spectrum of digitally modulated baseband waveforms is presented below. It can be used for most of the binary line codes. However, for other codes, different methods to calculate PSD will have to be employed.

A digital random signal $s(t)$ can be represented by

$$s(t) = \sum_k a_k g(t - kT_s) \quad (7)$$

where $\{a_k\}$ represents the binary or multilevel random data sequence and $g(t)$ is a filter that shapes the spectrum. For binary signaling, $T_s = T_b$ where T_b is the time it takes to send one bit and T_s is the symbol duration. The power spectral density of $s(t)$ is (Simon, Hinedi, and Lindsey 1995)

$$S(f) = \frac{|G(f)|^2}{T_s} \sum_n R[n] \exp(-j\omega n T_s) \quad (8)$$

where $R[n] = E(a_k a_{k+n})$ is the autocorrelation function of the data sequence and, in general, $E(XY) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} xy f_{XY}(x, y) dx dy$. Thus, the PSD of a line code is determined by its (1) pulse shape and (2) the statistical properties of the data sequence.

For uncorrelated $\{a_k\}$:

$$R[n] = \begin{cases} \sigma_a^2 + \eta_a^2 & n = 0 \\ \eta_a^2 & n \neq 0 \end{cases} \quad (9)$$

where σ_a^2 is the variance of $\{a_k\}$ and η_a^2 is the square of the mean of $\{a_k\}$. Using the Poisson sum formula for binary signals, we have (Simon, Hinedi, and Lindsey 1995):

$$S(f) = \frac{|G(f)|^2}{T_b} \sigma_a^2 + \frac{\eta_a^2}{T_b^2} \sum_n |G(nT_b^{-1})|^2 \delta(f - nT_b^{-1}) \quad (10)$$

The first term in Equation 10 represents the continuous part of the power spectral density and depends only on the pulse shape used. Pulse shape should be selected such that the desired properties of line codes (see the following section) are met. The second term in the above equation represents discrete components, weighted by the pulse shape, $1/T_b$ a part in frequency that aids in timing recovery. This term can be reduced to zero by (1) a zero mean sequence—that is, one that consists of equally likely and symmetrically placed symbols in the complex plane; or (2) a pulse shape whose spectrum is zero at all multiples of $1/T_b$. Later we will show that unipolar RZ codes, with rectangular pulses, have this discrete component at zero frequency. However, note that polar versions can be made unipolar by rectification, from which the timing can be easily recovered.

In the following, we will assume that 1's and 0's are equally likely in the data sequence. Moreover, $\{a_k\}$ may represent the original data sequence or its differentially encoded form. Later in the chapter, we will see that the NRZ (NRZ-L, NRZ-M, and NRZ-S), RZ (polar or unipolar) family, and pseudoternary (AMI-RZ, AMI-NRZ, dicode RZ, and dicode NRZ) families as well as biphase-L can be written as Equation 7. Thus, the above expression, for PSD—Equation 10—represents their spectral densities. However, biphase-M, biphase-S, and substitution line codes cannot be represented as Equation 7, so other means must be used to calculate their spectral densities (Xiong 2000).

To find the spectral density of a *wide sense stationary* (WSS) signal, we need to find the autocorrelation function $R(\tau)$ first and then, according to the Wiener-Khinchine theorem, the Fourier transform of the function will give the spectral density (Simon, Hinedi, and Lindsey 1995).

BASIC LINE CODES FOR WIRELINE SYSTEMS

This section compares various basic wireline line codes. The comparison is based on their spectral characteristics, bandwidth, error performance, error-detection capability, self-synchronization ability, redundancy, and transparency. The basic line codes considered are:

- the non-return-to-zero family, including *NRZ-level* (NRZ-L), *NRZ-mark* (NRZ-M), and *NRZ-space* (NRZ-S) (including unipolar and polar subclasses);
- the return-to-zero family, including unipolar and polar subclasses;

- the pseudoternary family, including alternate mark inversion, dicode NRZ, and dicode RZ;
- the substitution codes that include binary N zero substitution and high-density bipolar N ;
- the biphase family, which includes biphase-level (or Manchester), biphase-mark, and biphase-space; and
- the multilevel block code family, which includes $kBnT$ and $kBnQ$ codes.

There are other codes that do not belong to any of the classes while some may belong to more than one family.

The reason for a large selection of line codes is because of differences in performance that lead to different applications. The features to look for in choosing a line code are described below (Xiong 2000; Bellamy 2000; Barry, Lee, and Messerschmitt 2003).

Self-synchronization: A digital signal is preferred that includes timing information (self-synchronizing as opposed to sending a pilot signal that wastes bandwidth or synchronizes to a master clock) in the data being transmitted. This can be achieved if there are a suitable number of transitions in the signal that alert the receiver to the beginning, middle, or end of the pulse. Thus, formats with higher transition density are desired.

Spectrum suitable for channel: For lossless transmission, the spectra of the line codes should match the channels over which information is being transmitted. For example, for alternating current (AC) coupled channels, a line code whose spectrum has negligible energy near DC (zero frequency) should be used. Furthermore, line code should have a bandwidth that is small compared to the channel bandwidth so that channel-induced *intersymbol interference* (ISI) is not a problem.

Transmission bandwidth: The bandwidth should be as narrow as possible and may be reduced by using multi-level transmission techniques.

Low error probability: Receivers should be able to recover the information from the corrupted signal with a low probability of bit error.

Error detection capability: Line codes should preferably have a built-in error-detection capability.

Bit sequence independence (transparency): The bit pattern in a line code should not affect the ability to accurately recover the timing information.

Differential coding: If 1's and 0's are encoded such that they are negative of each other and then are transmitted over a medium on which it is impossible to determine an absolute phase reference, then 1's will be decoded as 0's and vice versa. To overcome this polarity inversion problem, either the source is differentially encoded or line codes that are inherently differential are used. In the latter case, a 1 or a 0 causes a transition in the code. Thus, decoding reduces to detecting whether the current state is the same or different from the previous.

Redundancy: By allowing redundancy (i.e., having an information bit rate less than the information-carrying capacity), we can make the transmitted data symbols statistically dependent, regardless of the statistics of the

Figure 2: Polar NRZ waveforms—(a) NRZ-L, (b) NRZ-M, (c) NRZ-S

information, and hence exercise control over the power spectrum of the transmitted signal.

Non-Return-to-Zero Codes

Digital transmission systems send pulses along a link, usually a wire or fiber line within a cable. Two levels of pulse amplitude are used to distinguish between a 1 and a 0 in polar NRZ-L format (see Figure 2a). For an equally likely binary data sequence, the waveform has no DC component. The line code is relatively easy to generate, but when the data contain a long string of 0's or 1's, the received signal may not carry enough timing-recovery information and therefore the receiver may lose synchronization.

In NRZ-M [or *NRZ-invert* (NRZ-I)] format, the level changes whenever a *mark* (or 1) occurs in the sequence and no change takes place for a *space* (or 0) (see Figure 2b). The NRZ-S waveform is similar but encoded in the opposite sense (see Figure 2c). Thus, NRZ-M and NRZ-S are differentially encoded versions of NRZ-L. The main advantage of NRZ-M and NRZ-S over NRZ-L is their immunity to polarity reversals.

The NRZ family can be made unipolar (i.e., only one polarity—positive or negative—is used) by changing the lower level ($-A$ volts) to zero. This line code is referred to as *on-off signaling* and is widely used in optical fiber systems where the sources and detectors operate in the non-linear region (Bellamy 2000). For equally likely 1's and 0's, unipolar waveforms have a nonzero DC level of $A/2$ volts, whereas their polar counterparts do not. The disadvantage of on-off signaling is waste of power because of the transmitted DC level; thus, the power spectrum is nonzero at DC (see Equation 19).

A constant level in the NRZ-encoded waveforms contains no transitions and hence a lack of timing content. This shortcoming can be overcome by (1) scrambling (or randomizing), which is a process that makes data look more random by eliminating long strings of 1's and 0's; or (2) transmitting a separate synchronization sequence.

NRZ-L is used in digital logic. NRZ-M is used in magnetic tape recording. In telecommunication applications,

the NRZ format is limited to short-haul links because of its timing characteristic.

Bit Error Rate of NRZ Codes

NRZ-L is polar with

$$\begin{aligned} s_1(t) &= +A & 0 \leq t \leq T_b \\ s_2(t) &= -A & 0 \leq t \leq T_b \end{aligned} \quad (11)$$

$\rho_{12} = -1$, $E_1 = E_2 = A^2 T_b$, therefore polar NRZ-L is antipodal with the best error performance—that is, $P_b = Q\left(\sqrt{2A^2 T_b / N_0}\right) = Q\left(\sqrt{2E_b / N_0}\right)$, where the average bit energy

$$E_b = (E_1 + E_2)/2 = A^2 T_b$$

For unipolar NRZ-L:

$$\begin{aligned} s_1(t) &= +A & 0 \leq t \leq T_b \\ s_2(t) &= 0 & 0 \leq t \leq T_b \end{aligned} \quad (12)$$

$\rho_{12} = 0$, $E_1 = A^2 T_b$, $E_2 = 0$, or $P_b = Q\left(\sqrt{A^2 T_b / 2N_0}\right) = Q\left(\sqrt{E_b / N_0}\right)$: 3 dB worse than polar NRZ-L where $E_b = A^2 T_b / 2$ (see Figure 3).

NRZ-M and NRZ-S are modulated by a differentially encoded data sequence. The coded sequence is then differentially decoded back to the original data sequence. The current and previous bits of coded sequence are used to produce the current bit of the original sequence. Thus, the error probability, P'_b , is (Xiong 2000)

$$\begin{aligned} P'_b &= (1 - P_b)P_b + P_b(1 - P_b) = 2(1 - P_b)P_b \\ &\approx 2P_b = 2Q\left(\sqrt{2E_b / N_0}\right) \quad \text{for small } P_b \end{aligned} \quad (13)$$

Note that if the current bit is in error, then it and the next bit (because the current bit is used as a reference) will be erroneously decoded. Thus, in differential decoding, one

Figure 3: Probability of bit error

bit error affects two decoded bits (see Figure 3). However, the ambiguity in the reference bit will only affect the first decoded bit and, if desired, can be removed by agreeing on the reference bit in advance or by calculating the phase of the reference bit from a known transmitted sequence.

Power Spectral Density of NRZ Codes. NRZ-M and NRZ-S are generated by modulating the differentially encoded data sequences using the NRZ-L format. If the original binary data are equally likely, then the differentially encoded data are also equally likely—that is, statistical properties of the sequences used for modulation are the same for NRZ-L, NRZ-M, and NRZ-S. From the section on the probability of bit error and power spectral density, we know that if their pulse-shaping function is also the same, then the spectral densities are also the same because the power spectrum depends on the pulse shape used and the statistical properties of the data sequence.

NRZ formats' pulse-shaping function is a square pulse in $[0, T_b]$ seconds—that is,

$$g(t) = \text{rect}\left(\frac{t}{T_b}\right) = \begin{cases} 1 & 0 \leq t \leq T_b \\ 0 & \text{else} \end{cases} \quad (14)$$

$$\begin{aligned} G(f) &= T_b \left[\frac{\sin(\pi f T_b)}{\pi f T_b} \right] \exp(-j\pi f T_b) \\ &= T_b \text{sinc}(\pi f T_b) \exp(-j\pi f T_b) \end{aligned} \quad (15)$$

Because the data sequence is equally likely, the correlation function in Equation 9 becomes

$$R[n] = \begin{cases} (A)^2 \frac{1}{2} + (-A)^2 \frac{1}{2} = A^2 & n = 0 \\ (A)(A) \frac{1}{2} \frac{1}{2} + (-A)(-A) \frac{1}{2} \frac{1}{2} + 2(-A)(A) \frac{1}{2} \frac{1}{2} = 0 & n \neq 0 \end{cases} \quad (16)$$

Thus, the power spectral density is

$$S(f) = A^2 T_b \left[\frac{\sin(\pi f T_b)}{\pi f T_b} \right]^2 \quad (17)$$

From Equation 17, we can see that the spectral density is a squared sinc function with first null at $fT_b = 1$. The signal energy is concentrated around zero frequency, and null bandwidth, B_{null} , is R_b . Note that the power spectral density is a non-bandlimited function. There are various definitions of bandwidth, and the interested reader is referred to Benedetto and Biglieri (1999). In this chapter, the bandwidth referred to is always null to null.

In Figure 4, A is selected such that the normalized average power of the polar NRZ-L signal is one. To calculate A , assume that the transmitted sequence is periodic—that is, $\{1 \ 0 \ 1 \ 0 \ 1 \ 0 \ \dots\}$. It can then be easily shown that $A = 1$ satisfies the unity normalized average power constraint.

A DC component of $A/2$ volts is present in unipolar NRZ and appears as an impulse function, with a strength

Figure 4: Power spectral density

$A^2/4$ watts at DC in the power spectrum. For equally likely data sequence the values of mean and variance are

$$\begin{aligned}\eta_a &= E(a_k) = (A)\frac{1}{2} + (0)\frac{1}{2} = \frac{A}{2} \\ \sigma_a^2 &= E[(a_k - \eta_a)^2] = (A - A/2)^2 \frac{1}{2} + (0 - A/2)^2 \frac{1}{2} = \frac{A^2}{4}\end{aligned}\quad (18)$$

Thus, the power spectral density, from Equation 10, is

$$S(f) = \frac{A^2 T_b}{4} \left[\frac{\sin(\pi f T_b)}{\pi f T_b} \right]^2 + \frac{A^2}{4} \delta(f) \quad (19)$$

because the sinc function is zero at multiples of nR_b and exists only for $n = 0$. For $A = \sqrt{2}$, the normalized average power of the unipolar NRZ signal equals 1. Thus, the power spectra of polar NRZ and unipolar NRZ are the same with the only difference that the unipolar NRZ contains an impulse at DC corresponding to the nonzero mean of the signal.

Multiline Transmission, Three-Level Codes. The scheme of *multiline transmission, three-level* (MLT-3) codes is similar to NRZ-I, but it cycles through the three levels (+1, 0, and -1) to transmit a 1—that is, signal transitions from one level (say positive or zero or negative) to the next (say, zero, negative, or positive) at the beginning of 1 and stays at the same level for 0 (see Figure 5). This line coding technique is used in 100BaseT Ethernet (“Line code” undated).

Return-to-Zero Codes

The shortcoming of the NRZ family—lack of timing information—can be overcome by introducing more transitions in the waveform or trading self-synchronization capability for increased bandwidth. The receiver can use these transitions to update and synchronize its clock. To change with every bit, we need more than just two values. One solution is return-to-zero encoding, which uses three values: positive, negative, and zero. However, its disadvantage is that it uses a wider bandwidth than the NRZ waveform.

In polar RZ format, 1's and 0's are represented by positive and negative half-period pulses, respectively

Figure 5: MLT-3

Figure 6: RZ waveforms—(a) polar, (b) unipolar

(see Figure 6a). This waveform ensures two transitions per bit and consequently has no DC component.

In the unipolar RZ format, a 1 is represented by a positive pulse for a half-bit period, which then returns to zero level for the next half period, resulting in a transition in the middle of the bit. A 0 is represented by the zero level for the entire bit period (see Figure 6b). A delta function (i.e., nonzero DC level) exists at $f = 0, \pm R_b$ in the power spectrum of the transmitted signal, which can be used for bit timing recovery at the receiver. However, the disadvantage of this code is that it requires 3 dB more power than polar RZ signaling for the same probability of symbol error. By making the sequence look more random (via scrambling), the long stream of 0's can be eliminated in the unipolar RZ scheme.

Bit Error Rate of RZ Codes. Polar RZ signals are:

$$s_1(t) = \begin{cases} +A & 0 \leq t \leq T_b/2 \\ 0 & \text{else} \end{cases} \quad (20)$$

$$s_2(t) = -s_1(t)$$

$\rho_{12} = -1$, $E_1 = E_2 = A^2 T_b/2$, therefore polar RZ is **antipodal** and has the best performance with $P_b = Q(\sqrt{2E_b/N_0})$. The average bit energy is

$$E_b = (E_1 + E_2)/2 = A^2 T_b/2$$

For unipolar RZ:

$$s_1(t) = \begin{cases} +A & 0 \leq t \leq T_b/2 \\ 0 & \text{else} \end{cases} \quad (21)$$

$$s_2(t) = 0$$

$\rho_{12} = 0$, $E_1 = A^2 T_b/2$, $E_2 = 0$ or $P_b = Q(\sqrt{A^2 T_b/4N_0}) = Q(\sqrt{E_b/N_0})$: 3 dB worse performance than polar RZ with $E_b = A^2 T_b$ (see Figure 3).

When the bit energy of unipolar RZ is the same as that of unipolar NRZ, the amplitude of the former must be $\sqrt{2}$ times that of the latter. However, if amplitudes are fixed, then unipolar NRZ will have twice the energy of unipolar; thus, its error probability is lower.

Power Spectral Density of RZ Codes. For RZ formats, the pulse-shaping function is a square pulse with half-bit duration—that is,

$$g(t) = \text{rect}\left(\frac{t}{T_b/2}\right) = \begin{cases} 1 & 0 \leq t \leq T_b/2 \\ 0 & \text{else} \end{cases} \quad (22)$$

$$G(f) = \frac{T_b}{2} \left[\frac{\sin(\pi f T_b/2)}{(\pi f T_b/2)} \right] \exp(-j\pi f T_b/2) \quad (23)$$

For an equally likely data sequence, the correlation function of the polar RZ signaling is the same as that for polar NRZ—that is,

$$R[n] = \begin{cases} A^2 & n = 0 \\ 0 & n \neq 0 \end{cases} \quad (24)$$

The power spectral density is

$$S(f) = \frac{A^2 T_b}{4} \left[\frac{\sin(\pi f T_b/2)}{(\pi f T_b/2)} \right]^2 \quad (25)$$

As can be seen from Equation 25, the spectral density is a stretched version with frequency axis scaled up twice—that is, all bandwidths are double that of NRZ (i.e., the null bandwidth, B_{null} , is $2R_b$). The value of $A = \sqrt{2}$ makes the normalized average power of the polar RZ signal equal to 1 and has been used to plot the PSD in Figure 4.

For the unipolar RZ format, the pulse shape is the same as above in Equation 22. The data sequence, its mean, and its variance are same as those for unipolar NRZ (Equation 18). Thus, the power spectral density, after substituting Equation 23 into Equation 10, is

$$S(f) = \frac{A^2 T_b}{16} \left[\frac{\sin(\pi f T_b/2)}{(\pi f T_b/2)} \right]^2 \times \left[1 + R_b \sum_{n=-\infty}^{\infty} \delta(f - nR_b) \right] \quad (26)$$

The value of $A = 2$ satisfies the constraint of unit normalized average power of the unipolar RZ signal. It can be easily seen from Equation 26 that the bandwidths are double those of the corresponding NRZ signal.

Pseudoternary Codes

The baseline or DC wander is caused by a slow decay in amplitude of a long string of 1's or 0's or whenever there is an imbalance in the number of 1's and 0's (Bellamy 2000). The impairment makes the receiver lose its reference to distinguish between the two levels and is a problem that can be solved through coding of transmitted data symbols—that is, a zero at DC is introduced in the spectrum by forcing the data symbols to be correlated. Moreover, the only way redundancy can be introduced without increasing the baud rate is by increasing the number of levels (Barry, Lee, and Messerschmitt 2003). In a pseudoternary line code, we use three-level data symbols to transmit one bit of information, which also helps reduce baseline wander. However, with these codes we also suffer a reduction in noise immunity because for the same peak power level, a smaller noise level causes an error (compared to biphasic codes).

Three levels ($\pm A, 0$ volts) are used. The most popular, *alternate mark inversion* (AMI) codes, belong to this group. They are often called *bipolar codes* (Bellamy 2000).

In AMI-RZ format, a 1 is represented by an RZ pulse and consecutive 1's are represented with alternating polarities. A 0 is represented by the zero-level, hence an average voltage level of zero is maintained (see Figure 7a). In AMI-NRZ, coding rule is the same as AMI-RZ except that the symbol pulse has a full length of T_b —100 percent duty cycle (see Figure 7b). The average level is still zero, but like unipolar RZ, the lack of transitions in a string of 0's causes synchronization problems.

Dicode NRZ and dicode RZ also belong to this group. These formats are also called *twinned binary* and encode the changes in a data sequence—that is, in dicode NRZ, a 1 to 0 transition or a 0 to 1 transition changes signal polarity. If the data remain constant, then a zero-voltage level is output (see Figure 7c). In dicode RZ, the same coding

rule applies except that the pulse is only half-bit wide (see Figure 7d). Dicoes and AMI codes are related through differential coding (Xiong 2000).

These formats are used in baseband data transmission and magnetic recording. AMI-RZ formats are used in telemetry systems and are also being used by AT&T for T1 carrier systems.

Bit Error Rate of Pseudoternary Codes. The AMI-NRZ code consists of three types of signals:

$$\begin{aligned} H_1 : s_1(t) &= A & 0 \leq t \leq T_b & \quad p_1 = 1/4 & \text{Transmit 1} \\ H_2 : s_2(t) &= -A & 0 \leq t \leq T_b & \quad p_2 = 1/4 & \text{Transmit 1} \\ H_3 : s_3(t) &= 0 & 0 \leq t \leq T_b & \quad p_3 = 1/2 & \text{Transmit 0} \end{aligned} \quad (27)$$

The probability of bit error in AWGN is given by the following expression:

$$\begin{aligned} P_b &= p_1 \Pr(\text{error}|s_1) + p_2 \Pr(\text{error}|s_2) + p_3 \Pr(\text{error}|s_3) \\ &= p_1 \int_{-\infty}^{-A/2} f_N(n|s_1)dn + p_2 \int_{A/2}^{\infty} f_N(n|s_2)dn + 2p_3 \int_{A/2}^{\infty} f_N(n|s_3)dn \\ &= 2p_1 \int_{-\infty}^{-A/2} f(n|s_1)dn + 2p_3 \int_{A/2}^{\infty} f(n|s_3)dn \\ &= \frac{1}{2} Q\left[\frac{A}{2\sigma_n}\right] + Q\left[\frac{A}{2\sigma_n}\right] = \frac{3}{2} Q\left[\frac{A}{2\sigma_n}\right] \end{aligned} \quad (28)$$

For the matched filter receiver, the above probability of error becomes (Couch 2001)

$$P_b = \frac{3}{2} Q\left[\sqrt{\frac{2E_b}{N_0}}\right] \quad (29)$$

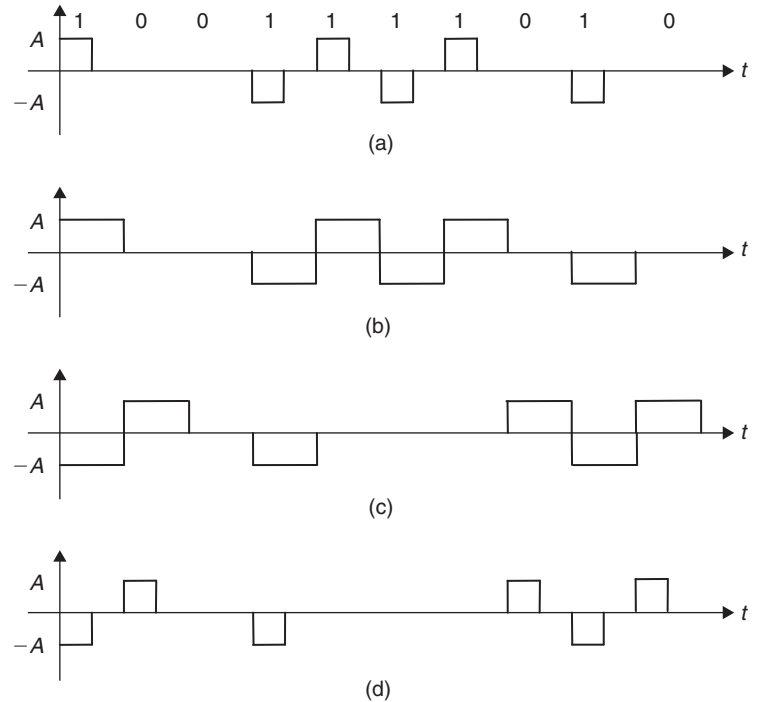

Figure 7: Pseudoternary waveforms—(a) AMI-RZ, (b) AMI-NRZ, (c) dicode NRZ, (d) dicode RZ

For AMI-RZ, the same error performance, as in Equation 29, is obtained (Couch 2001) (see Figure 3). Dicoes and AMI are related via differential encoding. Thus, similar to NRZ-M and NRZ-S, the probability of bit error for the dicode is twice the bit error probability of its AMI counterparts (Xiong 2000).

Power Spectral Density of Pseudoternary Codes. For AMI codes, the data sequence takes on three values:

$$a_k = \begin{cases} +A & \text{binary 1} & p_A = 1/4 \\ -A & \text{binary 1} & p_{-A} = 1/4 \\ 0 & \text{binary 0} & p_0 = 1/2 \end{cases} \quad (30)$$

$$R[0] = E(a_k^2) = \frac{1}{4}(A)^2 + \frac{1}{4}(-A)^2 + \frac{1}{4}(0)^2 = \frac{A^2}{2} \quad (31)$$

Adjacent bits are correlated because of alternate mark inversion. An adjacent bit pattern in the original binary sequence must be one of these: (1,1), (1,0), (0,1), and (0,0). The possible values of product $a_k a_{k+1}$ are: $-A^2$, 0, 0, and 0, and each has a probability of 0.25. Thus,

$$R[1] = E(a_k a_{k+1}) = \frac{1}{4}(A)(-A) + \frac{1}{4}(0) + \frac{1}{4}(0) + \frac{1}{4}(0) = -\frac{A^2}{4} \quad (32)$$

When $n > 1$, $a_k a_{k+n}$ are uncorrelated. Possible values of product $a_k a_{k+n}$ are $\pm A^2$, 0, 0, and 0, and each occurs with a probability of 0.25 (Couch 2001). Thus,

$$R[n > 1] = E(a_k a_{k+n}) = \frac{1}{8}(+A)(+A) + \frac{1}{8}(+A)(-A) = 0$$

$$R[n] = \begin{cases} A^2/2 & n = 0 \\ -A^2/4 & |n| = 1 \\ 0 & |n| > 1 \end{cases} \quad (33)$$

Thus, the power spectral density for AMI-RZ is

$$S(f) = \frac{1}{T_b} |G(f)|^2 \left[\frac{1}{2} - \frac{1}{4} \exp(j\omega T_b) - \frac{1}{4} \exp(-j\omega T_b) \right]$$

$$= \frac{1}{T_b} |G(f)|^2 \left[\frac{1}{2} - \frac{1}{2} \cos(\omega T_b) \right] \quad (34)$$

$$= \frac{A^2 T_b}{4} \left[\frac{\sin(\pi f T_b / 2)}{(\pi f T_b / 2)} \right]^2 \sin^2(\pi f T_b)$$

For $A = 2$, the normalized average power of the AMI-RZ signal is 1. The null bandwidth, B_{null} , is R_b (see Figure 4).

The power spectral density of AMI-NRZ can be obtained by replacing $T_b/2$ with T_b in $G(f)$ of AMI-RZ because both of them have the same coding rules; the only difference is in the pulse width. Thus,

$$S(f) = \frac{A^2 T_b}{2} \left[\frac{\sin(\pi f T_b)}{\pi f T_b} \right]^2 \sin^2(\pi f T_b) \quad (35)$$

a value of $A = \sqrt{2}$ satisfies the normalized average power constraint of unity. The null bandwidth, B_{null} , is R_b . Note that the bandwidths of AMI-RZ and AMI-NRZ are the same.

Dicoes can be constructed using AMI rules and a differentially encoded sequence—that is,

$$s(t) = \sum_{k=-\infty}^{\infty} d_k g(t - kT) \quad (36)$$

where $\{d_k\}$ is the pseudoternary sequence derived from the original data sequence $\{a_k\}$ and is

$$d_k = a_{k-1} - a_k = \begin{cases} +1 & \text{binary 1} & p_1 = 1/4 \\ -1 & \text{binary 1} & p_{-1} = 1/4 \\ 0 & \text{binary 0} & p_0 = 1/2 \end{cases} \quad (37)$$

Thus, the power spectral density of dicoes is the same as those of AMI; therefore, the bandwidth is also the same (Xiong 2000).

Substitution Codes

The AMI code is a preferred choice because of its (1) narrow bandwidth, (2) lack of DC component, (3) error-detection capability (resulting from alternate mark inversion), (4) ease in synchronization (because of transitions in each binary 1 bit), and (5) absence of DC wander (because of inefficient use of the ternary code space). However, a string of 0's will result in a long period of zero level that will cause loss of synchronization. This problem results from the linearity of the AMI code because linearity implies that an all-zero bit sequence is translated into a zero signal. The solution to this problem is therefore to modify the line code and make it nonlinear. One way to alleviate this problem is to substitute the long string of zeros with a special sequence with intentional bipolar violations that can be readily detected and consequently replaced at the receiver. Two popular zero substitution families are considered in this section: (1) *binary N-zero substitution* (BNZS) and (2) *high-density bipolar N* (HDBN). These codes have been used in T1 carrier systems.

Binary N-Zero Substitution Codes. The BNZS code modifies AMI by performing a substitution for a block of N consecutive zeros. The substituted block, which contains one or more positive or negative pulses to ensure timing recovery, takes advantage of the fact that only 2^{N+1} patterns of N transmitted symbols are allowed by AMI and therefore substitutes one of the nonallowed blocks for the all-zeros block. At the receiver, this nonallowed block is readily detected and replaced with the all-zero bit block (Barry, Lee, and Messerschmitt 2003).

All BNZS formats have no DC component and retain the balanced feature of AMI. There are two kinds of BNZS codes: (1) nonmodal and (2) modal.

In nonmodal code, two substitution sequences are allowed, and the choice among them is based solely on the polarity of the pulse immediately preceding the zeros to be replaced. Substitution sequences must contain an equal number of positive and negative pulses to maintain

DC balance. The substitution sequences may also contain zeros. For nonmodal codes, N must be at least 4 (Xiong 2000). Some practical balanced nonmodal codes are B6ZS and B8ZS. For example, in the B6ZS case, if the polarity of the pulse preceding the six zeros is negative ($-$), then the sequence to be substituted is $0 - + 0 + -$ whereas if the polarity of the pulse preceding the six zeros is positive ($+$), then the suggested substitution sequence is $0 + - 0 - +$ (Bellamy 2000). Thus, the polarity of the pulse immediately preceding the six zeros and the polarity of the last pulse in the sequence to be substituted is the same. For B8ZS, the two substitution sequences corresponding to a negative and positive pulse, preceding the eight zeros, are $0 0 0 - + 0 + -$ and $0 0 0 + - 0 - +$, respectively (Bellamy 2000).

In the modal case, more than two substitution sequences are provided, and the choice of the sequences is based on the polarity of pulse immediately preceding the zeros to be replaced as well as the previous substitution sequence used. For modal codes, N is 2 or 3 (Xiong 2000). Modal code substitution sequences need not be balanced, and balance is achieved by properly alternating the sequences. A block of $0 0 0$ is replaced by $B 0 V$ or $0 0 V$, where B represents a normal bipolar alternation that conforms to AMI rule, V represents bipolar violation, and 0 represents no pulse. If the polarity of the pulse preceding the three zeros, is negative (positive) and the number of bipolar pulses since last substitution is odd, then replace $0 0 0$ with $0 0 V$. However, if the preceding pulse is negative (positive) and if the number of 1's since last substitution is even, then replace $0 0 0$ by $B 0 V$ (see Figure 8). In a long-time average, the polarity of these extra pulses will cancel each other so that there will be no DC component.

B3ZS and B6ZS are specified for DS-3 and DS-2, respectively, and B8ZS is specified as an alternative to AMI for DS-1.

No results of bit error probability of BNZS codes are available in the literature. They are conditioned AMI codes, therefore their bit error probabilities must be quite close to those of AMI codes (Xiong 2000).

The power spectrum calculation for BNZS codes is based on a flow graph of the pulse states and is quite involved. Moreover, the spectrum depends on the substitution sequence used and the statistical property of the data sequence. The interested reader is referred to (Xiong 2000) and (Bellamy 2000).

High-Density Bipolar N Codes. High-density bipolar N codes limit the number of consecutive 0's to N by replacing the $(N + 1)$ th zero by a bipolar violation. Moreover, to

avoid a DC component, the code is made modal. Substitution sequences are (Xiong 2000)

$$\text{HDB: } B 0 0 \cdots 0 V \text{ or } 0 0 0 \cdots 0 V \quad (38)$$

In HDB3 line coding, strings of greater than three zeros are excluded. The coding algorithm is similar to the B3ZS algorithm described in the previous section. If the polarity of the pulse preceding the three zeros is negative (positive) and the number of bipolar pulses since last substitution is odd, then replace $0 0 0 0$ by $0 0 0 V$. However, if the preceding pulse is negative (positive) and if the number of 1's since last substitution is even, then replace $0 0 0 0$ with $B 0 0 V$ (see Figure 9).

Two commonly used HDBN codes are HDB2 and HDB3. HDB2 is identical to B3ZS. HDB3 is used for coding of 2.048, 8.448, and 34.368 Mbps streams within the European digital hierarchy.

Biphase Codes

With the help of substitution codes, the pseudoternary family of codes gains self-synchronizing capability. However, this comes at a price: not the bandwidth (NRZ-L has the same bandwidth) but the increased code space (from binary to ternary). The pseudoternary family does not use the code space efficiently. It will be seen in the section on multilevel block line codes that the code efficiency of AMI is only 63 percent; to achieve higher code efficiencies, the input block size will have to be increased. The desirable characteristics (error detection, self-synchronizing, and lack of DC wander capabilities) of pseudoternary codes can be achieved with binary codes but at the expense of bandwidth. The biphase family of codes uses one cycle of square wave to represent 1's and its opposite phase to represent 0's. The most famous code belonging to this family is the biphase level, which is better known as *Manchester* (or *diphase* or *split-phase*). The Manchester encoding signal is shown in Figure 10a. Note that the pulse shapes for 0 and 1 are arbitrary and can be exchanged. For Manchester encoding, the signal contains strong timing components because a transition is present in the center of each bit interval. Moreover, the positive and negative polarities of 0 and 1 are equal, therefore there is no DC wander. The only drawback—besides twice the bandwidth, which makes it vulnerable to near-end cross-talk and ISI (Barry, Lee, and Messerschmitt 2003)—is that it has no error-detection capability.

In the *biphase-mark code*, a transition is always present at the beginning of each bit. For a 1, there is a second transition in the middle of the bit, while there is no second transition for a 0—that is, it is encoded as a level

Figure 8: B3ZS-coded waveform

Figure 9: HDB3-coded waveform

Figure 10: Biphasic waveforms—(a) biphasic-L, (b) biphasic-M, (c) biphasic-S, (d) differential biphasic, (e) CMI, (f) DMI

(see Figure 10b). In the *biphase-space code*, the opposite coding rule applies (see Figure 10c). Because there is at least a transition in each bit interval, the codes contain adequate timing information.

Conditioned biphase level is differentially encoded biphasic-L and is also referred to as *differential Manchester*. Like all differentially encoded signals, the information resides in signal transitions—that is, a change in level—at the beginning of the bit interval, from the preceding one, which indicates that a 0 was transmitted; whereas absence of a transition means a 1 was sent (see Figure 10d). Because data are differentially encoded, this format is also immune from polarity reversals. The biphasic-S is identical to Differential Manchester if the zero reference of the former is changed by half a bit.

The *code mark inversion* (CMI) code is a combination of the AMI-NRZ and Manchester. It is similar to AMI-NRZ because 1's are alternately encoded as A or $-A$ volts. It is related to Manchester because a 0 is represented by a half-cycle square wave of a particular phase, such as level A volts for first half bit and $-A$ volts for second half bit, or vice versa (see Figure 10e). The signal has no energy at

DC, and the transition density over AMI-NRZ is improved significantly. Error detection is possible by monitoring occurrence of alternating 1's. There is no ambiguity between 1's and 0's. The technique is insensitive to polarity reversals because decoding is possible by simply comparing the second half of the bit with the first half.

The *differential mode inversion* (DMI) code is again a combination of AMI-NRZ and Manchester. Its coding rule for 1's is the same as that of CMI. However, its coding rule for 0's is different: $0 \rightarrow -A$, A or $0 \rightarrow A$, $-A$ so that no pulses in a sequence have pulse widths wider than the bit duration (see Figure 10f).

To be used for digital subscriber loops, the power spectrum of the transmitted signal should (1) be zero at zero frequency because no DC transmission passes through a hybrid transformer and (2) be low at high frequencies because transmission attenuation in a twisted pair is most severe at high frequencies and between adjacent twisted pairs increases dramatically at high frequencies because of increased capacitive coupling (Haykin 2004).

The biphasic code is a good choice where implementation simplicity is desirable and the distance between

transmitter and receiver is modest, as in a *local area network* (LAN). The biphase family has been used in magnetic recording, optical communications, and in some satellite telemetry links. The Ethernet or IEEE 802.3 standard for LAN uses Manchester coding. Differential Manchester has been used for IEEE 802.5 standard for token ring, using either baseband coaxial cable or twisted-pair. Because it uses differential coding and is immune to polarity inversions, differential Manchester is preferred for a twisted-pair channel. CMI has been chosen for coding of 139.246 Mbps multiplex within the European digital hierarchy.

Bit Error Rate of Biphase Codes. Biphase-L signals are antipodal with

$$\begin{aligned} s_1(t) &= \begin{cases} +A & 0 \leq t \leq T_b/2 \\ -A & T_b/2 \leq t \leq T_b \end{cases} \\ s_2(t) &= -s_1(t) \end{aligned} \quad (39)$$

$\rho_{12} = -1$, $E_1 = E_2 = A^2 T_b = E_b$, and therefore the probability of error is $P_b = Q\left(\sqrt{2A^2 T_b / N_0}\right) = Q\left(\sqrt{2E_b / N_0}\right)$, which is the same as NRZ-L because both have the same average bit energy and are antipodal (see Figure 3).

Conditioned biphase-L has a bit error probability approximately two times that of biphase-L because it is just differentially encoded biphase-L.

The error performance of CMI is 3 dB worse than Manchester signaling when bit-by-bit detection is used (Bellamy 2000):

$$P_b \approx Q\left(\sqrt{\frac{E_b}{N_0}}\right) \quad (40)$$

This error performance is the same as that of unipolar codes (see Figure 3). For details, see Xiong (2000). Improved performance can be obtained by using maximum likelihood Viterbi decoding (Bellamy 2000).

Power Spectral Density of Biphase Codes. For biphase-L, the pulse shape is half-positive and half-negative—that is,

$$g(t) = \begin{cases} 1 & 0 \leq t \leq T_b/2 \\ -1 & T_b/2 \leq t \leq T_b \\ 0 & \text{else} \end{cases} \quad (41)$$

$$G(f) = T_b \left[\frac{\sin(\pi f T_b / 2)}{(\pi f T_b / 2)} \right] \sin(\pi f T_b / 2) \exp(-j\pi f T_b) \quad (42)$$

The correlation of the data sequence is

$$R[n] = \begin{cases} (A)^2 \frac{1}{2} + (-A)^2 \frac{1}{2} = A^2 & n = 0 \\ (A)(A) \frac{1}{2} \frac{1}{2} + (-A)(-A) \frac{1}{2} \frac{1}{2} + 2(A)(-A) \frac{1}{2} \frac{1}{2} = 0 & n \neq 0 \end{cases} \quad (43)$$

Thus, the power spectral density is

$$S(f) = A^2 T_b \left[\frac{\sin(\pi f T_b / 2)}{\pi f T_b / 2} \right]^2 \sin^2(\pi f T_b / 2) \quad (44)$$

For $A = 1$, the normalized average power constraint of unity is satisfied (see Figure 4). The power spectrum of conditioned biphase-L is the same as that of the biphase-L because it is merely a differentially encoded biphase-L, and differential encoding does not change the probability density function of equally likely data.

Although biphase-M and biphase-S use different waveforms to encode data, they have the same power spectrum if marks and spaces are equally likely in a data sequence. Note that their waveforms are close to that of biphase-L in terms of pulse shapes and number of transitions (biphase-S is differentially encoded biphase-L if the zero reference is shifted by half a bit for the former), therefore their power spectrum is the same as that of biphase-L.

Multilevel Block Line Codes

In a block code, k bits are mapped into n data symbols drawn from an alphabet of size L with the constraint

$$2^k \leq L^n \quad (45)$$

When equality is not met, there is available redundancy that can be used to accomplish desirable goals such as minimizing baseline wander or providing energy for timing.

Two basic techniques used in block coding are (1) translation of a block of input bits to a block of output symbols that uses more than two levels per symbol or (2) insertion of additional binary pulses to create a block of n binary symbols that is longer than the number of information bits m . The first technique applies to cases in which bandwidth is limited but multilevel transmission is possible, such as metallic wires used for digital subscriber loops. The second technique is mainly used in optical transmission where modulation is limited to two levels (on-off, optical sources and detectors operate in a nonlinear mode) but can withstand a small increase in transmission rate because a wide bandwidth is available. All basic line codes can be viewed as special cases of block codes.

Ternary $kBnT$ Codes

This is a class of codes that maps k binary bits into n ternary symbols, where $n < k$. AMI can be considered as 1B1T code.

The efficiency of a block code is the ratio of the actual information rate to theoretical maximum information rate. NRZ encodes one bit into a 1-binary encoded symbol, therefore its efficiency is $\log_2(2)/\log_2(2) = 1$. AMI encodes one bit into a 1-ternary symbol, therefore its efficiency is $\log_2(2)/\log_2(3) = 0.63$. Manchester encodes one bit into two binary symbols, therefore its efficiency is $\log_2(2)/[2 \times \log_2(2)] = 0.5$.

AMI and its derivative pseudoternary codes (dicode RZ and dicode NRZ) transmit only one bit per symbol whereas the capacity of a ternary symbol is $\log_2(3) = 1.58$ bits.

Table 1: Efficiency of $kBnT$ Codes

k	1	3	4	6	7
n	1	2	3	4	5
$\eta = \frac{k \log_2(2)}{n \log_2(3)}$	0.63	0.95	0.84	0.95	0.89
	1B1T	3B2T	4B3T	6B4T	7B5T

Moreover, little control over the power spectrum is provided. A much broader class of pseudoternary codes—the $kBnT$ codes, where k is the number of information bits and n is the number of ternary symbols per block—addresses these shortcomings. If we choose the largest k possible for each n , we get a table of possible codes (up to $k = 7$) (see Table 1).

As the block size increases, we generally achieve greater efficiency. Greater efficiency implies better noise immunity on many channels, because it translates into a lower symbol (baud) rate for a given bit rate and hence a reduced noise bandwidth. However, greater efficiency also implies reduced redundancy, and hence less control over the statistics of transmitted signal (power spectrum, timing recovery, density of 1's, etc.). The 4B3T code seems to be a reasonable compromise between these competing goals and hence has been used widely in digital subscriber loop applications.

The 4B3T Code. This code maps a combination of four bits to twenty-seven possible combinations of three ternary digits. The ternary sequence 000 is not used, but all other combinations are used. The code uses three codebooks; a codebook defines a mapping between bit patterns of input and output for an encoder. The three codebooks contain words that are biased toward positive polarity, negatively biased, or neutral. The algebraic sum of recently transmitted symbols, also known as the *digital sum* or *disparity*, determines which codebook is to be used. If disparity is positive, then code words from the negatively biased codebook are selected and vice versa. If disparity is neutral, then code words from the neutral codebook are selected. This ensures that the transmitted code has zero DC content.

For the 4B3T line code, the power spectral density depends on the selection of a particular codebook. Multiple choices of codebooks exist because sixteen information bits can be mapped to twenty-seven different ternary codes in a variety of ways.

The 4B3T coding is used on T148 span lines developed by ITT Telecommunications (Bellamy 2000).

The 8B6T Code. The 8B6T code substitutes an eight-bit group with a six-symbol ternary code. Eight bits can represent 256 possibilities; a six-symbol ternary signal can represent 729 possibilities—that is, some codes are not used. Thus, a code can be designed that can maintain synchronization and also has error checking capability. This code is used in 100 Mbps Ethernet (Moloney 2005).

**Figure 11:** The 2B1Q waveform

Quaternary Code: 2B1Q. In this code, binary data are mapped into one of four levels. The disadvantage with multilevel signaling is that it requires greater SNR for a given error rate. Thus, the 2B1Q code represents a four-level pulse amplitude modulated signal (see Figure 11). Assuming 1 and 0 are equiprobable, the 2B1Q code has zero DC on the average. The signaling baud rate is half of the bit rate. It offers the greatest baud reduction and the best performance with respect to near-end cross talk and ISI. It is because of this desirable property that the 2B1Q code has been adopted as the North American standard for digital subscriber loops (“Line code” undated).

The power spectrum of the 2B1Q code is given by Chen (1998):

$$S(f) = \frac{5}{9} T_{2B1Q, \text{baud rate}} \left[\frac{\sin(\pi f T_b)}{\pi f T_b} \right]^2 \quad (46)$$

CODES FOR OPTICAL FIBER SYSTEMS

Line codes used in optical fiber systems should also satisfy the requirements that are desired for basic line codes (see the previous “Basic Line Codes for Wireline Systems”). Because the optical sources and detectors operate in non-linear mode, the best suited line code is the one that has two levels: unipolar scrambled (or randomized) NRZ-L or on-off keying. Because there is plenty of bandwidth available (no advantage is gained by using multilevel signaling) in optical fiber systems, the inherent disadvantage of a lack of timing information in the line code can be overcome by including extra timing transitions for a small bandwidth penalty. Moreover, there is no polarity ambiguity in direct detection optical receivers, therefore resorting to differential encoding is unnecessary. The DC level of the line code affects the gain of some photodiodes. However, it is easy to control variations in the DC level in an optical system than in a wireline system, so for optical fiber the line codes should be DC-constrained instead of DC-balanced.

In intensity modulated practical optical fiber communication systems, a symbol is represented by the optical source's light intensity, therefore AMI cannot be used in such systems because it uses three levels (−1 for off, 0 for half intensity, and +1 for full intensity) and thus suffers from nonlinearity of the source. However, in phase modulated optical fiber communication systems, optical AMI has been implemented by coding the phase of light with π phase difference to achieve the coding

of $+1$ and -1 . When high data speed is not a requirement, then Manchester or CMI codes are used in optical fibers. When CMI is used for optical transmission, two levels of $\pm A$ are replaced by A and 0 —that is, the code waveform is unipolar. This unipolar CMI has the same spectral shape as polar CMI with the only difference that the spectrum has a DC component. Unipolar DMI is also used in optical transmission systems (Xiong 2000).

Just as with wireline systems, block coding can also be used in optical fiber transmission systems. The m information bits are mapped to a block of n binary symbols where $n > m$. The additional pulses can be selected such that timing content is increased in the block line code. The modulation of choice is binary because the optical sources and devices operate in the nonlinear mode.

The $mBnB$ Block Codes

Transitions in a data stream can be ensured by scrambling (or randomizing) the long string of zeros. The same goal can be achieved by introducing *redundancy*. Redundancy not only gives flexibility over controlling timing and DC wander but also aids in detecting errors. Block coding to some extent achieves these two goals.

A special case of block codes occurs when $L = 2$, which means we transmit a binary signal. For this case, we have the simpler constraint $k \leq n$ —in other words, we must transmit a block of n bits that is larger than the number of bits k at the input to the line coder. These codes are useful for media such as optical fiber that prefer to operate in one of the two states (on or off) and for which the additional bandwidth required is easier to achieve.

One primary motivation in the design of line codes has been the elimination of the DC content of the coded signal because of AC coupling of the medium. It might appear that this problem goes away for media such as optical fiber and magnetic recording because there are no transformers required. However, this is not really the case because it is especially difficult to build DC-coupled high-speed electronics for preamplification and so forth (Barry, Lee, and Messerschmitt 2003).

When $n > m + 1$, because of decoding logic or a small look-up table, it is difficult to implement these codes in high-speed transmission systems. For $n = m + 1$, the $mB(m + 1)B$ codes are known as *bit-insertion codes* and are popular in high-speed fiber optical transmission because of its simple codec design. However, to increase code efficiency, a large m (greater than 1) must be chosen.

The 2B3B DC-Constrained Code. This code constrains rather than suppresses the DC component and thus makes it possible to use redundancy for error detection. Data bits 1 and 0 are converted to $+$ and $-$, respectively. Then a third symbol $+$ or $-$ is added to make combinations of one $+$ and two $-$'s. The code produces a constant DC component of $-1/3$ (Xiong 2000).

The 4B5B Code. With a four-bit input block, we can have sixteen different groups. With a five-bit code, we can have thirty-two possible codes. This means we can map some of the five-bit groups to four-bit groups. Some of the five-bit codes are not used. We can employ a strategy to

choose only the five-bit codes that help us in synchronization and error detection. To achieve synchronization, we can use the five-bit codes in such a way that we do not have more than three consecutive 0's or 1's—that is, select five-bit codes that contain no more than one leading 0 and no more than two trailing 0's. Because only a subset of five-bit codes are used, if one or more of the bits in the block is changed in such a way that one of the unused codes is received, the receiver can easily detect the error. After substitution, we can use one of the basic wireline line coding techniques discussed above to create a signal. This code is used for Ethernet 100 Mbps and *fiber distributed data interface* over optical fiber (Moloney 2005). The 4B5B code increases the line rate by 25 percent. CMI and biphasic (1B2B codes) increase the line rate by 100 percent.

The 7B8B code is being used in a 565-Mbps terrestrial system being developed by British Telecom and in a 280-Mbps NL1 submarine system being developed by STC of Great Britain.

The Carter Code (8B9B). This code was proposed for PCM systems. The eight-digit character is transmitted either unchanged or with the digits inverted (i.e., marks for spaces and spaces for marks), depending on which condition will reduce total disparity (the numerical sum of symbols in the sequence) since the start of transmission. Thus, the DC component will be zero over a long period. The efficiency of the Carter code is 0.9464.

The $mB1P$ Code. This code inserts an odd parity bit after every m bits. Odd parity ensures that there is a 1 in every $m + 1$ bits. A Manchester signal is a 1B1P signal. The 24B1P line code is being used in the trans-Pacific submarine cable (TPC-3) system.

The $mB1C$ Code. In the coding process, a complementary bit (i.e., complement to the last bit of the block) is inserted at the end of every block of m information bits. The maximum number of consecutive identical symbols is $m + 1$, which occurs when the inserted bit and m succeeding bits are the same. The Manchester code is a degenerate case of the 1B1C code (Bellamy 2000). The code has been adopted by Nippon Telegraph and Telephone (NTT) in its F-1.6G optical system in the form of 10B1C.

CONCLUSION

Based on the coding rules, the simplest of all line codes is the NRZ family. The NRZ signal occupies a narrow bandwidth, but it lacks other desired characteristics such as adequate timing content, error-detection capability, and lower signal energy near low frequencies. Timing content is increased in the RZ-coded signal by allowing more transitions at the expense of the signal bandwidth. The RZ-coded signals, however, still have substantial energy near DC, which also make them unsuitable for AC-coupled circuits. The three-level pseudoternary codes provide the same timing information as RZ-coded signals but in a narrower bandwidth. Their spectra have no DC components, and near-DC components are small, also making the codes suitable for transmission on AC-coupled circuits. Their performance, however, is worse than polar NRZ

Table 2: Line Codes and Digital Systems

Code	Digital system
Non-return to zero	Digital logic and short-haul telecommunication links
Differential NRZ	Magnetic tape recording
Multiline transmission-3	100baseT Ethernet
Alternate mark inversion	Telemetry systems, especially AT&T T1 carrier systems
Binary N zero substitution	DS1 ($N = 8$), DS2 ($N = 6$), and DS3 ($N = 3$)
High-density bipolar 3	European digital hierarchy: E2, E3, and E4
Biphase (1B1C or 1B2B)	Local area network
Differential biphase	IEEE 802.5 token ring
Code mark inversion (1B2B)	139.246-Mbps European digital hierarchy
4B3T	T148 span line
8B6T	100-Mbps Ethernet
2B1Q	Digital subscriber loops
Optical Fiber Systems	
4B5B	100-Mbps Ethernet and FDDI over optical fiber
7B8B	565-Mbps system of British Telecom
8B9B	Pulse coded modulation
24B1P	Trans-Pacific submarine cable (TPC-3)
10B1C	F-1.6 G optical by NTT

signals. Substitution codes can be used in conjunction with pseudoternary codes to alleviate the latter's timing recovery problem if a long string of zeros occurs. The biphase codes occupy the same bandwidth as the RZ-coded signals, but their spectra contain no DC or very small near-DC components. Their error performance is no better than the NRZ-coded signals. The diphase code contains ample timing recovery information because it contains at least one transition per symbol; this property makes it widely used. However, the AMI family of codes is more suitable for band-limited channels and is therefore preferred over diphase. The block line codes add redundancy, which aids in error detection and benefits timing recovery. However, the disadvantage is that the transmission rate is increased and should only be used on channels where bandwidth availability is not an issue. Block codes are not limited to only binary: Multilevel block codes increase the efficiency of the line codes, reduce bandwidth requirements, and can be designed to have a zero or constant DC component. Finally, the binary block codes that are easier to encode and decode—for example, bit-insertion block codes—are more suitable for optical transmission systems because the devices operate in the nonlinear mode.

Table 2 lists digital systems where the aforementioned line codes are being used.

GLOSSARY

Alternate mark inversion (AMI): A bipolar line coding technique that uses three levels—positive, negative,

and zero—and is the most widely used technique because it has good spectral characteristics, better error-detection capability, and superior timing recovery ability compared to other line codes.

Binary N zero substitution (BNZS): A line coding technique that replaces a string of N zeros by another sequence that is readily detected and replaced at the receiver by an all-zeros sequence.

Biphase codes: A line coding technique that uses half-period pulses with different phases. Manchester or diphase or split phase codes belong to this family.

Bipolar: A line coding technique that uses three levels: positive, negative, and zero.

Codebook: A codebook defines mapping between input and output bit patterns of an encoder.

Code mark inversion (CMI): A line coding technique that replaces the zero level in the AMI waveform by two levels: $+A$ for first half bit duration and $-A$ for the second half bit duration or vice versa.

High-density bipolar N (HDB N): A line coding technique that limits the number of consecutive zeros to N by replacing the $(N + 1)$ th zero by a bipolar violation.

k BnT codes: A family of line code that maps k binary digits into n ternary symbols, where $n < k$. AMI is a 1B1T code.

Line coding: The process of converting the binary digits to waveforms that are suitable for transmission over the baseband channel.

m BnB codes: This family of line codes converts a block of m binary digits into a block of n binary digits, where $m < n$. CMI and DMI are 1B2B codes.

Non-return to zero (NRZ): A line coding technique in which the signal does not return to zero during the duration of the bit.

Pseudoternary (PT): A line coding technique that uses three-level data symbols to transmit one bit of information. AMI codes also belong to this group and these are also called *bipolar codes*.

Return to zero (RZ): A line coding technique in which the signal returns to zero during the duration of the bit.

Unipolar: A line coding technique that uses only one signal level for bit representation in addition to zero.

INTRODUCTION

Information about spread spectrum was particularly hard to come by until the late 1970s because of its military origins and classified status. Starting in the 1980s, however, there was a huge growth in spread-spectrum research, followed in the 1990s by an explosive growth in civilian applications. Rather than attempting a likely futile summary of the technical literature on spread spectrum within the confines of this chapter, we will introduce a more intuitive glimpse of spread spectrum, concentrating on its general properties, touching on its well-known applications, and presenting simple results about its robustness.

OVERVIEW OF SPREAD SPECTRUM

A discussion of spread spectrum would be exceptionally dull, if not entirely impossible, without reference to its intriguing origins and captivating applications. Although volumes can be written on either of these subject matters, we introduce a brief summary here.

Historical Origins

Much of the early history of spread spectrum can be tied to military applications, mainly starting with World War II. Although *spark gap* transmitters of the early wireless era and wideband FM transmitters of the 1920s and 1930s transmitted spread spectrum-like signals, the first traceable patent on true spread spectrum, "Secret Communications Technique," was granted in 1942 to the most unlikely of co-inventors: an actress and a composer (Markey and Antheil 1942).

Hedy Lamarr (Markey), a Hollywood movie actress, and George Antheil, an avant-garde composer, turned

over their invention to the U.S. government for use in the war effort, and the details of their patent were kept as a military secret for several decades (Scholtz 1982). By the time military secrecy was lifted and commercial use of spread spectrum began, the patent had long expired, having awarded no monetary gain to the inventors.

Intentional use of spread spectrum can be considered to have started with World War II (Simon et al. 1984, 39–42). The early research and development were mainly for applications in communications, navigation beacons, and radar jamming countermeasures. Although it is known that both the Allies and the Axis powers developed and implemented spread-spectrum systems, much of that work remains classified. In fact, most of the research and development in spread spectrum from the 1950s until the early 1970s were supported by the military and kept classified. An example, however, of a well-known application of spread spectrum in the military is its use in satellites by the U.S. military through modems such as the USC-28 (Satellite Communications 2004).

The dawn of spread spectrum use in civilian applications came about in 1980, after the declassification of the technology by the military, when the Federal Communications Commission specified the regulations for civilian spread-spectrum transmissions through Title 47, Section 15.247 of *Code of Federal Regulations* (Federal Communications Commission 2004).

Modern Applications

Although civilian applications of spread spectrum started to appear in the 1980s, they have exponentially increased throughout the 1990s and early 2000s. Ironically, the world's largest single spread-spectrum system today has its

roots in the military and is used for navigation rather than communication. The *global positioning system* (GPS) was initially developed, funded, and operated by the U.S. Department of Defense primarily for the military (Parkinson and Spilker 1996), but it is now available for unrestricted civilian use around the world with full existing accuracy (Clinton 2000). The system incorporates a space segment consisting of satellites transmitting the GPS signal, a control segment monitoring and uploading the orbital and time reference data, and a user segment consisting of inexpensive GPS receivers for position fixing.

Another widespread application of spread-spectrum technology is in wireless multiple-access networking. The IEEE 802.11b standard (IEEE 802.11 Working Group 1999) for *wireless local area networks* (WLANs), for example, allows wireless networking at data rates up to 11 Mb/s using *direct sequence spread spectrum* (DSSS) over the 2.4-GHz band. Although there exist several different flavors of the 802.11 standard—collectively known by the popular name *Wi-Fi* (Wi-Fi Alliance 2005) but with some forms using techniques other than spread spectrum—802.11b has revolutionized wireless computing. Another example of wireless networking using spread spectrum is the Bluetooth technology (Bakker, McMichael Gilster, and Gilster 2002), which employs *adaptive frequency-hopping* spread spectrum for *personal area networks* (PANs). The use of Bluetooth has particularly exploded over the last few years.

Another modern application of spread spectrum that has enjoyed widespread acceptance is in digital cellular telephony. Simply known as CDMA (for *code division multiple access*), this application is based on DSSS and follows the IS-95 standard (Garg and Rappaport 2000) that was originally spearheaded by Qualcomm. CDMA technology is currently employed by several wireless service providers in the United States, including Sprint and Verizon. Also based on CDMA technology, *wideband CDMA* (W-CDMA) (Holma and Toskala 2002) and *CDMA2000* (Garg and Rappaport 2000) are candidate standards for third-generation (or 3G) wireless services.

Although there are many other applications of spread spectrum, one that has been explicitly obvious to the average consumer over the years—cordless telephones—has seen terms such as *direct sequence* and *spread spectrum* liberally used (Good, Cheng, and Hae-Seok 2000). Today, spread-spectrum technology is used to suppress interference and allow uncoordinated multiple access in several models of cordless phones.

BASIC CONCEPTS

Several basic concepts will help us understand the beneficial attributes of spread-spectrum modulation. Although these attributes can be well established through a rigorous theoretical development, here we seek a more intuitive treatment of the basic concepts leading to these attributes.

Robust Communications

A communication system is said to be *robust* if it is designed to work reasonably well, staying *strong* and *healthy*,

in the presence of varying and usually severe interference. One can argue that the main feature of spread spectrum in communication is its robustness. This robustness allows spread-spectrum communication systems to reliably operate under various types of interference, ranging from hostile jamming in the case of military applications to multiuser interference for mainstream civilian applications.

The robustness of spread-spectrum modulation can be explained in terms of several properties of the spread-spectrum signal such as bandwidth expansion, randomness, and redundancy. A spread-spectrum signal possesses a considerable amount of redundancy by its nature. Although this redundancy is attained through different means, depending on the type of spread spectrum being used, it can intuitively be tied to the fact that spread spectrum occupies a bandwidth that is much greater than would otherwise be required by the underlying modulation scheme. This redundancy, of course, can easily be interpreted as leading to robustness.

Another property of spread-spectrum modulation that leads to its robustness is the randomness property. As will be explained later, spread-spectrum modulation can be viewed as a random modulation scheme transmitting a signal that appears to be random to third observers. Of course, this signal is not random to the intended receiver, and any apparent randomness is *removed* by the receiver, which at the same time makes any interference—hostile or not—behave like random noise. This allows a spread-spectrum communication system to operate in a robust manner in the presence of arbitrary interference.

Spectrum Spreading

The main characteristic of spread spectrum is that it occupies a bandwidth that is much larger than what would ordinarily be needed for modulating the data to be transmitted. Such bandwidth expansion is not a unique characteristic of spread spectrum in itself, but it is exclusive in the sense that it is used in spread spectrum for combating interference other than *additive white Gaussian noise* (AWGN) (Pursley 2005, 560).

What makes bandwidth expansion work for spread spectrum in combating interference is the process of *despreading*, or contracting the bandwidth to its original size at the receiver. The same process that performs the despreading for the spread-spectrum signal works to spread the bandwidth of any interfering signal that would be added during transmission. As a result, the despread signal is in effect hit by an interfering signal with a *power spectral density* (PSD) that is much smaller than the PSD of the interference in the channel.

The PSD illustrations of Figure 1 show the effect of spectrum spreading. Figure 1a illustrates the PSD of a modulated arbitrary data signal before spectrum spreading. In Figure 1b, the PSD of this signal is shown as it is transmitted through the channel after the spreading process; the PSDs of narrowband and wideband interference are also shown. Here the signal bandwidth is expanded approximately four times, accompanied by a fourfold decrease in its PSD, while the PSDs of narrowband and wideband interference are as they would be in the channel.

Figure 1: Power spectral density (a and b) before and after the spreading process and (c) after the despreading process

Finally, Figure 1c shows the PSDs of the spread-spectrum signal, the narrowband interference, and the wideband interference after the despreading process. Although the despreading process at the receiver re-creates the original PSD of the modulated signal, it also spreads the PSDs of the interference terms picked up during transmission. The net result is smaller PSDs for the interference terms and thus less harm inflicted on the signal.

The underlying assumption for all of this to work is that the interference should have a bounded average power, or *bounded energy*. This is true, of course, for the types of interference that spread spectrum is good at combating. In the case of AWGN, for which this condition is not satisfied, spectrum spreading has no effect on performance (Pursley 2005, 560).

Processing Gain

In cases where spread-spectrum modulation is effective in combating interference, we might be interested in determining how much gain in performance can be attained by using spread spectrum instead of some classical narrowband modulation technique. *Processing gain* is the parameter that expresses this performance advantage. In fact, processing gain expresses this advantage not only for interference rejection but also for *any* application of spread spectrum.

There are various ways to define and evaluate processing gain depending on the particular application of spread spectrum. For arbitrary interference rejection, for instance, we may define it as the improvement in signal-to-interference ratio in going from a narrowband modulation scheme to spread-spectrum modulation. In most cases, however, processing gain turns out to be equal to

the bandwidth expansion factor (Sklar 2001, 735–8). For this reason, *processing gain* and *bandwidth expansion factor* are interchangeably used in many sources, even though this usage is technically incorrect.

Jamming Game Viewpoint

Most treatments of spread-spectrum modulation, especially when dealing with performance analysis, make reference to a *jammer* or a *jamming* signal (for example, Nazari and Ziemer 1988; Su and Milstein 1990; Teh, Kot, and Li 1999). Although this reference partially results from historical reasons and the military origins of spread spectrum, a jamming type of interference presents a perfect setting for illustrating the robustness and interference-rejection capability of this modulation scheme. A hostile jammer that is intentionally trying to impede communication can be considered to be the worst type of interference among those with the same average power, and a spread-spectrum system that does well under such interference is a robust communication system that is expected to do at least better under other types of interference. As such, performance analyses of spread-spectrum systems in the presence of jamming signals are equally valuable for non-military applications.

Communication in the presence of a jammer can be considered in terms of game theory (Osborne 2004), where one player (the communicator) is trying to incur the least damage while the opponent (the jammer) is trying to inflict the most damage on the first player. An analysis of this game would lead to a minimax solution in which the best communication and jamming strategies under a given set of constraints can be determined (Hughes and Hizlan 1990). Nevertheless, in the absence of such an approach,

spread-spectrum modulation has been shown over several decades to be a good strategy for the communicator regardless of the strategy followed by the jammer.

Random Modulation

Spread-spectrum modulation can be viewed as a random modulation scheme in which the data to be transmitted are modulated in a way that appears to be random to a third observer other than the transmitter and the receiver. The pseudorandom sequences and their various derivatives used in the creation of spread-spectrum modulation introduce this apparent randomness into the transmitted signal.

From an intuitive standpoint, the randomness of the transmitted signal allows spread spectrum to combat interference, whether it is hostile jamming or more benign forms of disturbance, by randomly and thus unpredictably occupying a small portion of the available signal space at any given time. This way, a hostile jammer does not know what portion of the signal space to jam *effectively*, and other types of interference do not cause any significant harm *most* of the time.

From a more rigorous standpoint, a form of random modulation in which the transmitted signal vector is uniformly distributed on the surface of an N -dimensional sphere has been shown to be asymptotically optimal for combating unknown and arbitrary interference (Hughes and Hizlan 1990), and spread spectrum is known to be a particularly effective special case of the general class of random modulation schemes. As such, spread-spectrum modulation is especially suited for combating unknown and arbitrary interference.

ADVANTAGES OF SPREAD SPECTRUM

Spread-spectrum modulation has several advantages or beneficial attributes that make it useful for various applications. Some of these make spread spectrum useful for military applications, while others make it effective for multiuser civilian applications.

Low PSD, Low Probability of Detection, and Low Probability of Intercept

One main attribute of a spread-spectrum signal is its low PSD. This is the result of spreading the bandwidth of a finite power signal over a much larger bandwidth, as illustrated in Figure 1a and 1b. In practice, the bandwidth expansion, and the resulting PSD reduction, can be by a factor of tens to hundreds for commercial applications to more than a thousand for military applications (Roberts 1995).

For civilian applications, the low PSD of the spread-spectrum signal allows it to coexist with narrowband signals of much higher PSD over the same band without causing undue interference on them. The spread-spectrum signal simply appears as low levels of background noise as far as the narrowband users are concerned. Of course, the spread-spectrum signal itself effectively combats interference from the narrowband signals.

Low power spectral density has other advantages for military applications. For one, the spread-spectrum signal with an extremely low PSD can be effectively buried under background noise, making it practically undetectable to anyone other than the intended receiver, resulting in what is known as *low probability of detection* (LPD) or *low probability of intercept* (LPI). Any adversary would try to detect the presence of a communicator's signal using a device called a *radiometer* (Dillard 1979). Spread-spectrum signals have been shown to exhibit good LPD and LPI properties (Sklar 2001, 722).

Even when detected, spread spectrum affords a level of security to the message that it carries. This is because of the pseudorandom nature of the spreading of the signal. By no means can this type of security be compared to cryptography, but it would be relatively secure from casual eavesdroppers. An adversary with sufficient computing power and sufficient time to observe the transmitted spread-spectrum signal can, however, determine the pseudorandom spreading sequence used and therefore decipher the message (Ziemer and Peterson 2001, 604–5).

Arbitrary Interference Rejection

Interference rejection is an attribute of spread spectrum that is advantageous for both military and civilian applications. For military applications, the interference takes the form of a hostile jammer that intentionally tries to hinder communication, arguably the most damaging kind of interference. For civilian applications, the interference might be from various sources such as narrowband users of the same frequency band, signals from other spread-spectrum users in a multiple-access setting, or reflections of the user's own transmission in a multipath situation, among others. Regardless of the kind of application, or the type of interference, spreading of the bandwidth before transmission and despreading after reception are what help with arbitrary interference rejection.

As illustrated in Figure 1b and 1c, the interfering signal itself gets spread during the process of despreading at the receiver, thus resulting in a much smaller PSD for the interference than before. Although only two examples of interference are illustrated in Figure 1, it should be obvious that any type of interference, whether from a hostile jammer or a more benign source, will undergo the same type of reduction in PSD.

Another way to explain interference rejection is to consider the spread-spectrum signal as randomly occupying only a small fraction of a huge number of available signal dimensions at any given time. Any interference with bounded average power has to occupy the whole available signal space with a small amount of power or only a small number of available signal dimensions (which most of the time will not coincide with the signal itself) with a large amount of power. In either case, the interference is rendered ineffective.

High Resolution Time-of-Arrival Measurements

Range measurement or position determination can be accomplished by measuring the time a given pulse takes

to propagate through a channel, assuming that the pulse propagates at the speed of light. Such a measurement suffers primarily from the uncertainty in determining the exact time of arrival of the pulse being detected. Because the rise time (or the fall time) of a pulse is inversely proportional to its bandwidth, high-bandwidth pulses afford much better resolution in time-of-arrival determination (Sklar 2001, 723–4).

A spread-spectrum signal is especially suited for time-of-arrival and therefore range measurements because of its markedly large bandwidth. In fact, some types of spread spectrum transmit long sequences of pulses of especially short duration, further aiding the time of arrival measurement through, in effect, an averaging of numerous highly precise measurements. The result is exceptionally precise range determination. The global positioning system is based on this very concept, accurately determining the user's location through precise measurements of the range between the user and satellites with known locations.

Code Division Multiple Access

Code division multiple access happens to be the most widespread civilian use of spread-spectrum technology, with the most common example being the CDMA wireless phone infrastructure. The idea is based on the fact that spread spectrum rejects interference, including those from other spread-spectrum users within the same frequency band. Unlike frequency division multiple access or time division multiple access, in CDMA all users occupy the same frequency band at the same time, separated by the spreading codes assigned to each user. This allows for better utilization of the available spectrum among multiple users and graceful degradation of the performance as more users are added.

In essence, each user in a CDMA setting transmits with quite low PSD, thereby inflicting little damage on any other user. Of course, as more users are added, the cumulative interference incurred by any one user gets larger, limiting the total number of users in the channel. In CDMA applications, the spreading codes assigned to each user are specifically designed to have as small a cross-correlation as possible so that the interference from one user on another is almost negligible. This, of course, requires a measure of collaboration among the users, which the nature of multi-access applications readily provides.

TYPES OF SPREAD SPECTRUM

Spread-spectrum modulation can be implemented in many different ways. Although two of these methods, *direct sequence spread spectrum* and *frequency-hopping spread spectrum*, overwhelmingly dominate, other methods such as *time-hopping spread spectrum* and various hybrids of these techniques have been defined and implemented.

Direct Sequence Spread Spectrum

Direct sequence spread spectrum arguably represents the most common implementation of spread-spectrum modulation. It involves the multiplication of a phase-modulated data signal by a pseudorandom *chipping*

sequence of ± 1 's running at a rate that is much higher than the data rate. This process can be equivalently perceived as multiplying the ± 1 data sequence by the higher-rate chipping sequence and then phase modulating the product sequence. The bandwidth of the resulting spread-spectrum signal is determined by the rate of the chipping sequence rather than the rate of the data sequence. The term *direct sequence* refers to the generation of spread spectrum through a direct multiplication of the data sequence with the chipping sequence.

To visualize this process, consider Figure 2. Figure 2a represents a bipolar data sequence of four bits taking on the values $+1$, -1 , $+1$, and $+1$, while Figure 2b represents a bipolar pseudorandom chipping sequence running at a rate that is eight times faster than the data rate. The product of the two sequences, which would phase modulate a carrier to generate the direct sequence spread-spectrum signal, is shown in Figure 2c. Clearly, in this example, the bandwidth of the spread-spectrum signal would be eight times larger than the signal bandwidth with only the data sequence performing the phase modulation.

The underlying modulation in direct sequence spread spectrum is either *binary phase shift keying* (BPSK) or *quaternary phase shift keying* (QPSK). Although QPSK has twice the bandwidth efficiency of BPSK for the same error performance, this is not the reason for choosing QPSK, even though it is slightly more complicated, for some direct sequence implementations. Rather, QPSK resists some types of jamming better and is more difficult to detect than BPSK (Ziemer and Peterson 2001, 577–83). The demodulation of DSSS is accomplished by multiplication of the received signal by a synchronously generated chipping sequence to remove spreading, followed by demodulation of the underlying signal.

Frequency-Hopping Spread Spectrum

Frequency-hopping spread spectrum is a commonly used type of spread-spectrum scheme that is based on frequency modulation. In this implementation, the carrier frequency is chosen from a large set of carrier frequencies that together constitute the spread-spectrum bandwidth. A pseudorandom sequence is used to select the carrier frequency to use at any given time. The name *frequency hopping* refers to the modulated carrier that appears to be hopping from one frequency to another.

There are two main types of frequency-hopping spread spectrum: *slow* frequency hopping and *fast* frequency hopping. In slow frequency hopping, one or more data symbols are transmitted per hop, whereas in fast-frequency hopping, one or more hops are made per data symbol. The underlying modulation in frequency-hopping spread spectrum can be *binary frequency shift keying* (BFSK) or *M-ary frequency shift keying* (MFSK). In either case, the demodulation is performed noncoherently because of the difficulty of phase synchronization among rapidly changing carrier frequencies.

To visualize the frequency-hopping spread spectrum, consider Figures 3 and 4. A slow frequency-hopping spread-spectrum system using 4-ary FSK with two data symbols per hop is illustrated in Figure 3. Every two symbols, a new set of four carrier frequencies (*a hop block*)

Figure 2: Illustration of direct sequence spread spectrum—(a) data sequence, (b) chipping sequence, and (c) product sequence

Figure 3: Illustration of slow frequency-hopping spread spectrum

Figure 4: Illustration of fast frequency-hopping spread spectrum

is pseudorandomly selected among the six possible sets. Within each hop, the carrier frequency is assigned in increasing order of the decimal representation of the two-bit symbol. In this example, the spread-spectrum bandwidth, denoted by $SS\ BW$, is six times the underlying 4-ary FSK bandwidth, denoted by $4FSK\ BW$. Using similar values and notation, a fast frequency-hopping spread-spectrum system using 4-ary FSK with three hops per data symbol is illustrated in Figure 4. Again, in this example, the spread-spectrum bandwidth is six times the 4-ary FSK bandwidth.

Although fast frequency-hopping spread spectrum would be more difficult to implement than a slow one because of the higher hopping rate, it is more advantageous because it introduces frequency diversity for each symbol, resulting in better resistance to partial band jamming. The demodulation in either case is accomplished by a noncoherent receiver synchronously hopping to the same set of frequencies as selected by the pseudorandom sequence at the transmitter.

Time-Hopping Spread Spectrum

In time-hopping spread spectrum, each data bit is transmitted as a short-duration pulse whose position within the bit time is determined by a pseudorandom sequence.

Although time hopping suppresses interference as well as direct sequence or frequency hopping does and can be employed for multi-access purposes, it does not provide nearly the level of security against eavesdropping afforded by either of the two other methods, and it is easier to jam as well.

To visualize the time-hopping spread spectrum, consider Figure 5. A four-bit data sequence is illustrated in Figure 5a, while the pseudorandom position modulation of a short-duration pulse is shown in Figure 5b. The product of the two signals, which is shown in Figure 5c, represents time-hopped data, which would then modulate a carrier. The bandwidth of the resulting time-hopping spread-spectrum signal, as determined by the duration of the pulse, would be much higher than the bandwidth of the underlying data in actual implementation.

Demodulation of the time-hopping spread spectrum involves detection during time intervals as determined by a hopping sequence synchronized to the one at the transmitter.

Hybrids and Other Methods

Combinations of the aforementioned methods can also be used to implement spread-spectrum modulation as hybrid systems. Although clearly more difficult to implement

Figure 5: Illustration of time-hopping spread spectrum—(a) data sequence, (b) pseudorandom pulse position modulation, and (c) time-hopped data pulses

than pure spread-spectrum methods, hybrid systems are sometimes employed in an effort to reap the unique benefits of different spread-spectrum techniques. Common hybrid techniques include *direct sequence and frequency hopping* hybrids and *direct sequence and time hopping* hybrids.

Another possible method for spread-spectrum modulation is to use *pulsed FM* or *chirp* modulation (Maes and Steffey 1996). In pulsed FM spread-spectrum systems, the carrier frequency is frequency modulated by a pseudorandom sequence at the beginning of each symbol. This method can also be viewed in a sense as a frequency-hopping spread-spectrum scheme in which hops are continuous in frequency rather than discrete.

DIRECT SEQUENCE SPREAD SPECTRUM

As a simple example of DSSS, consider an uncoded BPSK direct sequence spread-spectrum system with a correlation receiver operating in the presence of arbitrary interference.

System Definition

As illustrated in Figure 6, the transmitter transmits a binary message every T seconds through the BPSK direct sequence spread-spectrum signal

$$x(t) = b(t) \cdot c(t) \cdot \sqrt{2P} \cos(\omega_c t), \quad (1)$$

where $b(t) = \sum_i b_i u_{T_i}(t - iT)$ is the data waveform, $c(t) = \sum_j a_j u_{T_c}(t - jT_c)$ is the chipping waveform, $u_{\tau}(t) = \begin{cases} 1, & 0 \leq t < \tau \\ 0, & \text{otherwise} \end{cases}$ is the unit pulse wave-

form of duration τ seconds, $b_i \in \{\pm 1\}$ is the data sequence, $a_i \in \{\pm 1\}$ is the chipping sequence modeled as an independent and identically distributed sequence of equally likely random variables, $T_c = T/N$ is the chip duration for N chips per bit, P is the signal power, and ω_c is the carrier frequency.

The channel adds interference $s(t)$ to the transmitted signal. As shown in Figure 6, the receiver is a simple

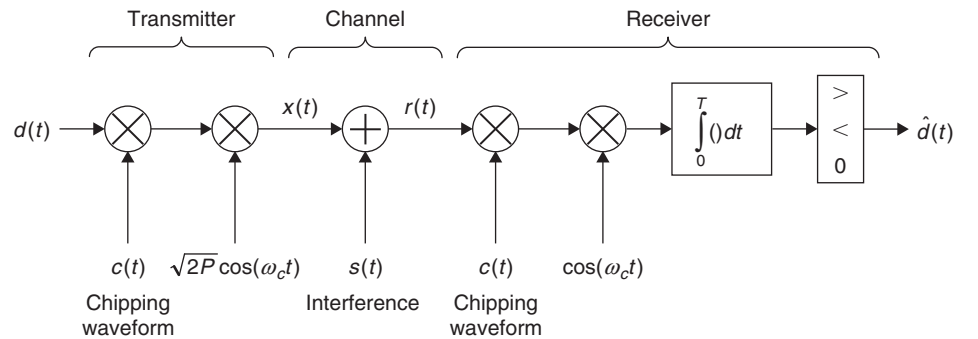

Figure 6: Conceptual block diagram of BPSK direct sequence spread spectrum

correlation receiver that performs an estimate of the transmitted bit by evaluating

$$\hat{b} = \text{sgn} \left(\int_0^T r(t) \cdot c(t) \cos(\omega_c t) dt \right) \quad (2)$$

It should be clear that multiplication of the received signal $r(t)$ with a replica of the chipping waveform despreads the spread-spectrum signal (because $a_j^2 = 1$) while spreading the interference at the same time.

Arbitrary Interference Performance

There is a significant body of knowledge regarding the performance of DSSS in the presence of various types of interference, ranging from numerous kinds of jamming signals to different multi-access settings. Rather than attempting to summarize all of these results, we consider DSSS from a robust communications point of view and present its worst-case performance in the presence of an unknown and arbitrary interference of bounded energy, the so-called arbitrarily varying channel (Hughes and Narayan 1987). This type of an analysis allows us to take into account any form of interference, as long as it is uncorrelated with the transmitted signal, without having to refer to specific statistical descriptions.

Assume that the transmitted signal $x(t)$ is corrupted by an unknown and arbitrary interfering signal, as shown in Figure 6, so that

$$r(t) = x(t) + s(t) \quad (3)$$

is received. The only restrictions on $s(t)$ are that it is independent of the transmitted signal $x(t)$ and it satisfies a constraint on its energy:

$$\int_0^T s^2(t) dt \leq E_I \quad (4)$$

Note that although $s(t)$ covers a substantial range of interference situations, it cannot model multipath interference (Sklar 2001, 771–2, 947–78) or repeat-back type jammers (Simon et al. 1994, 142) where the interference is correlated with the signal. The performance measure is defined as the worst-case error probability of the system under all $s(t)$ satisfying the energy constraint

$$\epsilon_{DS} = \sup_{s(t)} \Pr \left\{ \hat{b} \neq b \right\} \quad \text{subject to (4)} \quad (5)$$

In Figure 7, an upper and a lower bound to the worst-case error probability, ϵ_{DS} , of this system operating with $N = 20$ chips per bit are plotted as a function of signal-to-noise ratio, E_b/E_I (where E_b is the energy per bit), in the absence of AWGN (Hizlan and Hughes 1991). Also plotted in Figure 7 is a fundamental lower bound to the worst-case error probability of *any* random binary modulation scheme: No uncoded binary system of any kind can have a better worst-case error probability than this bound (Hizlan and Hughes 1991). We see from Figure 7 that at 10^{-6} , the worst-case error probability of uncoded direct sequence spread spectrum is no more than 1.8 dB

Figure 7: Arbitrary interference rejection performance of DSSS

away from what is theoretically possible. We can therefore claim that uncoded DSSS is remarkably good at arbitrary interference rejection.

Although not presented here, similarly remarkable worst-case performance results have been shown for uncoded DSSS in multipath channels (Hizlan and Liu 1999) and for coded DSSS in the arbitrarily varying channel (Hizlan and Hughes 1998).

FREQUENCY-HOPPING SPREAD SPECTRUM

A frequency hopping spread-spectrum system can be implemented as a *block hopper* or an *independent hopper*, regardless of whether it is a slow or fast frequency-hopping system. In a block hopper, each hop is made into a contiguous block of M frequencies, within which MFSK modulation takes places. In this type of a system, MFSK modulation and frequency hopping are separately performed. In the independent hopper, MFSK modulation and frequency hopping are combined into a single frequency synthesis process, resulting in hops to individual carrier frequencies rather than frequency blocks. Here a simple example of a block hopping system is presented.

System Definition

As shown in Figure 8a, the transmitter sends an M -ary message $1 \leq m \leq M$ every T seconds by transmitting the signal

$$x(t) = \sqrt{2P} \cos\left((\omega_c^{(m)} + \omega_h^{(j)})t\right), 1 \leq m \leq M, 1 \leq j \leq N \quad (6)$$

where $\omega_c^{(m)}$ is the carrier frequency corresponding to message m and $\omega_h^{(j)}$ is one of the N available hop block frequencies pseudorandomly selected by the *pseudonoise* (PN) sequence. Although $\omega_c^{(m)}$ stays fixed for the entire message duration of T seconds, the timing of $\omega_h^{(j)}$ depends on whether slow or fast frequency hopping is utilized, and it is not explicitly specified in this model. The high-pass filter in Figure 8a is in place to select the upconverted frequencies from the mixer.

The receiver illustrated in Figure 8b “de-hops” the received signal $r(t)$ to the original MFSK frequencies by downconverting through a synchronously running replica of the transmitter PN generator. The image-reject filter removes the image frequencies before the downconversion process. The rest of the receiver operates as a conventional noncoherent MFSK receiver to produce an estimate of the transmitted message, \hat{m} .

CODE DIVISION MULTIPLE ACCESS

Although *code division multiple access* refers to the multiple-access technique by which spreading codes are used to discriminate among users, the use of *CDMA* has become synonymous with the well-known implementation of this technology in wireless telephony. Rather than addressing this particular implementation, we consider a DSSS multiple-access system as a simple example of CDMA.

System Definition

Consider a communication scenario in which K asynchronous users share a multiple-access channel through

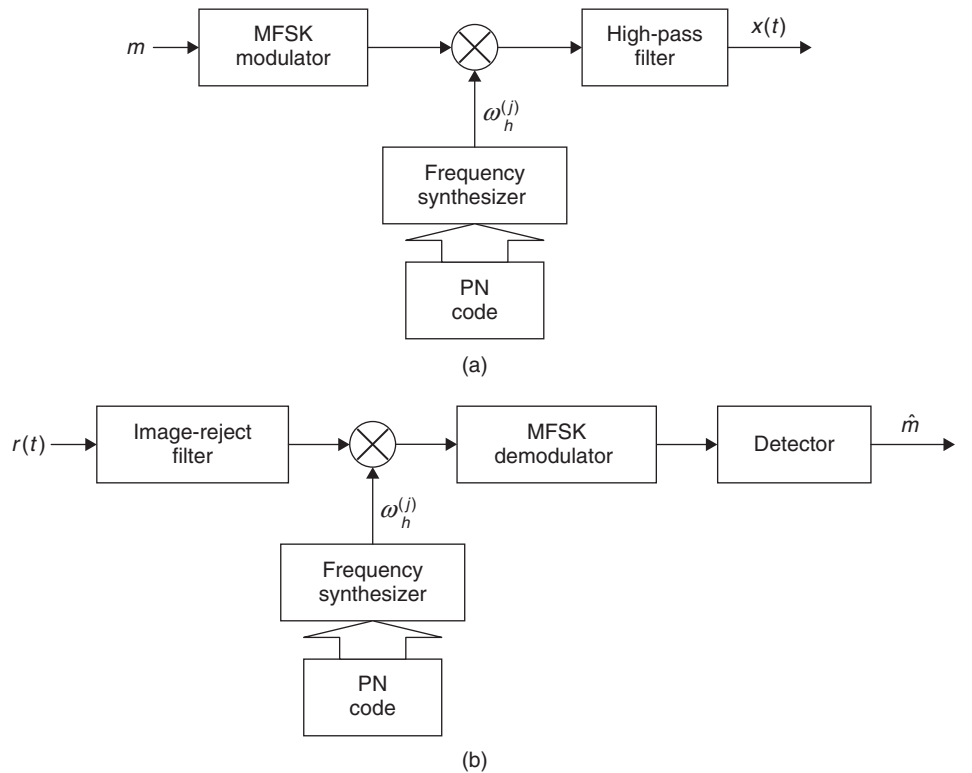

Figure 8: Conceptual block diagram of MFSK frequency-hopping spread spectrum for (a) transmitter and (b) receiver

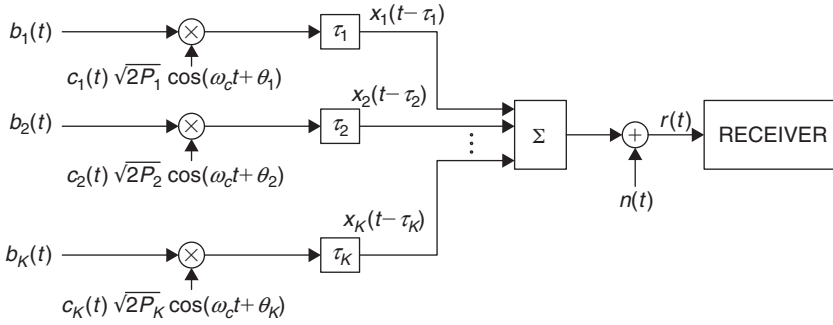

Figure 9: DSSS CDMA model

the use of BPSK direct sequence spread spectrum, as shown in Figure 9. Each user transmits a signal

$$x_k(t) = \sqrt{2P_k} b_k(t) c_k(t) \cos(\omega_c t + \theta_k), \quad 1 \leq k \leq K \quad (7)$$

where $b_k(t)$ is the data waveform and $c_k(t)$ is the chipping waveform as defined in the direct sequence example, P_k is the received power, and θ_k is the phase angle for user k . The receiver receives time-delayed signals from all of the transmitters corrupted by AWGN:

$$r(t) = \sum_{k=1}^K x_k(t - \tau_k) + n(t) \quad (8)$$

where τ_k is the propagation delay associated with transmitter k and $n(t)$ is AWGN. Without loss of generality, assume that the receiver is locked on to the phase and time delay of transmitter 1. As in the direct sequence example, the correlation receiver obtains an estimate of a transmitted bit b by computing

$$\hat{b} = \text{sgn} \left(\int_0^T r(t) \cdot c_1(t - \tau_1) \cos(\omega_c(t - \tau_1) + \theta_1) dt \right) \quad (9)$$

where the integral is over the T -second bit interval.

Multiple-Access Performance

It should be noted that multiple-access performance of spread spectrum can be expressed in terms of the interference rejection capability of spread spectrum. Multiple-access interference is wideband interference, which would be spread out by the despreading mechanism in the receiver, thereby reducing its effect by a factor that is essentially equal to the processing gain of the system. Rather than attempting to summarize the substantial amount of existing results on CDMA performance, we consider CDMA from a robust communications point of view and present its worst-case performance. The performance measure is therefore the worst-case error probability of the above-defined system where the worst case is taken over all transmitter powers $P_k \geq 0$, $2 \leq k \leq K$, phase angles $\theta_k \in [0, 2\pi)$, $2 \leq k \leq K$, and time delays

$\tau_k \in [0, T)$, $2 \leq k \leq K$ subject to a constraint on the detected interference power:

$$\epsilon_{CDMA} = \max_{\substack{P_k, \theta_k, \tau_k \\ 2 \leq k \leq K}} \Pr \{ \hat{b} \neq b \} \quad \text{subject to} \quad \text{detected interference power} \leq P_I. \quad (10)$$

In Figure 10 (Hizlan and Hughes 1988), an upper and a lower bound to ϵ_{CDMA} for this multiple-access system operating with $K = 15$ transmitters and $N = 31$ chips per bit are plotted as a function of postdetection signal-to-interference ratio, P_s/P_I (where P_s is the detected signal power), in the presence of AWGN with signal-to-noise ratio $E_b/N_0 = 15$ dB. Also plotted in Figure 10 is the average error probability of this system for the case of multiple-access interference being modeled as AWGN. We observe from Figure 10 that, at 10^{-5} , the worst-case error probability of the example system is no more than 2 dB away from its average error probability in the presence of AWGN with equivalent interference power. Even under worst-case assumptions, therefore, DSSS does a very good job of rendering multi-access interference harmless, making it behave much like low-level AWGN.

PSEUDONOISE SEQUENCES

Pseudonoise or *pseudorandom* sequences constitute a fundamental building block of spread-spectrum systems whether they are used directly as in DSSS or indirectly as in frequency-hopping or time-hopping spread spectrum. They are deterministic in nature so that they can be synchronously generated both at the transmitter and the receiver, but they exhibit several properties that make them appear like random sequences.

Methods of Generation

Because a pseudorandom sequence is essentially a sequence of numbers approximating the samples of a random variable, any random number generation algorithm can be used to generate it. On the other hand, because pseudorandom numbers used in spread spectrum are plain binary numbers, simple generation methods exist and are preferred for use.

One such method that is commonly used is the *linear feedback shift register* method, as illustrated in Figure 11. The tap coefficients c_i are 1 or 0, meaning there is either

Figure 10: Worst-case performance of DSSS CDMA

Figure 11: Linear feedback shift register PN sequence generators

a feedback connection or not; the addition is modulo-2 addition; and the shift register is initialized to a nonzero state before sequence generation begins. Because the maximum number of distinct states, excluding the all-zero state, is $2^K - 1$ for a K -stage shift register, the period of the longest sequence that can be obtained is also $2^K - 1$. The all-zero state is excluded because, if it occurs, the rest of the sequence will all be zeros.

If the tap coefficients are chosen just right, the longest period can be attained, resulting in what is called an *m-sequence*, or maximal length sequence. This method can clearly generate extremely long sequences with modest-size shift register implementations. These PN sequences exhibit good randomness properties as will be described later.

In multiple-access applications, PN sequences with low cross-correlation values are desired in order to minimize interference among multiple users. There are several common ways of generating such sequences. One well-known set constitute *Gold* codes (Gold 1967), which

are simply generated through a modulo-2 sum of two *m*-sequences. Each user in the multiuser environment has to use a different code from the set obtained by using different initial states for one of the two shift registers. The two *m*-sequences are specifically chosen to form what is called a *preferred pair*, resulting in the desired cross-correlation properties.

Another set of PN sequences with minimal cross-correlation values constitutes the *Kasami* sequences (Kasami 1966). Kasami sequences have better cross-correlation properties than Gold codes (smaller maximum autocorrelation), but they provide a smaller number of codes and therefore support a smaller number of users for a given code length.

The *Walsh* codes are still another well-known set of PN sequences for multiuser applications (Ziemer and Peterson 2001, 610–1). One way to generate them is through the use of a *Hadamard* matrix, in which each row is orthogonal to any other. As such, Walsh codes have zero cross-correlations, but only if they are perfectly synchronized.

Properties of PN Sequences

Although Gold codes, Kasami codes, and Walsh codes exhibit good cross-correlation properties, pure m -sequences display especially good randomness properties. Randomness properties of m -sequences can be stated in terms of the balance, run length, and autocorrelation properties (Haykin 2001, 482–3).

M -sequences are balanced in terms of the number of 1's and 0's generated in one period. In fact, because m -sequences have odd periods, it can be shown that the number of 1's generated in one period is always one more than the number of 0's generated. This distribution approximates the expected value for a purely random binary sequence of equally likely numbers.

Defining a run of length l as a subsequence of l identical symbols within the m -sequence, run lengths also exhibit a balanced distribution. More specifically, half of all the runs (of 1's and 0's) in an m -sequence have run length 1, one-fourth of all the runs have run length 2, one-eighth of all the runs have run length 3, and so on. Also, the number of runs of 1's and runs of 0's for each run length are equal. The only exception, resulting from the odd period of the m -sequence, is for the single 1 run and the single 0 run, where the length of the 1 run is one more than the length of the 0 run.

The normalized periodic autocorrelation function of an m -sequence with period N is 1 for a cyclic shift of the sequence by an integer multiple of the period, and $-1/N$ for any other cyclic shift. This, of course, is a tiny number for large N , approximating an uncorrelated sequence.

Choosing a PN Sequence

For arbitrary interference rejection, LPI or LPD applications, anti-jam applications, or ranging applications, m -sequences are usually adequate because they have good randomness properties. Note, however, that because m -sequences are based on linear generation methods, they are relatively easy to decode and therefore provide only minimal security against eavesdropping. If security is a concern, then nonlinear generation methods should be utilized (Key 1976).

For multiuser applications, minimal cross-correlation among PN sequences is more important than their individual randomness properties. For such applications, Gold codes, Kasami codes, or Walsh codes can be used. As stated before, Walsh codes have perfect (zero) cross-correlation but only if synchronized. Therefore, their application is limited to synchronous multiple-access systems. For asynchronous systems, Gold codes or Kasami codes can be considered. Although Gold codes support more users for a given code length, they exhibit larger cross-correlations than Kasami codes. However, with the larger number of users, the cumulative interference will also be larger. The trade-off between the two should therefore be considered.

CONCLUSION

Although spread spectrum led a quiet and secretive life of several decades under military safeguard, it is now enjoying a vibrant new lease on life in the civilian world. This should come as no surprise, however, given the many

desirable features of spread spectrum such as robustness, interference rejection, low power spectral density, and multiple-access capability. Even the sole fact that it can coexist in the same band with other narrowband applications is enough to make spread spectrum highly sought after in today's exceedingly crowded frequency spectrum. It is therefore safe to predict that spread spectrum will enjoy an ever-increasing number of applications in the future.

GLOSSARY

Anti-jam: A characteristic of a communication system designed to resist jamming or intentional blocking. *See also* Jammer.

Bluetooth: An industrial specification for wireless *personal area networks* (PANs), Bluetooth provides a relatively secure and low-cost way to connect and exchange information between devices such as wireless phones, PDAs, laptops, and computer peripherals through short-range wireless connections.

CDMA2000: A family of *third-generation* (3G) mobile telecommunications standards that utilize *code division multiple access* based on the older CDMA digital cellular telephony standard and remaining compatible with it.

Code division multiple access (CDMA): A method of multiple access that allows many users to share the same communication channel through the use of individual spreading codes. CDMA also refers to a particular digital cellular telephony system that utilizes this scheme.

Direct sequence spread spectrum (DSSS): A method of spread spectrum in which spreading the bandwidth is accomplished by directly multiplying the data signal with a much higher-rate pseudorandom sequence.

Frequency hopping spread spectrum (FHSS): A method of spread spectrum in which spreading the bandwidth is accomplished by pseudorandomly switching (or hopping) the carrier frequency over a wide range of frequencies.

IEEE 802.11: A set of *wireless local area network* (WLAN) standards developed by Working Group 11 of the IEEE LAN/MAN Standards Committee (IEEE 802).

Interim Standard 95 (IS-95): Developed under Telecommunications Industry Association and Electronic Industries Alliance standards to define the second-generation digital cellular telephony standard better known as CDMA.

Jammer: A transmitting device used in electronic warfare to obstruct or foil transmission of the adversary's signals; also, the entity that performs such action.

Low probability of detection (LPD): A characteristic of transmissions, such as spread-spectrum signals, that are difficult to detect because of attributes such as low-power spectral density or high directivity.

Low probability of intercept (LPI): *See* Low probability of detection.

Multiple access: Type of communications in which more than one user accesses and communicates over a common channel.

Pseudonoise (PN) or pseudorandom sequence: An algorithmically generated sequence of numbers that appear to be random.

Robust communications: Type of communications designed to provide a minimum specified level of performance regardless of the kind of interference in the channel in which it operates.

Spread spectrum: A class of modulation schemes in which the transmission bandwidth is made much larger than the information bandwidth through a process that is independent of the transmitted data.

Time hopping: A method of spread spectrum in which bandwidth spreading is accomplished by transmitting extremely narrow pulses that are pseudorandomly pulse position modulated.

Wideband code division multiple access (W-CDMA): A third-generation (3G) wideband digital cellular telephony standard utilizing spread-spectrum multiple access; it is slated to be a successor to the worldwide second-generation standard of the *global system for mobile communications* (GSM).

Wi-Fi: A shortened form of *wireless fidelity* and a trademark of the Wi-Fi Alliance. Wi-Fi defines product compatibility standards for *wireless local area networks* (WLANs) based on the IEEE 802.11 standards.

INTRODUCTION

Frequency division multiplexing (FDM) is a technique in which the available bandwidth of a transmission channel is divided by frequency into narrower bands such that each band is used for a separate voice, video, or data transmission. When *amplitude modulation* (AM) radio broadcasting started at the beginning of the twentieth century, the pioneering electrical engineers modulated different radio programs to different frequencies so that they could be broadcast simultaneously. FDM was first employed in the 1930s in the analog carrier system to transmit several voice channels on a single physical circuit. Based on FDM, *multicarrier modulation* (MCM) was invented in the late 1950s, and *orthogonal frequency division multiplexing* (OFDM), a special form of MCM with densely spaced subcarriers (typically dozens to thousands), was introduced in 1970. Unlike FDM, in which each signal is carried by one carrier on a particular frequency band, MCM transmits a signal by splitting it into several components and sending each component over separate subcarrier. The details of OFDM are discussed in Chapter 39 of this handbook.

Nowadays, the FDM technique has application in many modern communication systems: for example, telephone, mobile phone, wireless *local area networks* (LANs), TV broadcast systems, radio broadcast systems, broadband Internet connections, and microwave and satellite communication systems (Freeman 1998; Minoli 2003; Rappaport 2001; Roddy 2006). Although different modulation techniques are adopted in these systems, the theme of transmitting multiple signals by sharing the frequency resource is the same.

In this chapter, we introduce the basic theories underlying FDM and discuss a few of its applications. The concept corresponding to frequency division multiplexing in the optical domain is known as *wavelength division multiplexing* (WDM), and it is discussed in detail in "Wavelength Division Multiplexing."

This chapter is organized as follows. The next section introduces the fundamentals of signal and Fourier transform, which are useful for the discussion in the rest of the chapter. The following two sections explain the theories of amplitude modulation and frequency modulation and

illustrate several typical AM and *frequency modulation* (FM) schemes. We then describe the general mechanism of FDM and present a few of its exemplary applications. Finally, we draw conclusions in the final section.

SIGNAL AND FOURIER TRANSFORM

Fourier analysis can transform the representation of a signal in the time domain into a representation of the signal in the frequency domain. The Fourier transform can isolate individual components of a complex signal for easier detection and manipulation. Analyzing and processing a signal in the frequency domain is a powerful tool in signal processing, communications, and many other areas. In this section, we briefly introduce the continuous Fourier transform and some properties of Fourier transforms. For more details, please refer to the textbook by Oppenheim, Willsky, and Nawab (1996).

Let $x(t)$ be a signal in the time domain, where t is the time. The Fourier transform of $x(t)$, denoted by $F\{x(t)\} = X(f)$, where f is the frequency, is defined by the following formula:

$$X(f) = \int_{-\infty}^{\infty} x(t) \exp[-j2\pi ft] dt, \text{ where } j = \sqrt{-1}$$

With equal validity, $X(f)$ gives a representation of the original signal $x(t)$ in the frequency domain. Generally, $X(f)$ is a complex function, and it is often convenient to express $X(f)$ in exponential form: $X(f) = |X(f)|e^{j\Phi(f)}$. The magnitude function $|X(f)|$ is called the Fourier spectrum of $x(t)$, $\Phi(f)$ is its phase angle. The square of the spectrum $|X(f)|^2$ is commonly referred to as the *power spectrum* of $x(t)$.

Given $X(f)$, we can obtain $x(t)$ by applying the inverse Fourier transform:

$$x(t) = \int_{-\infty}^{\infty} X(f) \exp[j2\pi ft] df$$

The above two equations are called the *Fourier transform pair*. Table 1 lists the Fourier transform pairs of a few

Table 1: Fourier Transform Pairs of Typical Signals

$x(t)$	$X(f)$
1	$\delta(f)$
$\delta(t)$	1
$e^{j2\pi f_0 t}$	$\delta(f - f_0)$
$\cos(2\pi f_0 t)$	$\frac{1}{2}[\delta(f - f_0) + \delta(f + f_0)]$
$\sin(2\pi f_0 t)$	$\frac{1}{2j}[\delta(f - f_0) - \delta(f + f_0)]$
$\begin{cases} 1 & t < t_0 \\ 0 & \text{otherwise} \end{cases}$	$2t_0 \text{sinc}(2t_0 u)$, where $\text{sinc}(t) = \frac{\sin(\pi t)}{\pi t}$

Table 2: Property of Fourier Transform

Property	Formulae
Duality	$F\{X_1(t)\} = x_1(-f)$
Scaling	$F\{ax_1(t)\} = ax_1(-f)$
Linearity	$F\{ax_1(t) + bx_2(t)\} = aX_1(f) + bX_2(f)$
Translation	$F\{x_1(t - t_0)\} = X_1(f)e^{-j2\pi f t_0}$ $F\{x_1(t)e^{-j2\pi f_0 t}\} = X_1(f - f_0)$
Convolution	$F\{x_1(t) \otimes x_2(t)\} = X_1(f)X_2(f)$, where $x_1(t) \otimes x_2(t) = \int_{-\infty}^{\infty} x_1(\tau)x_2(t - \tau) d\tau$ $F\{x_1(t)x_2(t)\} = \int_{-\infty}^{\infty} X_1(u)X_2(f - u) du$

typical signals. Note that in the table, $\delta(\cdot)$ is the Dirac delta function.

The Fourier transform of a cosine signal, $\cos(2\pi f_0 t)$, contains two delta functions in the frequency domain, one at f_0 , and the other at $-f_0$, which is negative. The convention of negative frequency serves as a powerful mathematical tool in signal analysis. In fact, the use of negative frequency is mandatory for representing real signals—for example, the cosine signal in the frequency domain.

From the definition, it is straightforward to show that the Fourier transform satisfies a few nice properties, including linearity and duality. Assuming that a and b are two constants, $x_1(t)$ and $x_2(t)$ are two signals, and $X_1(f)$ and $X_2(f)$ are their Fourier transforms, we list several important properties of Fourier transform in Table 2. These properties will be referred to in the rest of this chapter.

When $x(t)$ is a real signal, $|X(f)|$ is symmetric with respect to the origin. Figure 1 shows the waveform and the power spectrum of a typical speech signal. To reveal the details of high frequency components of the signal, we plot $20\log|X(f)|$ in Figure 1b. The symmetry of the spectrum is clearly shown in that figure. The symmetry means that, for a real signal, no information is lost if we only consider the positive frequency components. The frequency component at $f = 0$ is called the *direct current* (DC) component, and the frequency components of nonzero frequencies are called the *alternating current* (AC) component. Although the human voice covers a wider frequency range (from 100 Hz to 8000 Hz), research has shown that the intelligent part of human speech is carried in the range of 300 Hz to 3400 Hz (Rabiner 1993). Figure 1b shows that the energy of the voice power spectrum actually concentrates in this band.

AMPLITUDE MODULATION

Modulation is the process of varying a carrier signal in order to convey information. The purpose of modulation is to create a signal with frequencies in a desired part of the spectrum that are more compatible with the system. A carrier signal is normally a cosine wave at a certain frequency. It can be represented by the following function:

$$v_c(t) = A_c \cos(2\pi f_c t + \Phi(t))$$

where A_c is the amplitude, and $2\pi f_c t + \Phi(t)$ is the angle.

Generally, there are two types of modulations: amplitude modulation and angle modulation. *Amplitude modulation* utilizes the carrier's amplitude to convey information, and *angle modulation* embeds the information in the angle of the carrier signal. Angle modulation can be further

**Figure 1:** Waveform and power spectrum of a voice signal—(a) waveform and (b) power spectrum

categorized into *frequency modulation* and *phase modulation*. In frequency modulation, the instantaneous frequency varies relative to the information signal; in phase modulation, the instantaneous phase varies with the information signal. Because phase modulation is similar to frequency modulation, we do not cover it in this chapter. Interested readers may refer to Schweber (2002).

In this section, we briefly introduce three common amplitude modulation techniques: the basic AM modulation, the suppressed carrier and single sideband AM, and vestigial sideband AM. The frequency modulation will be addressed in the next section.

The Basic AM Modulation

Assume $f(t)$ is the information signal and $v_c(t) = A_c \cos(2\pi f_c t)$ is the carrier signal; the basic AM modulation scheme modifies amplitude of the carrier, A_c , with $f(t)$ by the following formula:

$$s_{AM}(t) = [A_c + f(t)] \cos(2\pi f_c t)$$

To simplify the analysis, we assume that the information signal is a sinusoid, $f(t) = A_i \cos(2\pi f_i t)$. Then the above formula becomes

$$\begin{aligned} s_{AM}(t) &= [A_c + A_i \cos(2\pi f_i t)] \cos(2\pi f_c t) \\ &= A_c [1 + \beta_{AM} \cos(2\pi f_i t)] \cos(2\pi f_c t), \\ &\text{where } \beta_{AM} = A_i/A_c \end{aligned}$$

β_{AM} is called the AM index, and $|\beta_{AM}| \leq 1$. Figure 2(a) shows the waveforms of the carrier signal and the information signal, where $f_c = 10$, $A_c = 2$, $A_i = 1$, and $f_i = 1$. In the time domain, the envelope of the carrier follows the information signal.

Let $F(f)$ and $V_c(f)$ represent the Fourier transforms of $f(t)$ and $v_c(t)$. Table 1 tells us that $F(f) = A_i[\delta(f - f_i) + \delta(f + f_i)]/2$, and $V_c(f) = A_c[\delta(f - f_c) + \delta(f + f_c)]/2$. The two spectrums are shown in Figure 2b, each containing two Dirac delta functions at $\pm f_i$ and $\pm f_c$, respectively. Figure 3a shows the waveform of the modulated signal, $s_{AM}(t)$. Let $S_{AM}(f)$ denote its Fourier transform. From the convolution property listed in Table 2, we know that the Fourier transform of the product of two signals is the convolution of the Fourier transforms of the two signals. $S_{AM}(f)$ can be computed as follows:

$$\begin{aligned} S_{AM}(f) &= \frac{A_c}{2} [\delta(f - f_c) + \delta(f + f_c)] \\ &\quad + \left[\frac{A_i}{2} (\delta(f - f_i) + \delta(f + f_i)) \right] \\ &\quad \otimes \left[\frac{1}{2} (\delta(f - f_c) + \delta(f + f_c)) \right] \\ &= \frac{A_c}{2} [\delta(f - f_c) + \delta(f + f_c)] \\ &\quad + \frac{A_i}{4} [\delta(f - f_c - f_i) + \delta(f - f_c + f_i) \\ &\quad + \delta(f + f_c - f_i) + \delta(f + f_c + f_i)] \end{aligned}$$

Figure 2: Information signal and carrier signal—(a) waveform and (b) spectrum

Figure 3: Modulated signal of the basic AM modulation—(a) waveform and (b) spectrum

Figure 3b plots the spectrum of the modulated signal. It is composed of the spectrum of the original carrier at $\pm f_c$ and two copies of the spectrum of the information signal whose origins are shifted to $\pm f_c$. Let us take a closer look at the copy centered at f_c . The two delta functions at $f_c - f_i$ and $f_c + f_i$ are called the *lower sideband* (LSB) and the *upper sideband* (USB), respectively. Two observations from Figure 3b are that (1) more energy is spent on the carrier signal than on the information signal and (2) the modulated signal takes twice the bandwidth of the baseband information signal.

There are several methods to demodulate the basic AM modulation, and the simplest one is the envelope detector. It detects the envelope of the incoming signal by first rectifying the signal by a diode and then removing high frequency components that are outside of the spectrum of information signal by a resistor-capacitor low-pass filter. The main disadvantage of the envelope detector is that it is not particularly linear and the distortion level may be high. Coherent demodulation technique provides superior quality, and we will discuss it in the next section.

Suppressed Carrier and Single Sideband AM

Basic AM spends more energy on the carrier signal than on the information signal. Besides, the two sidebands carry the identical spectrum information, and they require twice the bandwidth of the modulating signal. To solve these two issues, the carrier and the one of the sidebands (LSB or USB) in Figure 3b could be removed. When only the carrier is removed, it is called *double-sideband suppressed carrier* (DSB-SC) AM. When both carrier and one sideband are removed, it is called *single-sideband suppressed carrier* (SSB-SC) AM.

The carrier can be suppressed by removing the DC component of the envelope in Figure 3a. The modulated signal becomes $s_{DSB-SC}(t) = f(t) \cos(2\pi f_c t)$, and its Fourier transform is $S_{DSB-SC}(f) = [F(f - f_c) + F(f + f_c)]/2$. Let $f(t) = \cos(2\pi f_i t)$, then we have $s_{DSB-SC}(t) = \cos(2\pi f_i t) \cos(2\pi f_c t)$, and the spectrum of the DSB-SC signal is shown in Figure 4a.

If we want to remove the LSB, an ideal high-pass filter with a cutoff frequency at f_c has to be applied. On the other hand, an ideal low-pass filter with a cutoff frequency at f_c can get rid of the USB. In reality, because either low-pass or high-pass filters have a certain transition

band, we cannot cleanly remove one sideband without affecting the other. If the information signal takes limited bandwidth, for example, a voice signal takes the frequency band from 300 Hz to 3400 Hz, a certain amount of transition band (in this case, 600 Hz) is tolerated.

Following the example shown in Figure 4a, if we just keep the upper sideband, then the spectrum of the SSB-SC signal is $S_{SSB-SC}(f) = [\delta(f - f_c - f_i) + \delta(f + f_c + f_i)]/4$, and its time domain expression is $s_{SSB-SC}(t) = 0.5 \cos(2\pi(f_i + f_c)t)$. The spectrum of $s_{SSB-SC}(t)$ is shown in Figure 4b. In this special case, the modulated signal actually has a constant amplitude, which is quite different from the basic AM and DSB-SC AM cases. It is obvious that the envelope detector cannot demodulate the SSB-SC modulated signal.

Both DSB-SC and SSB-SC can be demodulated by coherent demodulation, which is accomplished by remodulating the modulated signal with a local carrier signal with the same frequency and in phase with the original carrier signal—for example, $\cos(2\pi f_c t)$. In the frequency domain, the remodulation basically shifts the spectrum of the modulated signal by f_c and $-f_c$, which recovers the baseband spectrum of the original signal with a few high-frequency components (images). After filtering out the high-frequency components, the information signal is recovered.

Vestigial Sideband AM

Vestigial sideband (VSB) AM is a scheme between the basic AM and the suppressed sideband AM. When the information signal contains low frequency or even the DC component, it is impossible to implement the suppressed sideband AM. In VSB AM, while one sideband of the modulated signal is kept, part of the other sideband is kept also. The modulation procedure is shown in Figure 5a. $H_{VSB}(f)$ is the vestigial sideband filter. The Fourier transform of $s_{VSB}(t)$ is

$$S_{VSB}(f) = \frac{1}{2} H_{VSB}(f) [F(f - f_c) + F(f + f_c)]$$

Figure 5b gives an example of the vestigial sideband filter with part of the lower sideband and the entire upper sideband retained.

Figure 4: Spectra of (a) DSB-SC and (b) SSB-SC AM

Figure 5: Vestigial sideband amplitude modulation—(a) generation of VSB signal and (b) VSB filter

Figure 6: Demodulation of the VSB signal

The demodulation of the VSB signal can be achieved by coherent demodulation with the right low-pass filter. Figure 6 shows the diagram of a VSB demodulator.

From Figure 6, we have $s_p(t) = s_{VSB}(t)\cos(2\pi f_c t)$. By the convolution property listed in Table 2, we can compute the Fourier transform of $s_p(t)$ as follows:

$$\begin{aligned} S_p(f) &= \frac{1}{2}[S_{VSB}(f - f_c) + S_{VSB}(f + f_c)] \\ &= \frac{1}{4}[H_{VSB}(f - f_c)[F(f - 2f_c) + F(f)] \\ &\quad + H_{VSB}(f + f_c)[F(f) + F(f + 2f_c)]] \\ &= \frac{1}{4}[F_f[H_{VSB}(f - f_c) + H_{VSB}(f + f_c)] \\ &\quad + \frac{1}{4}[H_{VSB}(f - f_c)F(f - 2f_c) \\ &\quad + H_{VSB}(f + f_c)[F(f + 2f_c)]] \end{aligned}$$

The second item of $S_p(f)$ in the last equation contains high-frequency components, and it can be removed by a suitable low-pass filter. For the first item, to ideally recover the information signal $f(t)$, $H_{VSB}(f)$ has to satisfy the following condition:

$$H_{VSB}(f - f_c) + H_{VSB}(f + f_c) = \text{constant}$$

This means that $H_{VSB}(f)$ is complementary-symmetric about the carrier frequency f_c , as shown in Figure 5b. The most popular VSB filters are root-raised cosine filters and linear roll-off filters. They are widely used in data communication systems and TV broadcasting systems, respectively.

FREQUENCY MODULATION

In frequency modulation, the information signal is represented by the instantaneous frequency of a carrier signal.

In contrast to AM, it offers many advantages in noise reduction, signal fidelity, and power efficiency, but it also requires more complex circuits for the transmitter and receiver. In this section, we present the basic theory of frequency modulation.

Assume the information signal is $f(t)$ and the carrier signal is $v_c(t) = A_c \cos(2\pi f_c t)$. Then the time domain representation of the FM signal $s_{FM}(t)$ is given by the following formula:

$$s_{FM}(t) = A_c \cos\left(2\pi \int_0^t [f_c + K_{FM}f(\tau)]d\tau\right)$$

where K_{FM} is the constant that controls the frequency deviation. Based on the above formula, we can easily compute the instantaneous frequency of $s_{FM}(t)$ as $f_{FM}(t) = f_c + K_{FM}f(t)$.

Figure 7 shows an example of frequency modulation. The information signal $f(t)$ and the original carrier $v_c(t)$ are the same as those shown in Figure 2a. In this example, we set $K_{FM} = 1$.

Comparing Figure 7 to Figure 3a, we can see the difference between AM and FM: AM modulates the amplitude of the carrier without changing the carrier's frequency, and FM keeps the amplitude of the carrier constant but modulates the instantaneous frequency of the carrier.

To study the FM spectrum, we use a sinusoidal modulating signal $f(t) = A_i \cos(2\pi f_i t)$. In this case, $s_{FM}(t)$ can be written as

Figure 7: Waveform of a frequency-modulated signal

$$\begin{aligned}
s_{FM}(t) &= A_c \cos \left(2\pi \int_0^t [f_c + K_{FM} A_i \cos(2\pi f_i \tau)] d\tau \right) \\
&= A_c \cos \left(2\pi f_c t + \frac{K_{FM} A_i}{2\pi f_i} \sin(2\pi f_i t) \right) \\
&= A_c \cos(2\pi f_c t + \beta_{FM} \sin(2\pi f_i t)), \\
\text{where } \beta_{FM} &= \frac{K_{FM} A_i}{2\pi f_i} \\
&= A_c \cos(2\pi f_c t) \cos(\beta_{FM} \sin(2\pi f_i t)) \\
&\quad - A_c \sin(2\pi f_c t) \sin(\beta_{FM} \sin(2\pi f_i t))
\end{aligned}$$

β_{FM} in the above equation is called the *modulation index* of the FM signal, which is the ratio of the peak frequency deviation to the carrier's frequency. Depending on the value of β_{FM} , FM can be classified into narrowband FM when $\beta_{FM} < 0.2$ and broadband FM otherwise.

For narrowband FM, we have the following approximation:

$$\cos(\beta_{FM} \sin(2\pi f_i t)) \approx 1, \sin(\beta_{FM} \sin(2\pi f_i t)) \approx \beta_{FM} \sin(2\pi f_i t)$$

Then $s_{FM}(t)$ becomes

$$\begin{aligned}
s_{FM}(t) &= A_c \cos(2\pi f_c t) - A_c \beta_{FM} \sin(2\pi f_i t) \sin(2\pi f_c t) \\
&= A_c \cos(2\pi f_c t) + \frac{A_c \beta_{FM}}{2} [\cos(2\pi(f_c + f_i)t) \\
&\quad - \cos(2\pi(f_c - f_i)t)]
\end{aligned}$$

Comparing this equation to the time representation of AM signal $s_{AM}(t)$, we know that they are similar. Both modulated signals have a carrier component and two sidebands. The bandwidth of narrowband FM is also twice the bandwidth of the information signal. The Fourier transform of $s_{FM}(t)$ is

$$\begin{aligned}
S_{FM}(f) &= \frac{1}{2} [\delta(f - f_c) + \delta(f + f_c)] \\
&\quad + \frac{A_c \beta_{FM}}{4} [\delta(f - f_c - f_i) + \delta(f + f_c + f_i)] \\
&\quad - \frac{A_c \beta_{FM}}{4} [\delta(f - f_c + f_i) + \delta(f + f_c - f_i)]
\end{aligned}$$

Figure 8 plots $S_{FM}(f)$. Compared to Figure 3b, the spectrum of a narrowband FM signal is similar to the spectrum of an AM signal. One dissimilarity is that the signs of the two sidebands of $S_{FM}(f)$ are different.

For broadband FM, we can express $\cos(\beta_{FM} \sin(2\pi f_i t))$ and $\sin(\beta_{FM} \sin(2\pi f_i t))$ in series of the *Bessel functions* of the first kind $J_n(\beta_{FM})$ (Cantrell 2000):

$$\begin{aligned}
\cos(\beta_{FM} \sin(2\pi f_i t)) &= J_0(\beta_{FM}) + 2 \sum_{n=1}^{\infty} J_{2n}(\beta_{FM}) \cos(2n2\pi f_i t) \\
\sin(\beta_{FM} \sin(2\pi f_i t)) &= 2 \sum_{n=1}^{\infty} J_{2n-1}(\beta_{FM}) \sin(2n-1)2\pi f_i t
\end{aligned}$$

Interested readers can find more details about Bessel functions of the first kind in the appendix. Plugging these

Figure 8: Fourier transform of narrowband FM

two equations into the original $s_{FM}(t)$ and applying a few properties of Bessel functions, we get

$$S_{FM}(t) = A_c \sum_{n=-\infty}^{\infty} J_n(\beta_{FM}) \cos(2\pi(f_c + n f_i)t)$$

and its Fourier transform $S_{FM}(f)$ is

$$S_{FM}(f) = \frac{A_c}{2} \sum_{n=-\infty}^{\infty} J_n(\beta_{FM}) [\delta(f - f_c - n f_i) + \delta(f + f_c + n f_i)]$$

From the above equation, we know that the spectrum of an FM signal contains infinite components, where the component at the carrier's frequency is determined by $J_0(\beta_{FM})$ and the components of the n th sideband are determined by $J_n(\beta_{FM})$. Figure 9 illustrates the spectrum of a broadband FM signal. Theoretically, the bandwidth of an FM signal is infinite, but normally we can safely ignore the high-order sidebands when $|J_n(\beta_{FM})|$ is small enough. The bandwidth can also be estimated by *Carson's rule*, which is $W = 2f_i(1 + \beta_{FM})$.

The simplest way to demodulate the FM signal is through the use of an FM discriminator such as that shown in Figure 10. The output of the differentiator $s_d(t)$ is

$$s_d(t) = A_c 2\pi [f_c + K_{FM} f(t)] \sin \left(2\pi \int_0^t [f_c + K_{FM} f(\tau)] d\tau \right)$$

$s_d(t)$ is basically a sinusoidal function with envelope $f_c + K_{FM} f(t)$. This form is similar to the modulated signal of the basic amplitude modulation, and an envelope detector can extract the signal $f_c + K_{FM} f(t)$.

FREQUENCY DIVISION MULTIPLEXING

Multiplexing refers to a process by which multiple information signals are combined for transmission in one physical channel. Basically, there are two types of multiplexing: *frequency division multiplexing* (FDM) and *time division multiplexing* (TDM). Figure 11 illustrates the concepts of FDM and TDM. In FDM, each signal takes a certain band within the bandwidth of the channel, and all signals are transmitted simultaneously. In TDM, all signals take the entire available bandwidth, and each signal is transmitted for a certain period of time.

Figure 9: Spectrum of FM signal

Figure 10: Diagram of FM discriminator

Figure 11: Illustration of FDM and TDM (a) FDM (b) TDM

Figure 12 shows the diagram of an FDM system. Normally, the system consists of three main parts: the transmitter, the channel, and the receiver. The entire bandwidth of the channel is split into a set of nonoverlapping bands, and each band is used for transmitting one information signal. On the transmitter side, because the input signals may not be strictly band-limited signals, low-pass filters must be applied to remove any unwanted high-frequency component of the input signals. Then the spectrum of each information signal is moved to the desired band of frequency by the modulator. Before summing all modulated signals together and sending them through the shared channel, each modulated signal goes through a bandpass filter to prevent any spectral overlap among the modulated signals.

On the receiver side, the received signal is passed to a set of bandpass filters to extract the modulated signals. Then each modulated signal passes the demodulator and a low-pass filter to recover the corresponding baseband signal.

One key challenge in an FDM system is to eliminate the interference among different frequency bands, mainly because of the harmonics of the modulated signals caused by the nonlinearity of the modulators. This type of

interference is called *cross talk*. To effectively reduce the cross talk, the carriers' frequencies have to be designed carefully, and certain guard bands need to be inserted between the adjacent frequency bands.

FDM has been widely used in many communication systems. Although some communication systems rely on proprietary wires or cables, many other systems actually share the same radio frequency spectrum, which is a finite nature resource. Table 3 lists the radio frequency spectrum that is suitable for radio communications. Note that in the table, ITU refers to the International telecommunication Union, which is responsible for many global communication standards and recommendations.

To meet the increasing demand of this limited resource because of rapid development of new radio-based services and to optimize the usage of the resource, it has to be regulated by governments and international standards organizations (U.S. Department of Commerce 2003; Roke Manor Research 2004). The way to manage the spectrum is to divide the radio frequency spectra into blocks of various sizes that meet the requirements of different services and to allocate them to services on an exclusive or shared basis, either for free use or licensed usage. Table 4 lists the spectrum range of a few common broadcast services in the United States.

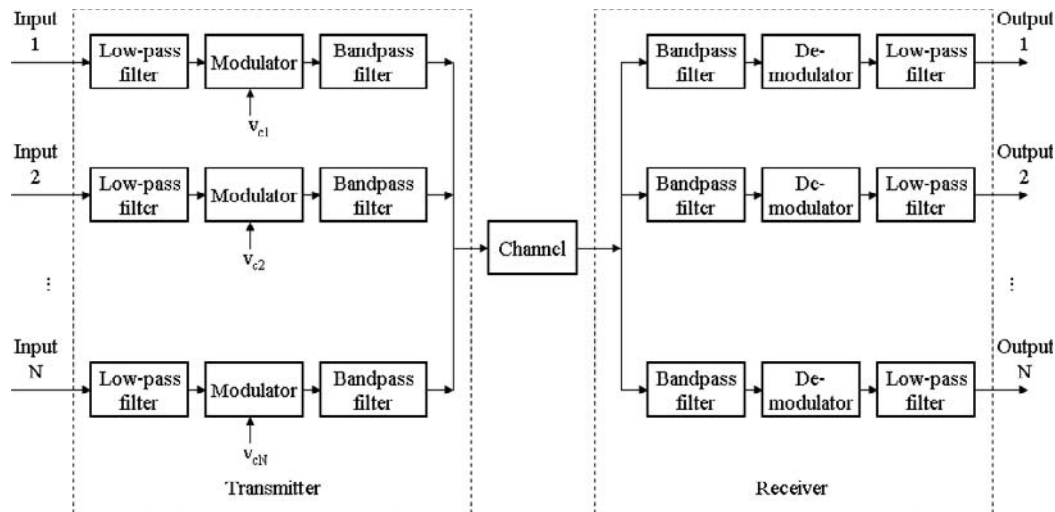

Figure 12: Diagram of the FDM system

Table 3: Radio Frequency Spectrum

ITU band / Designation	Frequency	Wavelength	Sample application
1 ELF (extreme low frequency)	3–30 Hz	100–10 mm	Communication with submarines
2 SLF (super low frequency)	30–300 Hz	10–1 mm	
3 VF (voice frequency)	300–3000 Hz	1–0.1 mm	Communication within mines
4 VLF (very low frequency)	3–30 kHz	100–10 km	Avalanche beacons
5 LF (low frequency)	30–300 kHz	10–1 km	AM (long-wave) broadcasts
6 MF (medium frequency)	300–3000 kHz	1–0.1 km	AM (medium-wave) broadcasts
7 HF (high frequency)	3–30 MHz	100–10 m	Shortwave broadcasts and amateur radio
8 VHF (very high frequency)	30–300 MHz	10–1 m	FM and television broadcasts
9 UHF (ultrahigh frequency)	300–3000 MHz	100–10 cm	Television broadcasts, mobile phones, wireless LANs
10 SHF (super high frequency)	3–30 GHz	10–1 cm	Microwave devices, wireless LANs, radars
11 EHF (extreme high frequency)	30–300 GHz	1–0.1 cm	Radio astronomy
Decimeter	300–3000 GHz	1–0.1 mm	Night vision

Table 4: Broadcast Frequencies

Broadcast service	Broadcast frequencies
AM radio	535 kHz–1605 kHz
TV band I (channels 2–6)	54 MHz–88 MHz
FM radio	88 MHz–108 MHz
TV band II (channels 7–13)	174 MHz–216 MHz
TV band III (channels 14–69)	470 MHz–806 MHz

APPLICATIONS OF FREQUENCY DIVISION MULTIPLEXING

As mentioned previously, FDM has been widely used in various areas, including the analog carrier system, FM radio, terrestrial TV broadcast systems, and space remote

sensing. In this section, we discuss a few representative FDM applications: specifically, the analog carrier system, the NTSC TV broadcast system, and the FM radio broadcast system.

Analog Carrier System

In an analog carrier system, *single sideband* (SSB) is adopted to combine multiple voice channels in one medium such as analog microwave and coaxial cable. The frequency of speech can range from approximately 100 Hz to 8 kHz. However, the primary components necessary for speech are contained in the range of 300 to 3400 Hz. Considering the guard band, each voice channel is assigned 4 kHz as its bandwidth. In this section, we represent the spectrum as a triangle, as shown in Figure 13. The voice spectrum is marked by the gray area in the figure. Representing the spectrum by a triangle makes it easy to locate the low- and high-frequency components simply by their spectral

Figure 13: Spectrum of one voice channel

Table 5: FDM Multiplex Levels

Level	Capacity (Channels)
Group	12
Basic supergroup	60
Basic mastergroup	300
Basic supermastergroup	900

densities. In Figure 13, the low-frequency component has small spectral density, and the high-frequency component has large density. This is normally not true in reality, but the representation is convenient in illustrating the multiplexing scheme in the analog carrier system. For example, we can easily identify the two sidebands of a modulated signal based on the shapes of their spectra.

The U.S. carrier system was initiated by the American Telephone and Telegraph (AT&T) and the ITU-T (originally the CCITT, Consultative Committee on International Telegraph and Telegraph). They are responsible for the

international standard for the FDM hierarchy. In this section, we will focus on the hierarchy specified by the ITU-T. Table 5 lists a few hierarchies in the ITU-T recommendations (ITU-T 1993). The FDM hierarchy ranges from a single voice channel up to a basic super master group as illustrated in Figure 14.

The basic group is composed of twelve voice channels, as shown in Figure 15. The basic group occupies 48 kHz of bandwidth between 60 kHz and 108 kHz. Single side-band suppressed carrier modulation is utilized. In an ITU-T recommendation (ITU-T 1993), the lower sidebands are universally selected.

Five basic groups are translated up to a higher frequency range, and they become the basic supergroup. As shown in Figure 16, the carrier frequencies are 420 kHz for group 1, 468 kHz for group 2, 516 kHz for group 3, 564 kHz for group 4, and 612 kHz for group 5. The basic supergroup occupies 240 kHz of bandwidth between 312 kHz and 552 kHz.

Similarly, one basic mastergroup contains five supergroups. Figure 17 shows the formation of a mastergroup. There is a guard band of 8 kHz between adjacent supergroups. For example, the upper band of the first modulated supergroup is 1052 kHz, and the lower band of the second modulated supergroup is 1060 kHz, leaving 8 kHz in between. Consequently, each basic mastergroup takes a total of 1232 kHz bandwidth between 812 kHz and 2044 kHz.

The multiplexing procedure for the supermastergroup is shown in Figure 18. It is composed of three mastergroups and occupies the band between 8516 kHz and 12,388 kHz. Each mastergroup takes 1232 kHz, and there

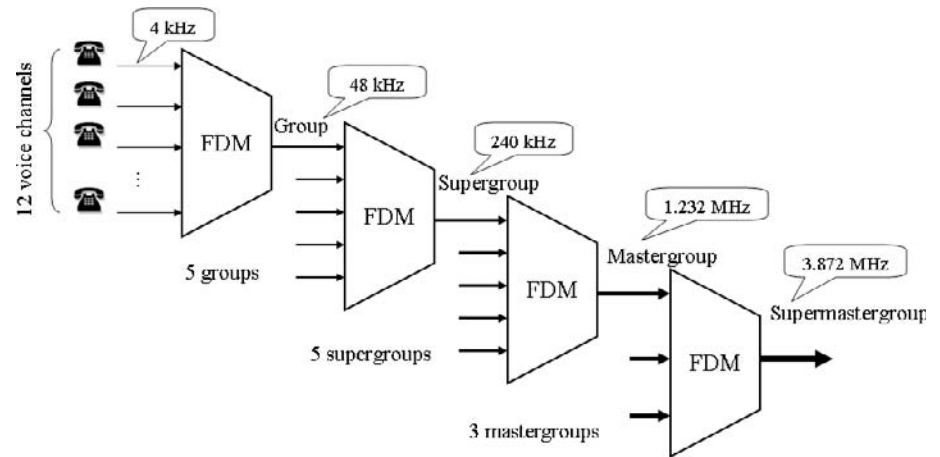

Figure 14: DFM hierarchy

Figure 15: The ITU-T basic group

Figure 16: Formation of supergroup (ITU-T G.233)

Figure 17: Formation of mastergroup (ITU-T G.233)

is a guard band of 88 kHz between adjacent mastergroups. The carrier frequencies are 10,560 kHz, 11,880 kHz, and 13,200 kHz, respectively.

In the U.S. telephone network, there are more multiplex levels (Minoli 2003). For example, AR6A level has the capacity of 6000 voice channels, L5 level has 10,800, and L5E has 13,200 voice channels. Although the analog carrier system had dominated the global telephone network for many decades, it has given way to the recent digital technology.

NTSC TV Broadcast System

There are three major analog television systems: *National Television System Committee* (NTSC), *phase alternating*

line (PAL), and *sequential color with memory* (séquential colour avec mémoire, or SECAM). Figure 19 shows the geographical distribution of the three systems around the world (Wikipedia undated). NTSC is the committee that developed the television standards for the United States, which are also used in Canada, Japan, South Korea, and several Central and South American countries. Both the committee and the standard are called NTSC. In this section, we focus on the spectrum structure of the NTSC channel and the FDM scheme in the NTSC system.

In a television set, color pictures are displayed by producing the three primary colors, red (R), green (G), and blue (B). For the purpose of efficient transmission and backward compatibility to the black-and-white television system, the RGB components in the NTSC system are

Figure 18: Formation of super-mastergroup (ITU-T G.233)

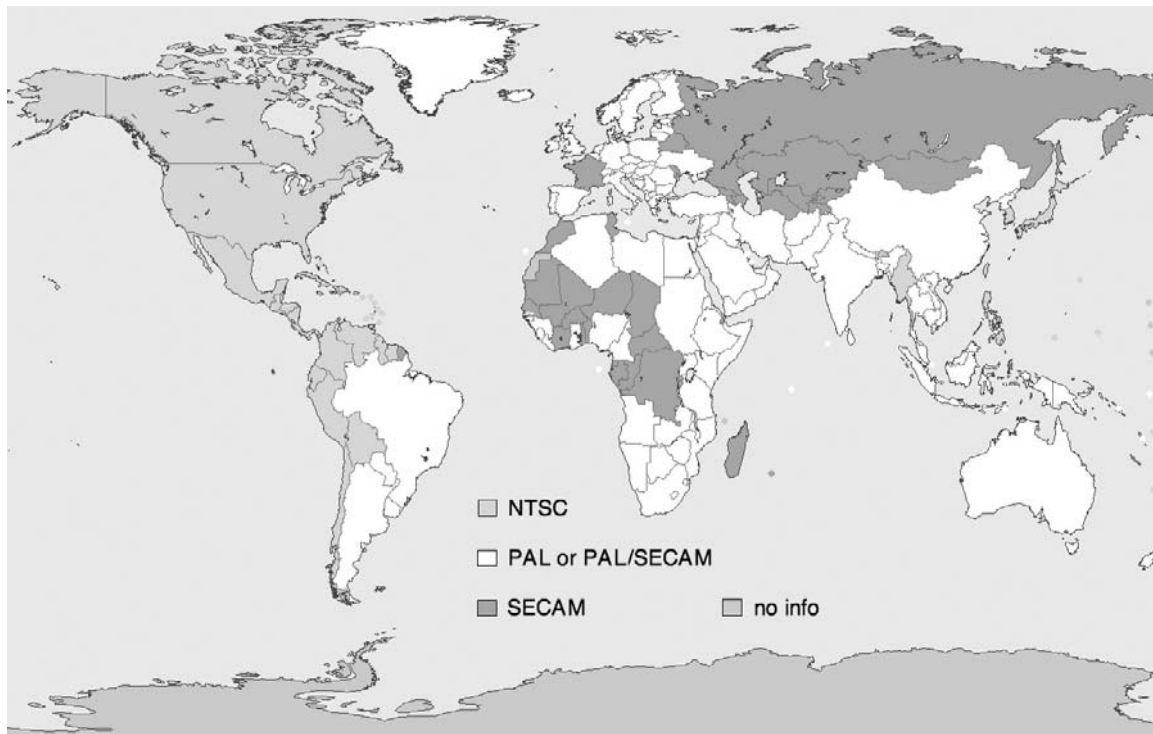

Figure 19: The global distribution of NTSC, PAL, and SECAM systems

transformed into one luminance component, Y , and two chrominance components I (orange-cyan balance) and Q (green-magenta balance). I and Q components have the virtue of requiring much less bandwidth for subjectively acceptable picture quality than the Y component. Y component takes 4.2 MHz bandwidth, but very good picture rendition can be achieved in most cases with I and Q band-limited to 1.4 MHz and 0.5 MHz, respectively (Netravali and Haskell 1995).

Figure 20 shows how the video signal and audio signals are multiplexed into a 6 MHz bandwidth. The Y component is modulated using vestigial sideband AM. Each sideband of the Y component is 4.2 MHz wide, and the entire upper sideband and only 750 kHz of the lower

sideband are transmitted. The video carrier is 1.25 MHz above the lower bound of the channel. The I and Q components are *quadrature amplitude modulated* (QAM) with suppressed carrier. QAM is a modulation scheme that modulates two carrier waves by the information signals. These two waves, usually a sine and a cosine signal with the same frequency, are called *quadrature carriers*. The color subcarrier is 4.79545 MHz above the lower bound. The modulated I signal covers from -1.5 MHz to $+0.5$ MHz from the color subcarrier, sent as double sideband; and the modulated Q signal covers from -0.5 MHz to $+0.5$ MHz from the subcarrier, also sent as double sideband. The audio signal is frequency modulated at the highest 250 kHz of each channel. The main audio carrier is

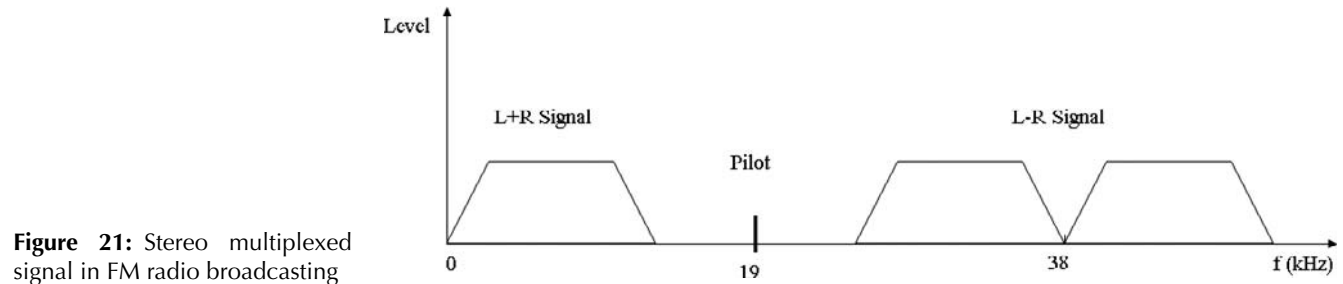

Figure 21: Stereo multiplexed signal in FM radio broadcasting

The stereo multiplexing system has been further extended to add an extra, even higher frequency 57 kHz subcarrier (the third harmonic of the pilot), which is used to carry low-bandwidth digital radio data system information, allowing digitally controlled radios to provide extra features.

Normally, the content of FM broadcasting is speech and music, and their spectrum energy concentrates at the low frequencies within the baseband. The noise power spectral density at the output of the FM demodulator is proportional to the square of the frequency (Stremmer 1990) with the effect that noise dominates at the high frequencies within the baseband. This deteriorates the signal-to-noise ratio for the high-frequency band. One technique to solve this problem is pre-emphasizing the high-frequency components of the audio or music signals

before transmission and de-emphasizing the high-frequency components after receiving, such that the high-frequency noise is effectively reduced without affecting the fidelity of the original audio signal.

CONCLUSION

In this chapter, we presented the frequency division multiplexing technology. To give a reasonably complete and in-depth coverage of this topic, we introduced the underlying theories, including the basic Fourier transform, amplitude modulation, and frequency modulation; described the principles of FDM; and discussed three exemplary applications of FDM—the analog carrier telephone network, the TV broadcast system, and the FM radio broadcast system.

Figure 22: Bessel functions of the first kind, $J_n(x)$, with $n = 0, 1, 2$, and 3

FDM technologies have enabled a wide range of historical and modern telecommunication systems, and hence significantly affected our daily lives and contributed to the civilization of the human being. Surely, FDM will continue to serve as the basis for many new communication technologies and services in the future.

APPENDIX: BESSEL FUNCTION OF THE FIRST KIND

Bessel functions of the first kind, denoted by $J_n(x)$, are defined as the solutions to the Bessel differential equation

$$x^2 \frac{d^2 y}{dx^2} + x \frac{dy}{dx} + (x^2 - n^2)y = 0$$

which are nonsingular at the origin. They can also be represented by their Taylor series expansions around $x = 0$,

$$J_n(x) = \sum_{m=0}^{\infty} \frac{(-1)^m \left(\frac{x}{2}\right)^{n+2m}}{m!(m+n)!}$$

Figure 22 illustrates $J_n(x)$ with $n = 0, 1, 2$, and 3 .

The following are a few useful properties of Bessel functions of the first kind when n is an integer.

1. Relationship of $J_n(x)$ and $J_{-n}(x)$:

$$J_{-n}(x) = (-1)^n J_n(x)$$

2. Sum identity:

$$\sum_{n=-\infty}^{\infty} J_n(x) = 1, \quad \text{for } \forall x$$

3. Approximation when x is small ($x \rightarrow 0$):

$$\begin{aligned} J_0(x) &\approx 1 \\ J_1(x) &\approx x/2 \\ J_n(x) &\approx 0, n > 1 \end{aligned}$$

4. Derivative identity:

$$\frac{d}{dx} [x^n J_n(x)] = x^n J_{n-1}(x)$$

For an in-depth discussion about the Bessel functions, please refer to Cantrell (2000).

GLOSSARY

Amplitude modulation: A process of varying a carrier signal in which the amplitude of the carrier varies relative to the information signal.

Analog carrier system: A system that transmits more than one voice channel over a wideband path by modulating each channel on a different carrier frequency.

Carrier signal: Normally, a single frequency signal that can be modulated to carry analog or digital signal information.

Frequency division multiple access (FDMA): A technology that enables multiple users to share a physical communication channel by frequency division multiplexing.

Frequency division multiplexing (FDM): A technique in which the available bandwidth of a transmission channel is divided by frequency into narrower bands such that each band is used for a separate voice, video, or data transmission.

Frequency modulation (FM): A process of varying a carrier signal in which the instantaneous frequency of the carrier varies relative to the information signal.

Modulation: A process of varying a carrier signal in order to convey information.

Multiplexing: A process in which multiple information signals are combined for transmission in one physical channel.

National Television System Committee (NTSC): The committee that developed the television standards for the United States and which are also used in Canada, Japan, South Korea, and several Central and South American countries. Both the committee and the standard are referred to by *NTSC*.

INTRODUCTION

Shared Communication Lines

When it comes to data transmissions, most would agree that higher bit rates are better. If you have ever upgraded to a faster computer or disk drive or switched from a dialup Internet connection to broadband or DSL service, then you no doubt discovered that the faster response times helped you work (or play) more efficiently. Some of us old-timers remember when the first 3.5-inch drives became available. The ability to get a file in just a couple of seconds was a wonderful improvement over the 5.25-inch drives. Now with the hard disk drives and flash memory sticks available today, those 3.5 inch disks are all but obsolete.

The same is true of communication networks: Faster is generally better. Speed does have its drawbacks, however. First, it is more expensive; second, there is a point of

diminishing returns. In other words, after a certain point, many users cannot use the increased speed and there is little to gain by further increasing the bit rate capacities. For example, communications links in some networks are now capable of bit rates of more than 1 Gigabit per second (Gbps). However, devices such as telephones and workstations simply do not generate the volume of data necessary to make use of that speed. One might infer from this that developing high-speed networks is therefore not important because most users cannot utilize their full potential. This is not true, however. Suppose the communication network shown in Figure 1 supports a bit rate of 10 Megabits per second (Mbps). If the only activity involves two PCs communicating at that rate, then the network likely serves its purpose. However, if several hundred PCs need to communicate with one another, then the total amount of data that must be transmitted per second will in all likelihood exceed the 10-Mbps rate. Thus, in

Figure 1: Many users communicating over a network

this case, the 10-Mbps limit creates a serious bottleneck. Increasing the bit rate will reduce that bottleneck.

A good analogy is a road through a large city. If there were only a few cars using it, then a single lane road would be sufficient. If, however, during rush hour the road is shared by many more vehicles, then there is a need to move them quickly. Consequently, the vehicle-carrying capacity of a single lane becomes insufficient and multiple lanes are required to increase the capacity. Similarly, communication links in a network are shared by many, and there is a need to move far more data than can be generated by a single workstation.

Multiplexer

Now that we have established the need for high-speed capabilities to transmit data from many devices, we must connect those devices to the network. One could provide a high-speed connection between a communications network and every device that uses it. It would be a little like building multilane highways directly to everyone's house. However, the cost of doing this is not justified. One approach is to develop high-speed communication networks but somehow reduce the cost of connecting devices to them by using links with lower bit rates. Because many devices do not require high bit rates, those links should service the devices just fine. However, defining connections to the network for each possible device becomes an issue. In Figure 1, each device has a separate connection to the network. Figure 2 shows an alternative using a *multiplexer* (sometimes called *MUX*), a device that combines transmissions from multiple sources onto a single communications link. These devices could be telephones, workstations, cable TV stations broadcasting TV signals, or any of a variety of devices capable of sending and receiving information. The multiplexer may also route transmissions in the reverse direction—that is, from the network to any of the devices.

In general, a multiplexer's output line to the network has a much higher bit rate than any of the input lines from the sources. This way it can utilize the network's high bit rate and, by providing a single connection for multiple users, provide a more efficient way for multiple users to connect to the network.

There are several forms of multiplexing. One is *frequency division multiplexing*; it deals with analog signals

such as those in an analog cable television network. It works by modulating different analog signals onto different frequency ranges and producing a single but more complex analog signal consisting of frequencies from all the different ranges. This technique is discussed in "Frequency Division Multiplexing (FDM)." Another form is *wavelength division multiplexing* and works by combining multiple optical signals, each with a different wavelength of light, into a different optical signal consisting of the combined wavelengths. It is typically used for transmission over an optical fiber. "Wavelength Division Multiplexing (WDM)" discusses this approach. There is also *optical multiplexing*; as the name suggests, it deals with the combining of optical signals (see "Synchronous Optical Code Division Multiplexing Systems"). The focus of this chapter is on time division multiplexing, which works primarily by combining digital data from different sources into a common bit stream.

TIME DIVISION MULTIPLEXERS

Basic Operations

A *time division multiplexer* (TDM) will interpret its inputs as a collection of *bit streams*. These bits are then combined and transmitted together. Figure 3a illustrates the basic process. Suppose A, B, C, and D represent bit streams from distinct sources headed into the multiplexer. The multiplexer scans each input line, grabs some bits from each line, combines them into a single bit stream, and then sends the stream over the output line. As the bits are being sent, the TDM repeats the process by grabbing more bits from each of the input lines and then combines and transmits them as soon as the previous bits have been sent. If the timing is right, the multiplexer will grab more bits just in time to transmit them immediately following the previous ones. This process keeps the output line active and makes full use of its capacity. Each group of bits is allocated a small amount of time for transmission over the output line, hence the term *time division multiplexing*.

Because the bit groups came from different sources, it is logical to assume they each have different destinations and that the multiplexer has a companion device on the other end of the transmission line. Figure 3b shows the device called a *demultiplexer* accepting a single bit stream from its input, extracting substreams of bits as they arrive, and routing the substreams out along different output lines. As with the multiplexer, timing is an issue. If the timing is right, a substream of bits destined for the first output line arrives just as the demultiplexer routes the previous substream over the last output line.

Bit-Interleaved Multiplexers

Although the previous discussion outlines the general approach to multiplexers, there are different types of multiplexers. For example, a *bit-interleaved multiplexer* will take one bit at a time from each input line and combine them before transmitting them over the output line. Figure 4 shows an example. One bit from each stream is taken from each input line and transmitted one after another. The spaces between each set of four bits are

Figure 2: Multiplexing low-speed devices onto a high-speed network

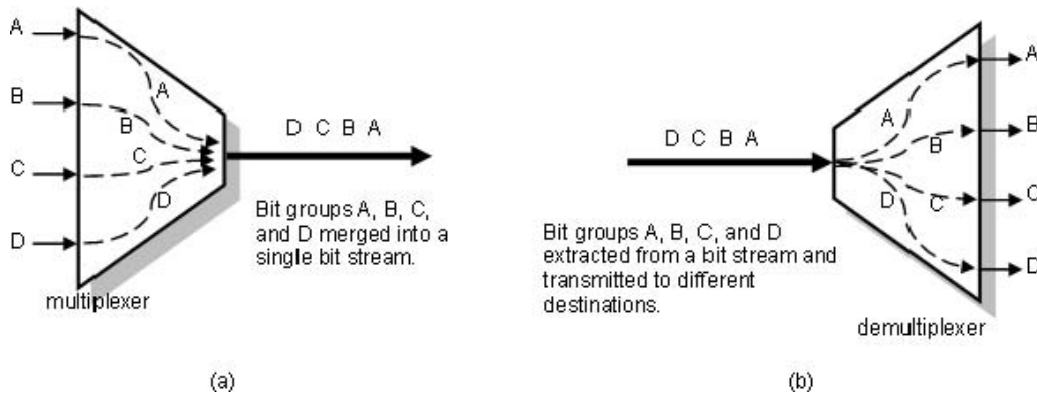

Figure 3: Merging bit groups from multiple sources into a single frame for transmission

Figure 4: Bit-interleaved multiplexing—one bit from each input line is combined into a common stream

Figure 5: Byte-interleaved multiplexing

inserted there for clarity. The main idea is that the rightmost group, 0101, consists of the rightmost bits from each input stream. The adjacent group to the left consists of the second rightmost bits from each input stream. This pattern continues for each group.

Bit-interleaved multiplexing tends to be efficient and requires little buffering capabilities, in contrast to other forms described shortly. However, bit-interleaved multiplexing is not usually the best match for many microprocessor-based devices, whose data are organized by bytes. However, a few applications use the technology. For example, Tsukada et al. (1996) describe an application for bit-interleaved multiplexing in the design of photonic ATM switches. Bit-interleaved multiplexing is also used in the T-carrier system. We discuss T-carrier system later, and Goralski (2002) also provides a more detailed discussion of the technology.

Byte-Interleaved Multiplexers

Byte-interleaved multiplexing works in a similar fashion except that a full byte is transferred from an input line to the output line between bytes from adjacent lines. For example, suppose the inputs in Figure 5 are expressed in hexadecimal format. Then every two hexadecimal digits represent one byte. The multiplexer routes one byte from an input line to the output line before getting the byte from the next input line. Byte-interleaved multiplexing is also used in the previously mentioned T-carrier system. However, we need to present additional topics before we describe its use.

Framing

A common approach in multiplexing involves framing the output. In other words, data that are transmitted over the output line are placed into a *frame*, a unit of transmission that is consistent with the protocol governing the output line. Figure 6 illustrates how this works. The bit streams A_1 , B_1 , C_1 , and D_1 enter the multiplexer through different input lines. The multiplexer creates a frame with those bits as input and then transmits the frame over the outgoing line. It then gathers A_2 , B_2 , C_2 , and D_2 , creates another frame, and sends it. The process continues as long as the sources are providing bit streams for the outgoing frames.

Transmission Rates

An important part of the multiplexer's design depends in part on the input and output transmission rates. How quickly should the multiplexer transmit bits over the outgoing line? For example, suppose data from a source arrive at a rate of 10 Mbps. If the multiplexer transmits them at the same rate, there is a problem because bits from other inputs are also arriving, thus making the combined input bit rate much larger than 10 Mbps. If there were ten such inputs, then the combined bits arrive at the multiplexer at a rate of 100 Mbps and the multiplexer should be able to send them at that same rate.

In general, if source bits from the combined inputs arrive faster than the previous frame can be sent, then frames are generated more quickly than they can be forwarded. If the multiplexer has no capacity to store the extra frames, then there will be problems. Input lines must

Figure 6: Framing TDM output

not provide the multiplexer with information faster than it can release the information without some type of buffering capacity. On the other hand, if the source bits arrive too slowly, then the previous frame will have been sent and the multiplexer either waits for enough bits to arrive or sends a frame that is only partially full. Either way, the output line is not used to its fullest capacity.

An ideal situation occurs when the combined input rate (the sum of bit rates from each source) equals the output bit rate. For example, suppose that there are n sources, r_i is the input rate from the i th source, and r_{output} is the bit rate of the output line. Mathematically, we express this as

$$\sum_{i=1}^n r_i = r_{output}$$

This is consistent with our previous example of ten ($n = 10$) inputs, each with a 10-Mbps rate, and one output line with a rate of 100 Mbps. However, we will discuss an alternative shortly.

Synchronous TDM

There are two different types of TDMs, and we introduce one here: *synchronous TDM*. However, we must first define the concept of a time slice. A *time slice* is a portion of the outgoing frame that is reserved specifically for data from one of the input lines. A synchronous TDM is a multiplexer that reserves a time slice for each input line, thus guaranteeing that every outgoing frame will carry some data from each input line, assuming that such data are available. In Figure 6, each frame consists of four time slices, each containing bits from one of the four input lines. Furthermore, those slices are guaranteed. For example, as long as there are bits arriving from the first input line, some of them are guaranteed to go out with each departing frame. Similar comments can be made for each of the other input lines.

Synchronous TDMs have an important advantage in applications where a certain amount of bandwidth between two points must be guaranteed to meet the needs of the application. Perhaps the most visible example is the infrastructure that we know as the telephone system. Making a telephone call involves establishing a real-time connection between two telephones. The underlying

hardware ensures that digitized voice data will travel between numerous pairs of telephones simultaneously with almost no noticeable delays. It does this, in part, by using synchronous TDMs that guarantee that each link in the path between two phones is able to carry part of the telephone conversation with every frame it transmits. This provides for a smooth and consistent flow of voice data without the delays that buffering data at intermediate sites might cause. Note the contrast with performance you may have observed while downloading large files where the rate of arriving data increases and decreases over time. We will describe additional details of this process later in this chapter.

Variable Input Rates

Not all multiplexers operate in as simple an environment as we have described. Sometimes there is an issue that deals with the relative rates of input lines with respect to each other. The previous scenario has assumed that bits arrive from all sources at the same rate. Under this assumption, each source is assigned to one time slice inside of each frame. However, what if the rates among the input lines differ? For example, what if the bits from the first source, A, arrive at a rate twice that of all the other sources? In such a case, the process shown in Figure 6 does not work well. When all the bits in A₁ arrive, only one-half of the bits from each of groups B₁, C₁, and D₁ have arrived; the multiplexer cannot fill the time slices associated with those groups. One approach is to simply transmit the frame with the time slots reserved for groups B, C, and D only half full. This, of course, underutilizes the outgoing bandwidth capacity.

Figure 7 shows another way to deal with this situation. Because the bit rate of the first input line is twice that of each of the other lines, the multiplexer receives bit groups A₁ and A₂ in the same amount of time that it receives B₁, C₁, and D₁. Because the multiplexer has these five bit groups, it can allocate five time slices of the outgoing frame, one for each group. Thus, A₁ and A₂ occupy two consecutive time slices but otherwise occupy the same frame as B₁, C₁, and D₁. Similarly, bit groups A₃ and A₄ occupy the same frame as B₂, C₂, and D₂, and so on.

However, even this example does not cover all cases. The assumption that the first input had a rate twice that of the others was convenient. However, what if the rate

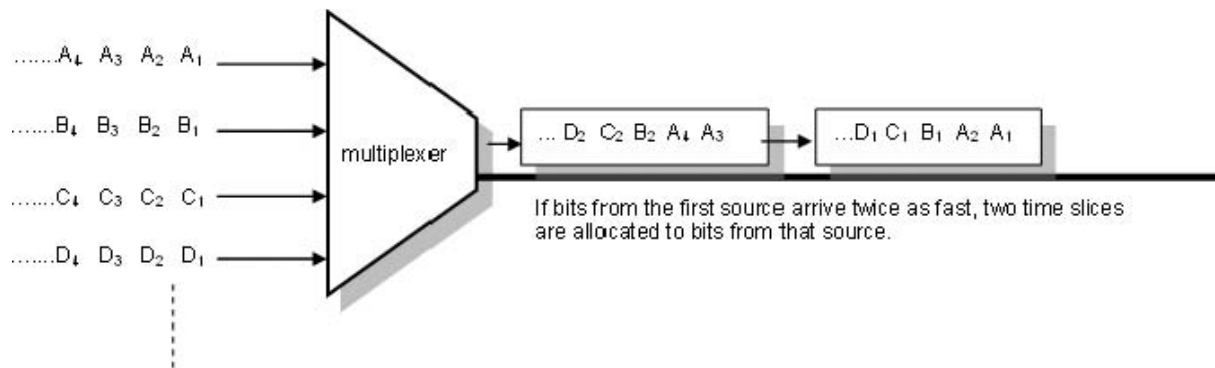

Figure 7: Framing data assuming different input rates

from source A was 1.4 times that of the others? As before, when the first bit group from A arrives, there is still an insufficient number of bits from the other groups to fill the respective time slices. If the TDM waits for the other bit groups to arrive, then there are too many bits from source A to fill one time slice but not enough to fill two time slices. One approach to this problem is for the TDM to perform *bit stuffing*, sometimes called *bit padding*. This means the TDM will fill as many time slices in a frame as is possible for the fastest input line. If the last time slice is not full, then the TDM will insert extra bits so that the time slice has the same number of bits as the other slices. These bits are not part of the data flow and are there solely to maintain a constant size for all the time slices in the frame. At the opposite end, the demultiplexer removes the padded bits and discards them. For example, assuming that A provided bits at 1.4 times the rate of other sources, then bits from A would fill the first time slice but only 40 percent of the second. The remaining 60 percent of that slice would consist of padded bits.

Inactive Input Lines

There are still other scenarios we have not mentioned. The discussion so far has assumed the input lines are always transmitting bits. As long as bits are arriving on an input line, the time slices in the outgoing frame are occupied, even if only partially. However, a logical question to ask is, What if there are no bits arriving on a particular input? One approach is to simply do bit stuffing in an entire time slice (or more if several lines are quiet). In such cases, the number of meaningful bits transmitted per unit of time may fall well below the bit rate of the outgoing line and the line becomes underutilized. In an extreme case, the number of stuffed bits could actually be larger than the number of data bits.

In response, another alternative is to increase n , the number of input lines, so that

$$\sum_{i=1}^n r_i > r_{\text{output}}$$

Although the bits would then potentially be arriving faster than they can be sent, such designs are used in cases where it is expected that some of the inputs will generally

be inactive and that active lines would produce bits at a rate comparable to r_{output} . Of course, these multiplexers must also be designed to account for periodic bursts where, for short periods of time, they can handle the extra bits. This may involve buffering the input streams and creating variable-sized frames. Such a device is called a *statistical multiplexer*. Some variations are called *concentrators* or *asynchronous TDMs*.

In general, a statistical multiplexer will allocate a time slice of an outgoing frame to whatever input line needs it. Data from different inputs may occupy different time slices in the outgoing frame. Furthermore, there is no guarantee that arriving input will be sent out with the next outgoing frame. If there is a surge of activity, then the input may have to be buffered until another outgoing frame can accommodate it, thus causing a delay in the transmission of the data. Note the contrast with synchronous TDMs that guarantee that a part of every outgoing frame is reserved for data from each of its inputs. The potential delay in the transmission is a disadvantage in systems where data must be transmitted in timely fashion without delay. On the other hand, it is useful in cases where data transfer is bursty such as with the Internet. For example, there may be periods of high transfer rates if a PC is downloading a large file and periods of extremely low rates if the PCs user is casually following Web links. In such cases, the TDM can handle a larger number of input lines than a synchronous TDM could. Other examples include *point-of-sales* terminal (cash registers) in stores, remote meters, and even lottery or gaming machines.

An analysis of statistical multiplexers can be difficult because of the random way in which the sources send data. Many questions must be answered. How frequently will the combined input rates exceed the output rate? How often will all sources be busy? How large must the internal buffers be to handle temporary surges? Because data from different input lines may occupy different times slices, how does the demultiplexer know how to handle them? How long are the delays when surges occur? One approach to the analysis uses *queuing theory*, a field of mathematics that defines models for studying events such as waiting in lines (queues) for events to occur. It can be applied to many areas, including communications systems in which input streams may arrive in random patterns. In such cases, the events are the transmissions over the output lines. Stallings (2004), Walrand (2000), and Martin (1972)

contain introductory discussions of queuing theory. Also, because statistical time division multiplexing is the topic of the chapter “Statistical Time Division Multiplexing (STDM),” we will not discuss it further here.

T-CARRIER SYSTEM

Our next step is to describe a common environment in which TDMs are used. Much of what we think of as the telephone system was designed to transmit digitized voice signals over high-speed media such as optical fiber or microwaves. In fact, years ago AT&T developed a complex hierarchy of communications systems used to multiplex voice and data signals and transmit them all over the United States. The *T-carrier system* is used primarily in North America and Japan. European countries and most of the rest of the world use a similar but different system known as the *E-carrier system*.

History

The history of the T-Carrier System dates back to the 1960s when AT&T developed the technology to deal with the growing number of telephone users. As new homes were built, telephone wires had to be installed between them and the existing central offices of the local phone company. As neighborhoods grew, there was a need for additional central offices to accommodate them, and communication links had to be established between central offices. Rather than provide wires for all of the new users, AT&T needed a better way to route all of the customers' phone calls between central offices. This was the beginning of what is known as the *T1 line*.

T1

The T-carrier system consists in part of a synchronous byte-interleaved multiplexer that combines digital signals from twenty-four different sources into a common frame called a *digital signal 1 (DS-1) frame* (Figure 8). This frame is then transmitted over a T1 line. The T1 multiplexer takes eight bits at a time from each source and places each eight-bit group into a time slice of the outgoing DS-1 frame. This time slice defines a channel between a specific source and destination. If the source and destinations are telephones, then each time slice in effect transmits part of a telephone conversation between those phones. In such cases, the T1 multiplexer is sometimes called a *T1 channel bank*.

In addition to the twenty-four channels, the frame contains an extra bit, called a *framing bit*, at the beginning of each frame. Thus, each frame contains $24 \times 8 + 1 = 193$ bits. The framing bit allows the demultiplexer to determine the beginning of the frame and, consequently, identify the exact location of each channel inside the frame so that it may extract those bits and route them appropriately. The framing bit also has other functions that we describe shortly.

Figure 9 provides one possible context for using a T1 carrier system. At each source is a telephone. The telephone generates an analog signal that represents the sound of the person's voice. However, because most of the telephone system is digital, the analog signals must be converted to a digital representation. A device called a *codec* does this. It will sample the analog signal at a rate of 8000 samples per second using a method called *pulse code modulation* to take the samples. Depending on the signal's characteristics at the time of the sample, the codec generates eight bits that are then transmitted to the multiplexer.

The reason for the sampling rate of 8000 samples per second results from the well-known Nyquist theorem (Forouzan 2007), which states that an analog signal can be reconstructed from its digital representation if samples are taken at a rate at least twice that of the signal's highest frequency. Because 4000 Hz is at the upper end of the telephone's bandwidth range, a sampling rate of 8000 times per second is used.

Each eight-bit sample then occupies one time slice in the DS-1 frame, and consecutive samples from the same source are stored in successive DS-1 frames. The voice messages are thus transmitted using many DS-1 frames to a demultiplexer. This demultiplexer extracts the bits from each time slice and routes them toward their appropriate destination, where they eventually are converted back to analog signals that represent the sound of a person's voice. The net effect is that up to twenty-four phone conversations are transmitted over the same T1 line using the channels in a DS-1 frame.

We stated previously that the bit rate of a synchronous multiplexer's output must be able to accommodate the combined rates of the input lines. Each eight-bit sample is generated at a rate of 8000 samples per second, yielding a bit rate of 64 kbps. To support this speed, T1 must transmit a DS-1 frame every $1/8000$ of a second, or 8000 frames per second. In other words, it must transmit 8000×193 bits each second for a bit rate of 1.544 Mbps. However, because one bit for each frame is overhead, the

Figure 8: A 193-bit DS-1 frame

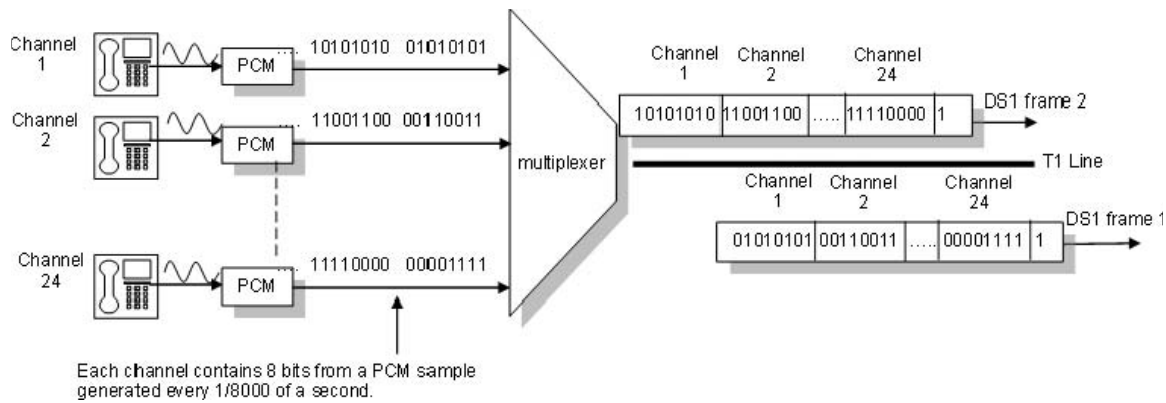

Figure 9: T1 carrier system

bit rate to move real data (also called *payload data*) is actually reduced by 8 kbps to 1.536 Mbps.

Superframe and Extended Superframe Format

Typical implementations of T1 actually combine multiple DS-1 frames into a larger frame structure to facilitate administration and synchronization. In fact, there are two different framing techniques in which multiple DS-1 frames are combined into either a *superframe* (SF) or *extended superframe* (ESF) format. A superframe consists of twelve DS-1 frames as shown in Figure 10; the process of creating it is called *D-4 framing*. However, not all DS-1 frames are the same. For example, the framing bits from the twelve frames occur in the pattern 1-0-0-0-1-1-0-1-1-0-0. Although this bit pattern may seem arbitrary, there is a reason for it. Inside a superframe, the framing bits are divided into two categories. The framing bits from each of the odd-numbered frames are *terminal framing* bits and occur in the pattern 1-0-1-0-1-0. The receiving demultiplexer knows the pattern and uses the alternating sequence to keep the frames and, of course, the channels synchronized.

The framing bits in even-numbered frames are *signal framing* bits and occur in the pattern 0-0-1-1-1-0. In this case, the transition of a signal framing bit from a 0 to a 1 (or vice versa) is significant. For example, the signal framing bit changes from 0 to 1 in the sixth frame and from a 1 to a 0 in the twelfth frame and identifies those frames as ones that carry additional control information. Superframes store that information in the least significant bits

of each of the twenty-four channels in both the sixth and twelfth frames. This means that two bits can be used to describe the status of each channel for each superframe. For example, if the channel corresponds to a telephone connection, then the bits can specify whether either phone is “on-hook” or “off-hook.” The use of these bits for control removes a small part of the voice data. This process is called *bit robbing* but has little effect in cases where the data are a voice signal.

The ESF is similar to the SF and was designed to provide more functionality and control information such as error detection and maintenance communication. It also makes use of more advanced technology so that fewer synchronization bits are needed. One difference from the SF format is that the ESF consists of twenty-four DS-1 frames instead of twelve. Another difference is in how the 193rd bit in each of the twenty-four DS-1 frames is used. Of those twenty-four bits, only six are used for synchronization; they appear in frames 4, 8, 12, 16, 20, and 24. Six more bits (from frames 2, 6, 10, 14, 18, and 22) are used for *cyclic redundancy check* (CRC). These bits are calculated from existing data and are used to detect transmission errors. More information about CRC can be found in Shay (2004). The remaining twelve bits from the odd-numbered frames define an administrative channel that is used to communicate performance information and alarms (problems on the T1 line).

Like the SF format, the ESF also uses bit robbing from DS-1 frames 6, 12, 18, and 24. Using more bits than in the SF format allows more options in describing the status of each channel. To be sure, the details of T1 are complex and impossible to cover in this chapter. Additional

Terminal Frame alignment bit pattern (first bit in each odd numbered frames): 1-0-1-0-1-0

information may be found in Hajbandeh (2000) and is also available from Wikipedia (undated, “Digital signal 1”) and NComm (2001).

Plesiochronous Digital Hierarchy

The T1 rate of 1.544 Mbps is slow when compared with the capabilities of optical fibers and the needs for high-speed traffic along the backbone of a communications network. However, T1 is only one part of a digital hierarchy of services known as the *plesiochronous digital hierarchy* (PDH). As defined by the ITU-T standard G.702, PDH is designed to transmit large amounts of information over a digital transport infrastructure. The standard specifies additional carrier and signal designations with more channels and faster bit rates. Figure 11 shows how the carriers and channels relate, and Table 1 lists the designations, number of channels, and bit rates for each.

According to Figure 11, four T1 lines enter a T2 multiplexer, which multiplexes them to generate a DS-2 frame, and then transmits the frame on the outgoing T2 line. There are important differences between multiplexing at this level and the previous one. First, the DS-2 frame is formed by bit multiplexing the incoming data from T1 lines. Second, the multiplexer also adds control bits to the T2 line at the rate of 136 kbps. These control bits perform similar functions as previously mentioned, distinguishing between successive DS-2 frames, but also include stuffed bits to account for any differences in the timing of incoming DS-1 signals. Four DS-1 frames collectively provide input at a rate of $4 \times 1.544 = 6.176$ Mbps. Add

the overhead of 136 kbps, and the required bit rate of a T2 line is 6.312 Mbps.

Proceeding in similar fashion, seven T2 lines are input to another bit-interleaved multiplexer, which generates a DS-3 frame on an outgoing T3 line. This multiplexer adds another 552 kbps of overhead, pushing the required bit rate of a T3 line to $7 \times 6.312 \text{ Mbps} + 552 \text{ kbps} = 44.736 \text{ Mbps}$. Finally, the last multiplexer combines the data from six T3 lines into a DS-4 frame, adds yet more overhead bits, and sends them over a T4 line at a rate of 274.176 Mbps.

The exact format of the various frames and the specifics of all the overhead and control bits are beyond what this chapter can cover. For those who are interested, more information is available in Goralski (2002), Cisco Systems (2004), Juniper Networks (1998), and Digital Link (1996).

As mentioned previously, this system is used in North America and Japan. However, most of the rest of the world uses the E-carrier system (“E” for European) that, although similar in concept, is incompatible to the T-carrier system. For example, where T1 defines twenty-four 8-bit channels and a bit rate of 1.544 Mbps, E1 defines thirty-two 8-bit channels and a bit rate of 2.048 Mbps. It also provides methods similar to T1 for synchronization and conveying channel status. This standard also groups multiple E1 frames together into a multiframe format, but we will not elaborate on specifics. Also, as with the T-carrier system, there is a hierarchy defined by different levels of multiplexing. Table 2 shows the designations and rates at each of the levels.

Table 1: ITU G.702 PDH Specifications

Carrier	Frame designator	Number of channels	Transmission rate (Mbps)
T1	DS-1	24	1.544
T2	DS-2	96	6.312
T3	DS-3	672	44.736
T4	DS-4	4032	274.176

Table 2: E-Carrier Service

Carrier	Number of channels	Transmission rate (Mbps)
E1	30	2.048
E2	120	8.448
E3	480	34.368
E4	1920	139.264

SONET AND SDH

PDH and the E-carrier system are by no means the only digital carrier systems. In fact, before the breakup of AT&T in 1984, each telephone company had its own TDM technology. After 1984, local companies had to interface with multiple long-distance providers, which generated a need to develop standards. One standard that grew from this need is the *synchronous optical network* (SONET) developed by Bellcore (Bell Communications Research). It is described by ANSI standards T1.105, T1.106, and T1.117. Yet another system is the *synchronous digital hierarchy* (SDH) defined by ITU-T standard G.707, G.708, and G.709. Although there are differences, the two systems share much; at this level, we will make no distinction and simply refer to the technology as SONET-SDH. "SONET/SDH Networks" discusses these technologies, as does Shay (2004), Kularatna (2004), Ramaswami and Sivarajan (2002), Leon-Garcia and Widjaja (2000), Goralski (2002), and Wikipedia (undated, "Synchronous"). However, two components relate to our discussion on time division multiplexing and we describe them here.

Add-Drop Multiplexer

Figure 12 shows a simplified view of the components that make up a SONET-SDH network. One important component in SONET is the *add-drop multiplexer* (ADM). SONET ADMs may form a ring, often connecting points in large metropolitan areas, in a state, or even across a multistate region. The ADM is a synchronous byte-interleaving multiplexer that extracts traffic from outside the ring and merges it with existing traffic already on the ring. An ADM also works in reverse by providing an exit for ring traffic.

Although the term *multiplexer* is used, it is a little different from the time division multiplexer we described previously. The ADM need not multiplex all external signals into a common frame. In fact, a frame may already contain multiplexed data from a previous ADM and may be traveling the ring when it arrives at another ADM. That ADM, in turn, may add data from an external source to that frame. In other words, the entire frame is not multiplexed, just part of it. Demultiplexing works analogously. Some, but not necessarily all, of the data may be extracted from a frame at an ADM and routed elsewhere; it is not

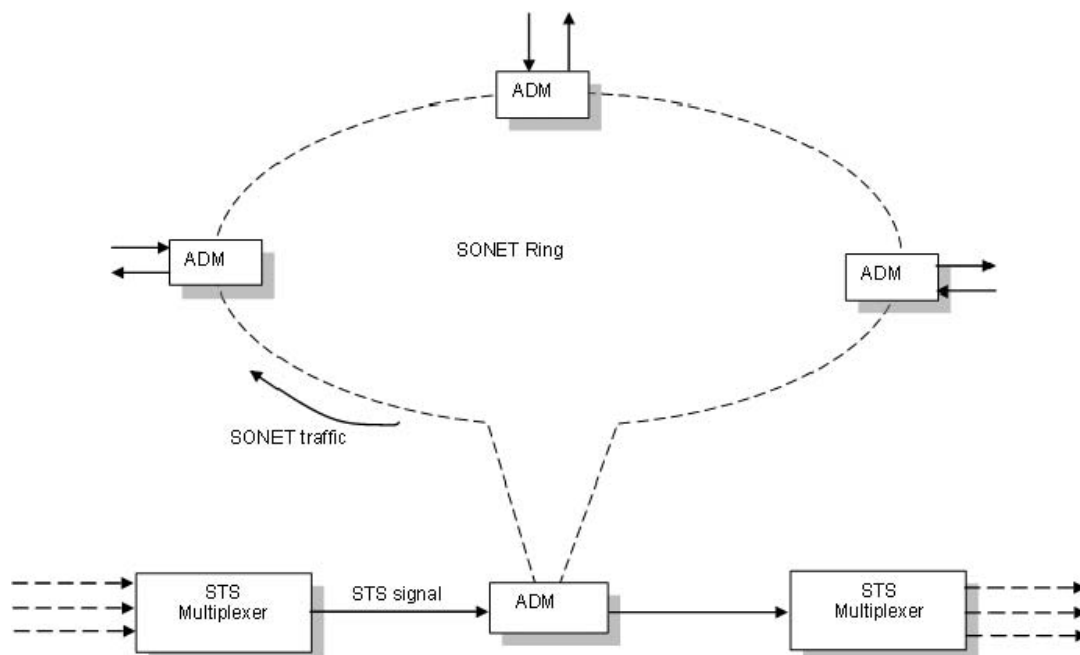

Figure 12: Multiplexing in a SONET network

Table 3: SONET-SDH multiplexing hierarchy

STS level	Optical carrier designation	Bit rate (Mbps)
STS-1	OC-1	51.840
STS-3	OC-3	155.520
STS-12	OC-12	622.080
STS-24	OC-24	1244.160
STS-48	OC-48	2488.320
STS-192	OC-192	9953.280
STS-768	OC-768	39813.120

necessary to demultiplex the entire frame's contents. This is perhaps analogous to a rapid transit system. At the beginning of the run, all passengers board a bus and find a seat (complete multiplexing); at the end, everyone leaves (complete demultiplexing). However, along the route, passengers can board or depart at designated stops (add-drop multiplexing).

SONET-SDH Hierarchy

Just as there is a hierarchy for the T-carrier system, there is one for SONET-SDH also. The basic unit of transmission is the *synchronous transport signal 1* (STS-1) frame, which contains 810 bytes. Each frame is transmitted once every 125 microseconds along an optical fiber line. Lines that carry STS-1 frames have the designation *optical carrier 1* (OC-1). Sometimes, the signal is called an *OC-1 signal*. Previously cited references describe the contents of this frame, and we restrict our attention here to the hierarchy defined by multiplexing slower lines into faster ones.

Bytes from multiple STS-1 frames can be byte-multiplexed into higher level STS- n frames, and each is transmitted over another fiber with a designation of OC- n . The value of n represents the number of STS-1 frames contained by the STS- n frame. Furthermore, because of the synchronous nature of the technology, no additional overhead bits are added as was the case in the T-carrier system. As a result, the bit rate of OC- n signals is obtained by multiplying the bit rate of the OC-1 signal by the value of n . So, for example, the bit rate of an OC-3 signal is three times the bit rate for an OC-1 signal or 3×51.84 Mbps = 155.52 Mbps. The bit rate for an OC-48 signal is $48 \times 51.84 = 2488.32$ Mbps = 2.48832 Gbps. Table 3 summarizes the SONET-SDH rates and designations.

CONCLUSION

In summary, time division multiplexing combines bits from multiple sources into a single bit stream. Bit-interleaved TDMs combine individual bits from multiple sources, and byte-interleaved TDMs combine bytes from multiple sources. Frequently, the multiplexed data are stored in a single transmission unit called a *frame* (the process is called *framing*). Synchronous TDMs guarantee that some data from each input will occupy a time slice of

an outgoing frame. In such cases, the bit rate of the outgoing line must match the combined bit rates of the input lines. In contrast, statistical TDMs do not dedicate a particular time slice in a frame to a given input. Data may be buffered, waiting to be transmitted in a subsequent outgoing frame. Carrier systems that rely on multiplexing are the T-carrier system, E-carrier system, and SONET-SDH. All define a hierarchy of frame types and bit rates and use multiplexing to combine lower bit-rate lines into a single higher bit-rate line. However, the manner in which they perform the multiplexing varies.

GLOSSARY

Add-drop multiplexer: Device used to extract traffic from outside a SONET-SDH ring and merge it with existing traffic already on the ring.

Bit-interleaved multiplexer: The process of routing one bit at a time from each of several inputs and transmitting the bits in sequence over a shared communication line.

Bit rate: Number of bits that can be transmitted per second.

Bit stream: Term used to describe the bit interpretation of an incoming or outgoing electrical or optical signal.

Bit stuffing: Process of inserting extra bits into a frame to fill out a time slice that can only be partially filled.

Byte-interleaved multiplexer: The process of routing one byte at a time from each of several inputs and transmitting the bytes in sequence over a shared communication line.

DS-1 line: A digital signal designator for the transmission of data over a T1 line.

Framing: The process of grouping a bit stream into a physical unit of transmission called a *frame*.

Framing bit: An overhead bit added to a data stream to mark the beginning of a frame and to synchronize the receiver with the frame's time slices.

Plesiochronous digital hierarchy: Standard for a digital service system, defined in part by a hierarchy of multiplexers, each generating signals that are input to the next multiplexer in the hierarchy.

Pulse code modulation: A process that samples analog signals and generates a bit stream dependent on the signal's characteristics.

Synchronization: Making sure that two or more devices use timing that is consistent with each other.

Synchronous time division multiplexer: A multiplexer that reserves a fixed portion of the outgoing frame to data from each of the input lines.

T1 carrier: A digital carrier service with twenty-four channels and a bit rate of 1.544 Mbps.

Time division multiplexing: Process of accepting digital signals from several sources, storing them into a single bit stream, and sending the stream over a communications link.

Time slice: A small amount of time during which bits from a specified source are placed into a frame before transmission.

INTRODUCTION

A communications network is defined by its access components and its local and backbone transport infrastructures. Transmission lines such as copper wire, coaxial cable, optical fiber, microwave, and radio frequency links serve to interconnect these components enabling information transfer to take place over long distances. With the exception of the copper wire pair transmitting analog signals between the telephone and the central office switch, almost all other levels in a network implement digital transmission. In digital networks, access devices convert an analog information signal such as voice or video to digital format through the process of sampling, quantization, and coding. Using digital modulation principles, blocks of digital data are mapped to time waveforms and are propagated over the transmission medium. The transport infrastructure is often hierarchical in design. The transmission capacities of the links progressively increase as one moves from the point of access to the core of the network. Access networks aggregate the traffic generated by individual subscribers for transport over higher-capacity links. Traffic from multiple access networks may be further concentrated at successive stages along the transmission path. The process of traffic concentration, also referred to as *multiplexing*, is integral to network design, allowing network providers achieve economies of scale.

Multiplexing refers to the process of combining multiple information-bearing signals onto a single output line. A multiplexer is composed of a set of input and output channels with associated control circuitry, buffers, and a switching mechanism. This concept emerged in the early 1900s with the evolution of the *public switched telephone network* (PSTN). Major George O. Squier (Schwartz 2004) is credited with inventing the carrier multiplexing of telephone signals, having filed a prominent patent in 1911 titled "Multiplex Telephony and Telegraphy." Subsequently, AT&T developed commercial carrier multiplexing systems that modulated several analog voice signals onto high-frequency carrier signals. Each voice grade channel was allocated a 3-kilohertz signal bandwidth with 500-hertz guard bands on each side and shifted to a unique carrier frequency. Frequency division multiplexing was the basis for the successful increase in the capacity of the AT&T L series carrier coaxial systems. The series that began in 1944 with the L1 system carrying 600

telephone conversations, was followed by the improved 1800-call capacity of the L3 system and ended in the 1970s with the L5 system carrying more than 100,000 circuits that multiplexed both telephone and television signals. The coaxial cable-based L systems in the telephone network were supported by microwave radio transmission links and relay stations that were built in the 1950s for transcontinental and interstate calls.

Digital transmission began in the early 1960s, and Time Division Multiplexing (TDM) became a networking standard. AT&T introduced a *digital signaling* (DS-N) hierarchy with supporting carrier systems to transport digitized voice signals, where *N* represents the level. The T1 carrier for example, operating at 1.544 Mbps and referred to as the DS-1 rate, offered an order-of-magnitude capacity improvement over analog carrier systems. The transmission took place using two twisted-pair copper lines for full duplex communication. Digital carriers were originally used by AT&T to ease congestion in heavily populated areas and in the core switching network. Subsequently, these systems became available to the public and were used for carrying voice and data traffic from private networks to the local exchange switch or to an Internet access router. The long-haul microwave transmission systems and L-carrier coaxial systems were eventually replaced in the 1980s by fiber-optic transmission lines. After AT&T's divestiture, optical transmission systems were standardized under the *synchronous optical network* (SONET) hierarchy in North America and a corresponding *synchronous digital hierarchy* (SDH) in the rest of the world. SONET also implements TDM but uses a synchronous time format—byte interleaving—in contrast to the multiple clock rates or plesiochronous timing used in the DS hierarchy.

Multiplexing principles are fundamental also to the operation of packet-switched data networks. Packets are variable-sized, information-carrying units generated from audio, video, and data applications. Multiplexing on data networks takes place asynchronously on the time scale of the packet. Until recently, the delay and loss performance of Internet traffic was controlled by provisioning high-capacity links and operating at low to moderate levels of link utilization. The need to provide service guarantees for real-time voice and video applications led to the *asynchronous transfer mode* (ATM) network, which was proposed in the 1990s as a platform for a broadband integrated services

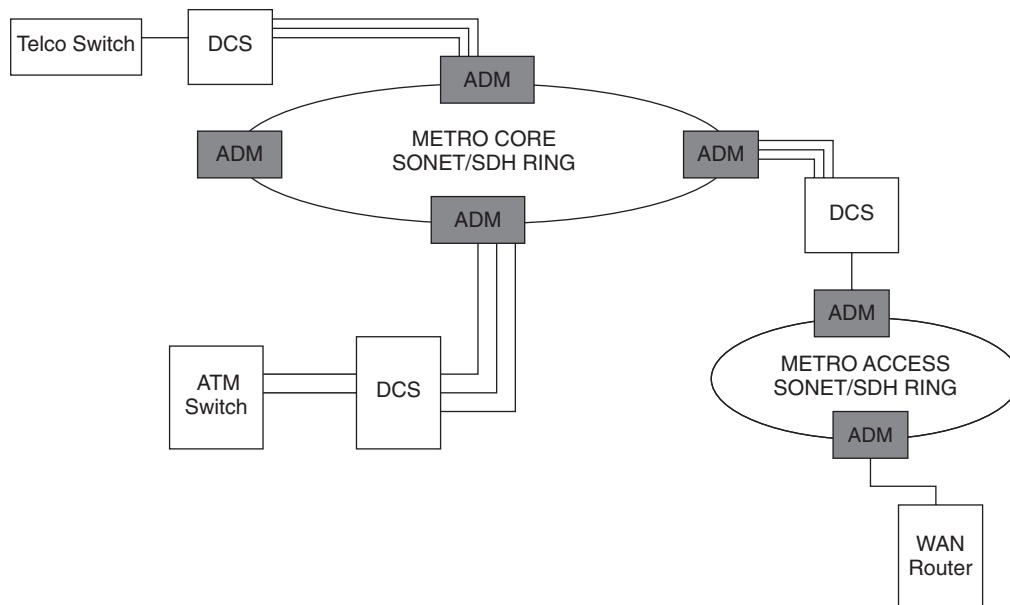

Figure 1: Current architecture of metro core and access networks

digital network. ATM networks implement virtual circuits with varying quality classes for controlling the performance of traffic flows. During this time, network traffic measurement, modeling, and methods for evaluating the capacity gains achieved by statistical multiplexing became important research fields in the data network community. These studies identified the difficulties in the exact characterization of the complex traffic patterns and prediction of the resulting multiplexing efficiency. With respect to the *open systems implementation* (OSI) model for data networking, ATM networks typically appear as a layer 2 (data link) technology and access the SONET-SDH backbone for long-haul transport. SONET backbones also admit a variety of other access interfaces that generate both TDM voice and packet multiplexed data.

The general architecture of a metropolitan area network serving both voice and data transport is depicted in Figure 1. In this figure, the core network is accessed by telephone company switches, ATM switches, and SONET access rings through *digital cross connect* (DCS) systems and *add-drop multiplexers* (ADMs). ADMs can add or drop lower-rate signals to or from higher-rate optical signals, respectively. The synchronous nature of SONET allows addition or dropping without the need for demultiplexing the original signal. DCS systems serve to interface links of varying capacity and provide functions of switching, multiplexing, and demultiplexing. Typically, interface-specific equipment is needed and provided by different vendors. In this architecture, data traffic is time division multiplexed onto a reserved circuit on the SONET backbone. Because these circuits are provisioned with minimum capacities in units of DS-1 rates and data traffic is inherently a variable rate process, it can result in an inefficient utilization of network resources. Packet data traffic continues to be the dominant consumer of network bandwidth, thus creating a critical need for various levels of multiplexing control for transport over optical backbones.

The next section provides an overview of the design and functionality of time division multiplexers. The section titled “Statistical Packet Division Multiplexing” discusses packet division multiplexing and presents packet traffic features that affect multiplexing performance. New protocols proposed for improving statistical multiplexing performance on the SONET-SDH transport infrastructure are discussed in the section preceding the conclusion.

TIME DIVISION MULTIPLEXING

A functional diagram of a time division multiplexer (Held 1999) is shown in Figure 2. The n source streams at the input are aggregated into TDM frames composed of a fixed number of time slots. The position of the data and the number of time slots allocated per source in each frame are fixed parameters. The frames are transmitted over an output link with a transmission rate that is typically greater than the sum of the average bit rates of the input streams. To compensate for the lower arrival rates, each stream is individually buffered by input and output adapters. The central controller polls each input buffer in a pre-determined sequence, blocks a sequence of bits from each buffer, and packs the information into the format of a TDM frame along with necessary synchronization information. These frames are buffered again at the output, compensating for any difference in the switching speed of the controller relative to the available frame transmission rate.

The block size associated with each source can range from one bit per source to one character per source or a combination of these levels, based on the application. In the case of a telephone network, the input streams to the multiplexer are digitized speech signals arriving at a rate of 64 kbits/sec. The multiplexer admits $n = 24$ source streams and allocates eight bits per source in each TDM frame and one bit for synchronizing the transmitter and

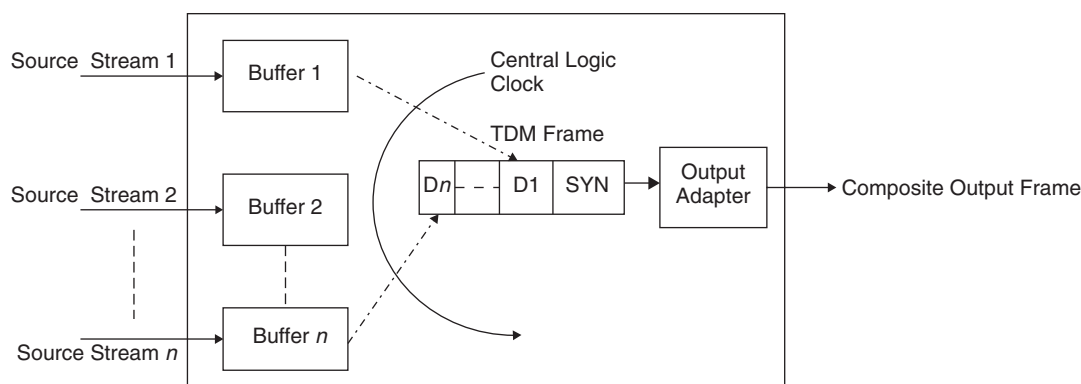

Figure 2: Time division multiplexer

receiver. The resulting TDM frame consist of 193 data bits and is 125 microseconds in duration for transmission over a link with a capacity of 1.544 Mbps. The digital signal transmission hierarchy specified by the American National Standards Institute (ANSI) refers to the 64-kbps signaling rate of each voice channel as a base rate, denoting it DS-0. The next level, DS-1, corresponds to 1.544 Mbps, the transmission rate of the T1 carrier, and onto which twenty-four DS-0 channels can be multiplexed.

The T1 carrier was implemented in telephone networks with the objective of improving the utilization of trunk lines between central office switches (Fultz and Penick 1965; Travis and Yaeger 1965). Current T1 carriers use twisted-pair copper, coaxial cable, optical fiber, or microwave transmission technology. Note that the T1 standard is prevalent in North America and Japan. The European counterpart to T1 is the E1 carrier, standardized by the International Telecommunications Union (ITU) and operating at 2.048 Mbps with capacity for thirty-two voice channels. Higher levels of signaling hierarchy include DS-2 (96 voice channels at 6.312 Mbps on T2 carriers), DS-3 (672 channels at 44.736 Mbps on T3 carriers), and DS-4 (4032 channels at 274.176 Mbps on T4

carriers). Figure 3 shows the progressive time division multiplexing hierarchy from the DS-0 rate of the voice channel up to the DS-4 level that terminates with a backbone of the long-distance network. The digital channel bank provides the encoding and formatting required for multiplexing the received signals onto a higher-capacity carrier. It can also demultiplex the aggregate stream into individual source signals. The multiplexer denoted M12 can aggregate four DS-1 streams and generate a DS-2 signal with a rate of 6.312 Mbps carrying ninety-six voice channels. The intermediate M1C multiplexer combines two DS-1 signals for transmission over a T1C carrier at 3.152 Mbps. Similarly, an M13 multiplexer combines three DS-1 streams into a signal with a bit rate of 44.7 Mbps for transport over a T3 carrier system. The M23 aggregates seven DS-2 signals onto the T3 carrier, and the M34 multiplexes six DS-3 signals for transmission over a higher-order T4 carrier at 274.176 Mbps.

To understand how this signaling hierarchy maps in the transport architecture, consider the PSTN. At the lowest level, the transport network consists of the copper wire local loops from subscriber telephones connecting to line concentrators that may be located in a neighborhood or

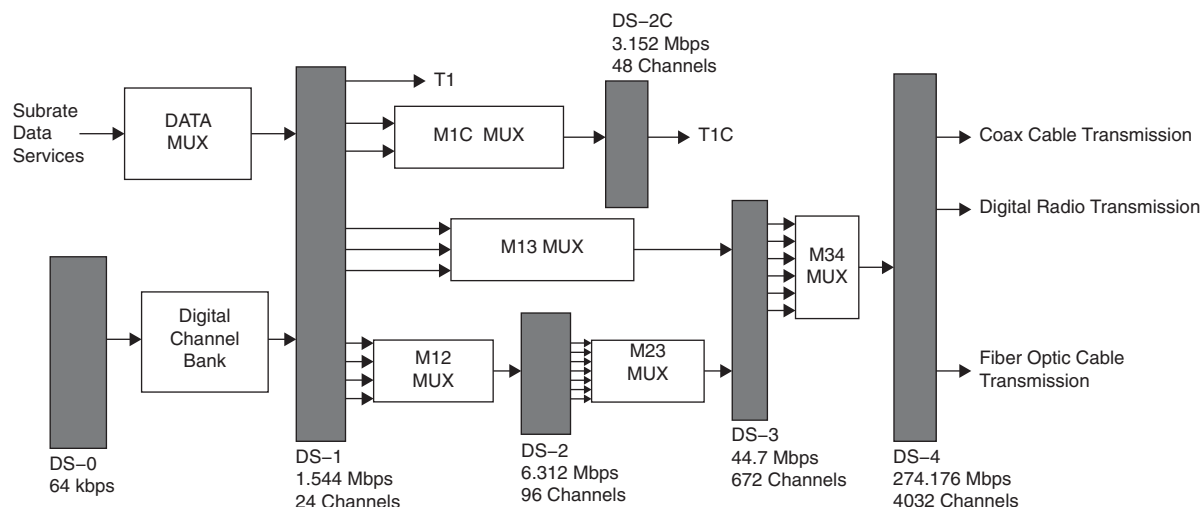

Figure 3: North American digital signal hierarchy

directly to switches in central offices belonging to a *local exchange carrier* (LEC). The line concentrators, also referred to as *digital loop carriers*, extend service to remote areas by performing functions of routing, analog-to-digital conversion, multiplexing, and demultiplexing of outgoing and incoming calls respectively. These systems connect to a circuit switch located within the LEC through fiber-optic or microwave links. AT&T's SLC-96 introduced in 1979, for example, supports ninety-six lines on five T1 line pairs, the additional pair being required for reliability. The LECs connect to the interexchange carrier network operated by long-distance providers through their points of presence. The long-distance network consists of fiber-optical cable and ground- and satellite-based microwave systems. After the divestiture of AT&T in 1984, ANSI proposed the SONET standard for fiber-optic transmission to overcome existing proprietary systems. To enable interoperability between systems satisfying North American standards and those in the rest of the world, the ITU subsequently created the synchronous digital hierarchy such that SONET may be considered a subset of the global standard SDH.

The SONET digital hierarchy is defined using *synchronous transport signals* (STS) and *optical carriers* (OC) starting with the base rate of 51.84 Mbps (STS-1) and optical connect OC-1. It is followed by STS-3 at 155.5 Mbps and the OC-3 carrier onto which three DS-3 signals can be multiplexed. Higher-bandwidth carriers include the OC-12 (622 Mbps), OC-48 (2.488 Gbps), OC-192 (9.953 Gbps), and OC-768 (39.813 Gbps). From the multiplexing viewpoint, SONET admits input streams of different capacities and performs a byte-interleaved multiplexing starting from the base signal STS-1. In the synchronous hierarchy, all systems in SONET have the same average clock rate. This feature allows many STS-1 signals to be concatenated for multiplexing without the need for bit stuffing that is required in the plesiochronous hierarchy. The STS-1 frame length is maintained at 125 microseconds, repeating at a rate of 8000 frames per second. It contains 810 bytes organized in 9-byte rows and 80-byte columns. SONET-SDH is therefore optimized to carry voice traffic that is predictively encoded and generating fixed source rates. SONET also supports the multiplexing of asynchronous streams from T1 and T3 systems as well as streams arriving from other synchronous or plesiochronous systems. Sub-STs-1 levels can also be defined using low-rate *virtual tributaries* (VTs) such as VT 1.5 (1.728 Mbps), VT 2 (2.3 Mbps), VT 3 (3.456 Mbps), and VT 6 (6.912 Mbps). When the required service rate is below DS-3, it is allocated using VTs that are synchronously multiplexed and visible as individual streams at the higher rates. Therefore each tributary can be extracted from the multiplexed stream without need for demultiplexing the higher-rate signal. Although this hierarchy is optimized to carry digital voice from the PSTN, the transport of data traffic using the available levels of granularity in link capacity can be inefficient. It is often the case that the TDM circuit will be underutilized. This feature results from the variable data rate and burst type of transmission patterns that characterize most data applications. To examine the integration of data services on TDM systems, packet division multiplexing is discussed next.

STATISTICAL PACKET DIVISION MULTIPLEXING

Introduced in the 1970s for data transfer on ARPANET (Kleinrock 1972; Kleinrock and Naylor 1974), the first computer network, packet multiplexing continues to be the basic transmission mode on the Internet. It is enabled by the *transmission control protocol and Internet protocol* (TCP/IP) suite (Cerf and Kahn 1974) that ensures reliable end-to-end data delivery between hosts and across networks. In the 1980s, the Internet consisted of a single backbone utilizing T1 and T3 lines to interconnect *local area networks* (LANs) at universities and national laboratories. The Internet is now composed of many backbones under the control of commercial network providers who establish peering arrangements to ensure connectivity across the different networks. The backbone networks are typically SONET-based and served by various types of access and data-link layer technologies.

On packet networks, routers and switches perform multiplexing on a packet-by-packet basis. The features of the multiplexed output stream will be governed by the statistical characteristics of all of the traffic flows that are aggregated. Statistical multiplexers can be modeled as queueing systems with finite waiting room and served by transmission links of fixed capacity. The output link capacity is higher than the aggregate average rate of the input streams but typically lower than their aggregate peak rate. Packets arriving at the input ports and destined to an output link are admitted and served, typically on a first-in, first-out (FIFO) basis. The buffers smooth out large variations in the input rate but also produce variable queueing delays and packet losses. Priority-based service may also be implemented by allocating *virtual paths* (VPs) as in ATM networks. The VPs are occupied by traffic flows multiplexed under a specified packet loss or delay tolerance constraint. By allocating output link capacities that are between the average and peak rates of the input traffic, statistical multiplexers attempt to balance the performance requirements of the source traffic flows while efficiently using the available output link capacity. The *statistical multiplexing gain* (SMG) represents the ratio of the number of sources admitted under statistical multiplexing and the number admitted under peak rate allocation. An efficient system operates with SMG values that are greater than 1. Admission control rules for grouping traffic into an ATM virtual circuit or for general packet multiplexing relate input traffic parameters to the performance metrics and determine the type and number of flows that can be aggregated.

To characterize the multiplexing efficiency of packet switched networks, many studies have examined the traffic patterns generated by packet data, voice, and video applications. It is well known that data traffic sources originating from applications such as file transfer or Web browsing alternate between bursts of high-rate transmission activity and periods of low or no activity. Streaming video and audio applications, based on the coding mechanism used, generate either a constant or a continuously varying packet rate. One measure of traffic variability is the ratio of peak to average packet rate exhibited by the traffic source. The objective of multiplexing traffic at successively higher

levels of the network hierarchy is to reduce this ratio, thus creating a more uniform traffic rate that can efficiently use network resources. Queueing delays and blocking can also be controlled in these cases because capacity overflow will be a low-probability event. Such a feature requires that the traffic flows being multiplexed satisfy certain statistical properties, such as having a low degree of determinism or correlation in their temporal arrival patterns and independence from the traffic variations of other flows being multiplexed. A brief review of packet traffic measurement and modeling studies conducted over the last three decades is presented next.

Packet Traffic Features

Packet traffic arriving at a multiplexer is characterized by considering the dynamics of the packet interarrival times and the packet sizes. These features determine the workload generated on the link and the network. Analyses of workload measurements on LANs (Jain and Routhier 1986; Schoch and Hupp 1980; Murray and Enslow 1984) and wide area networks (Tobagi 1978) have identified random periods of activity during which packet clusters occur with small interarrival times and are followed by random durations of relatively slow to moderate packet rate. Jain and Routhier (1986), in their measurement and modeling study of traffic on a token ring network, determined that the system hardware and network protocols had significant impact in shaping the traffic patterns. They proposed a packet train model and attributed the time between packet clusters to be a function of user access at the application level, whereas the intracluster statistics were a function of the network hardware and software. The influence of protocol-dependent features in Internet traffic has been presented also by Paxson and Floyd (1996) and Caceres et al. (1991).

Traffic features generated by flows consisting of a mix of voice, data, video, and control information have been found to exhibit some of the most complex behavior. In particular, this intermix shows evidence of deterministic trends as well as statistical variations. The interarrival times of *integrated services digital network* (ISDN) traffic generated from a user's terminal was shown (Meier-Hellstern et al. 1991) to be modeled by superposing gamma and power-law type of probability density functions. Nonstationary features such as a time-varying mean rate and a slow decay rate in the tail of the interarrival time distributions were found in Ethernet traffic generated by workstations (Gusella 1991). To describe Ethernet traffic invariance when observed on multiple time scales, Leland et al. (1994) proposed that traffic be modeled as a *self-similar* process. This model implies that traffic features such as its variance remain statistically invariant even when aggregated over increasing time scales. In comparison, teletraffic models that capture the arrival patterns of telephone calls to a switch and the call holding times are simpler and more tractable for predicting the multiplexing performance. As shown by Erlang (1909), teletraffic processes can be adequately represented by Poisson distributions for the number of call arrivals in a time interval and by a negative exponential probability density function for characterizing the call holding times.

Although no single model has been able to capture all of the complexity observed in packet traffic measurements, approximate models that capture some of the features that affect queueing performance have been proposed. *Fractional Brownian motion* (FBM) is considered by Norros (1995) as the fundamental model for generating self-similar features. Although this model can represent the trend in the long-range correlation of the traffic, it fails to capture short-range variations that affect the performance of finite buffer queues (Ryu and Elwalid 1996). To account for the limitations of the FBM model, a multifractal representation has been proposed in later studies (Vehel and Riedi 1997; Feldmann, Gilbert, and Willinger 1998). This model allows characterization of the high-frequency end of the traffic spectrum, allowing short-term effects to be modeled.

Zhang et al. (2003) investigated traffic carried on OC-3, OC-12, and OC-48 backbone links using multiple time scales ranging from 1 to 10^4 milliseconds. The small time-scale variations were found to be essentially uncorrelated, unlike the fractal and multifractal features observed in previous studies of LAN traffic. This feature may be attributed to the large-scale aggregation that takes place on high-capacity links, generating marginal distributions of the workload that approach Gaussian statistics. In an analysis of Web traffic collected on a 100-Mbps Ethernet link, Cao et al. (2001 "Nonstationarity") modeled the traffic distributions as a function of the connection rate. With increase in the connection rate, the traffic features tended toward Poisson characteristics and independence. At lower rates, a Weibull distribution with a rate-dependent shape parameter was shown to characterize the packet interarrival times. The features of traffic generated on an OC-48 backbone link of an Internet service provider were investigated by Karagiannis et al. (2004). They showed that in the subsecond time scale, traffic approaches Poisson behavior; whereas at the multisecond time scales it exhibits nonstationarity oscillating around a global mean value. This study also points to nonstationary features in the Bellcore Ethernet data previously studied in Leland et al. (1994). The origin of nonstationarity is hypothesized to result from aggregation of arrival processes with a high degree of variability among the individual streams.

The effect of statistical multiplexing of Internet traffic on long-range dependence (LRD) features is examined in (Cao et al. 2001). The statistical multiplexing effect was quantified with respect to the *number of active connections* (NAC), considering traffic from 100-Mbps Ethernet, 156-Mbps ATM interfaces, and 622-Mbps packet over SONET interfaces. It was shown that both traffic workload and interarrival times exhibited LRD at all levels of NAC but generally tended to decrease with the NAC. The emphasis on examining LRD in traffic is primarily to describe the expected value and variance of the queueing delay and the blocking probabilities in network multiplexers. Livny, Melamed, and Tsiolis (1993) showed that when the arrival process is characterized by LRD, the expected queueing delays and blocking probabilities are higher than those generated by Poisson processes at the same level of utilization. Under these traffic assumptions and to preserve *quality of service* (QoS), network service providers have been operating at less than

50 percent network utilization levels. The study in Cao et al. (2001 "Effect"), however, points out that when multiplexing level is taken into account by considering the number of active connections, networks that are subject to high NAC can afford to operate at higher levels of utilization.

The exact analysis of queueing delays and blocking generated by correlated arrival processes is generally intractable. Stochastic models of traffic that can capture some if not all of the correlation features inherent in traffic measurements have been proposed for analyzing the multiplexer performance. A review of some of these approaches is presented next.

Performance Models for Packet Multiplexers

Various approaches for estimating the queueing and multiplexing performance have been proposed considering descriptors that capture the level of correlation in the traffic. In this context, the *index of dispersion of counts* (IDC) and the *index of dispersion of intervals* (IDI) have been useful traffic descriptors for a qualitative prediction of the effect of correlated traffic bursts in queues (Sriram and Whitt 1986; Heffes and Lucantoni 1986). Using the random variable $N(t)$ to represent the number of packets arriving in a time interval t , the IDC is derived as the ratio of the variance and expected value of $N(t)$. The IDI is obtained similarly using the packet interarrival times instead of the counts given by $N(t)$. The limiting value of $N(t)$ as $t \rightarrow \infty$ for a stationary arrival process can be shown to be directly related to the normalized autocorrelation coefficients of the arrivals (Gusella 1991). Sriram and Whitt (1986) consider a highly variable renewal process (Sevast'yanov 2001 "Renewal") to model a single voice source and apply the IDI to characterize the superposition of these processes. The limiting value of IDI as the number of sources tend to infinity can characterize the effect of the arrival process on the congestion characteristics of a FIFO queue in heavy traffic. This work also shows that the positive dependence in the packet arrival process is a major cause of congestion in the multiplexer queue at heavy loads. Buffer sizes larger than a critical value as determined by the characteristic correlation time scale will allow a sequence of dependent interarrival times to build up the queue, causing congestion. Limiting the size of the buffer, at the cost of increased packet loss, is proposed as an approach for controlling congestion. To control packet loss that occurs from dependence in the arrival process, Sriram and Lucantoni (1989) propose dropping the least significant bits in the queue when the queue length reaches a given threshold. They show that under this approach the *queue performance* is comparable to that of a Poisson traffic source.

Another performance parameter that encompasses the features of both the traffic and the queue parameters is the *peakedness* value (Eckberg 1983, 1985). The peakedness captures the ratio of the variance and expectation of the number of busy servers in a queue that can theoretically be approximated to have an infinite number of servers. The calculation requires a functional description of both the probability distribution function and autocorrelation function of the workloads arriving at the queue.

In addition, the arrival process may be characterized by a time-varying random arrival rate and its covariance density function. The application of peakedness to estimate the blocking probability of finite server systems is presented in Fredericks (1980), and its application for analysis of delay systems is given by Eckberg (1985).

To characterize the probability distribution of the buffer occupancy in a statistical multiplexer, at least two characteristic time scales must be taken into consideration. The small time-scale correlations that are a result of packets arriving back to back generate what is known as *packet level congestion* and a characteristic decay rate in the queue distribution for small queue sizes. At the other end of the time scale, referred to as *burst-scale congestion*, large queue sizes are formed by the occurrence of multiple traffic sources transmitting at their peak rate (Norros et al. 1991; Roberts and Virtamo 1991; Roberts 1992). If the multiplexer buffer sizes are large enough, both of these effects are manifest in the queue and affect the transmission performance. Finite state Markov chain models designed to capture the correlation features of traffic (Sevast'yanov 2001 "Markov") can be applied to model the temporal features at small to moderate time scales. Considered jointly with a workload distribution that specifies the state dependent arrival rate, the steady-state distributions of buffer occupancy can be derived.

Methods for efficiently multiplexing digital video sources are of particular importance. Packet video exhibits significant variations in the packet rate during scene changes and when the encoder is refreshed to adapt to new information. By aggregating frames from independent video sources, a moderate to high link utilization may be achieved with statistical multiplexing. To evaluate this hypothesis, finite state Markov chains have been applied to model packet video frame rate variations. Markov chains have a limited ability to capture some of the short- and long-range correlations evident in the intra- and interscene variations of the video frame rates. Applying a two-state, on-off Markov process to model a low-activity videophone signal, Maglaris et al. (1988) derived the multistate Markov chain representation for the multiplexed process. The superposition of moderate activity videoconference data was modeled by Heyman, Tabatabai, and Lakshman (1992). Considering a multistate Markov chain model for the source, they assumed the transitions from a given state to other states followed a negative binomial probability distribution. The state dimension ranged from 400 to 500. This structure, however, could not address the short-term correlations in the traffic of a single source (Heyman and Lakshman 1996). Video sources with moderate activity (Sen 1989) and full-motion video (Yegenoglu, Jabbari, and Zhang 1993; Skelly, Schwartz, and Dixit 1993) have also been represented by discrete time Markov chains and state-dependent autoregressive processes. The problem of selecting an adequate number of states and spectral content in the Markov chain model of a single source so as to capture the scaling effects under multiplexing is discussed in Chandra and Reibman (1999).

There are several advantages in representing a traffic source using a discrete or continuous time Markov chain. Two or more sources represented using Markov chains can be combined to yield another Markov chain that

represents the statistically multiplexed process. The queueing performance of the multiplexed stream and the multiplexing efficiency can be computed using fluid buffer models (Anick, Mitra, and Sondhi 1982). Fluid flow analysis assumes that the source rate varies continuously in time as captured by a finite state continuous time Markov process. This approach is suitable when the packet sizes are small relative to the link capacity and a large number of sources are multiplexed. The computational model allows the estimation of the delay and loss distributions in multiplexers fed by Markov-modulated fluid sources and served at a constant rate.

Markov chains described using K states are completely characterized by a K -dimensional square matrix Q whose off-diagonal elements specify the rates of transition between states and an associated diagonal rate matrix R that specifies the rate-generation process in each state. The result of multiplexing N statistically identical sources, each represented by (Q, R) , is a new Markov process represented by square matrices (Q_N, R_N) of dimension $M = K^N$. The matrices Q_N and R_N can be computed using the N -fold Kronecker sums $Q \oplus Q \oplus \dots \oplus Q$ and $R \oplus R \oplus \dots \oplus R$, respectively. The cumulative probability distribution $F(x) = \text{Prob}[X \leq x]$ of the buffer occupancy X can be obtained by solving the first-order differential equation $\frac{dF(x)}{dx} = \underline{F}(x)[Q_N D_N^{-1}]$, where the vector $\underline{F}(x) = [F_1(x) F_2(x) \dots F_M(x)]$ and elements $F_i(x)$, $i = 1, 2 \dots M$ represent the cumulative probability when the source is in state i . The matrix $D_N = [R_N - CI]$ represents the drift between the input rates and the link capacity or service rate denoted by C . Here I is the identity matrix. The solution to the differential equation can be represented using the eigenvalues and eigenvectors of $Q_N D_N^{-1}$. The cumulative probability is

given as $F(x) = \sum_{i=1}^M F_i(x) = 1 + \sum_{i: z_i < 0} a_i e^{-z_i x}$, where the summation is over those eigenvalues z_i that are less than zero. The coefficients a_i are functions of the eigenvalues and eigenvectors (Walrand and Varaiya 1996; Schwartz 1996) of $Q_N D^{-1}$, solved using the appropriate boundary conditions of X . The asymptotic decay rate of the complementary distribution function $G(x) = \text{Pr}[X > x] = 1 - F(x) = \sum_{i: z_i < 0} a_i e^{-z_i x}$ for large x is an important performance metric that determines the multiplexing efficiency. The dominant eigenvalue will govern this feature.

The fluid buffer analysis described above becomes computationally intensive as N increases for sources with a large dimension K . In such situations, asymptotic approximations to the model may be obtained for large buffer sizes and small delay or loss probabilities (Abate, Choudhury, and Whitt 1994). In this approximation, $G(x) \sim \alpha e^{-\beta x}$, $x \rightarrow \infty$, where α is referred to as the asymptotic constant and β is the largest negative eigenvalue of the matrix $Q_N D^{-1}$. The asymptotic decay rate $-\beta$ is a function of the service rate C and may be determined with relative ease. The asymptotic constant, however, requires knowledge of all of the system's eigenvectors and eigenvalues. Approximate methods for estimating for Markovian systems are derived in Addie and Zukerman (1994) and Elwalid et al. (1995). Although most of the asymptotic representations have considered Markovian sources, there have been some results for traffic modeled as stationary Gaussian processes

(Choe and Shroff 1998) and fractional Brownian motion (Norros 1995).

Often, $G(0)$ is assumed to be unity in the heavy traffic regime. From this assumption, an effective bandwidth representation of a source, which serves as a descriptor of multiplexer performance, can be derived. The limiting form of the tail probabilities as $x \rightarrow \infty$ can be represented as $G(x) \approx e^{-\beta x}$. To achieve a specified value of β that satisfies given performance constraints, the required capacity may be shown (Elwalid and Mitra 1993) to be obtained

as the maximal eigenvalue of the matrix $\left[R_N + \frac{Q_N}{\beta} \right]$. This

capacity is referred to as the *effective bandwidth* (EB) of the multiplexed source. In the limit, as β approaches zero and ∞ , the EB approaches the source average and peak rate, respectively. However, as noted by Choudhury, Lucantoni, and Whitt (1996), the effective bandwidth approximation can lead to conservative estimates for highly variable traffic sources that undergo significant smoothing under multiplexing. It was shown that the asymptotic constant was itself asymptotically exponential in the number of multiplexed sources N . For traffic sources with indices of dispersion greater than those of Poisson sources, this parameter decreased exponentially in N , reflecting the multiplexing gain of the system.

The EB characterization of a multiplexed system is particularly useful for admission control in multiservice networks (Elwalid and Mitra 1993; Kesidis, Walrand, and Chang 1993; Chang and Thomas 1995). Its utility has been compared with other types of admission control in Knightly and Shroff (1999): scheduling based on average and peak rate information (Ferrari and Verma 1990), refinements of EB from large deviation principles (Kelly 1996), and maximum variance approaches based on estimating the upper tails of Gaussian process models of traffic (Choe and Shroff 1998). To examine how EB can be utilized, assume that K classes of traffic are to be admitted into a node served by a link capacity C packets per second. If N_i sources of type i exist, each characterized by an effective bandwidth E_i , the simplest admission policy is given by the linear control law, $\sum_{i=1}^K N_i E_i \leq C$. The effective bandwidths are derived taking into consideration the traffic characteristics and performance requirements of each class and available capacity C . Defining the traffic generated by type i source on a time scale t by a random variable $A_i[0, t]$, the effective bandwidth derived from large-deviations principles (Kelly 1996) is given by $E_i(s, t) = \frac{1}{st} \log E \left[e^{s A_i[0, t]} \right]$, where the parameter s is related to the decay rate of $G(x)$ and captures the multiplexing efficiency of the system. It is calculated from the specified probability of loss or delay bounds (Schwartz 1996). The term on the right is the log moment generating function of the arrival process (Weisstein 1999 "Moment"). The workload can be described over a time t that represents the typical time taken for the buffer to overflow starting from an empty state. For a fixed value of t , the EB is an increasing function of s and lies between the mean and peak values of $A_i[0, t]$. This may be shown by a Taylor series approximation of E_i as $s \rightarrow 0$ and $s \rightarrow \infty$, respectively (Weisstein 1999 "Taylor"). Methods for deriving E_i for different traffic classes are discussed in Chang (1994). The

mentioned model assumes that all of the multiplexed sources have the same QoS requirements. If they do not, all sources achieve the performance of the most stringent source. Kulkarni, Gun, and Chimento (1995) consider an extension of this approach for addressing traffic of multiple classes. For the superposition, because the total workload is given by $A[0,t] = \sum_{i=1}^K A_i[0,t]$, the effective capacity C_e of the multiplexed system is $C_e = \sum_{i=1}^K E_i$. The admission control algorithm compares C_e with available capacity C and if $C_e < C$ allows the new source to be admitted into the system.

The problem of statistical multiplexing has been discussed in this section with reference to traffic characteristics and approaches for evaluating the performance of multiplexers modeled as queues. To support these algorithmic approaches, the network infrastructure must include appropriate protocols and technology. A brief review of proposals in this area is presented in the next section.

PROTOCOLS FOR STATISTICAL TIME DIVISION MULTIPLEXING SUPPORT

Transport architectures in next generation networks must be designed to better support the demand for packet data, voice, and video services. This will require more flexible approaches for integrating packet-switched services into the optical transport plane and protocols that can improve the control of end-to-end quality of packet traffic. To better utilize the existing SONET-SDH circuit capacity, a statistical time division multiplexing framework will be required at both access interfaces and network elements within the optical backbone. A packet-aware optical transport paradigm will allow customization of packet delivery services while leveraging the stability and security of the well-tested optical transport systems. At the access level, legacy Ethernet services will probably continue to expand through Fast and Gigabit Ethernet technologies.

A hybrid integrated service, *Ethernet over SONET* (EoS), is envisioned by most network providers as the emerging model for which controlled service and improved bandwidth utilization are to be designed. In support of this, several technologies and protocols are under various stages of investigation and evaluation. These include *virtual concatenation* (VCAT), *link capacity adjustment scheme* (LCAS), *generic framing procedure* (GFP) (Hernandez-Valencia, Choltan, and Zhu 2002; Henrique-Valencia 2002; Cavendish et al. 2002) and *resilient packet ring* (RPR) (Davik et al. 2004) for integrating Ethernet and SONET. In addition, *multiprotocol label switching* (MPLS) (Awduche 1999; Rosen, Viswanathan, and Callon 2001) and *generalized MPLS* (GMPLS) protocols (Mannin 2004) provide approaches for controlling quality through label-switched paths on Internet protocol (IP) and optical networks respectively.

In the current transmission architecture, IP packets are carried over SONET-SDH using packet-over-SONET standards. Here the packets are transported using link layer point-to-point protocol after being encapsulated into byte-stuffed high-level data link control frames. They are then byte mapped into the contiguously concatenated SONET-SDH payload envelopes. Contiguous concatenation allows the transport of payloads that exceed the basic

STS-1 *synchronous payload envelope* (SPE) by concatenating multiple SPEs contiguously and transporting them as one unit. The concatenated containers are referred to as STS- nc , where n takes values of 3,12,48,192 generating rates of 155,622,2448 and 9792 Mbps, respectively. The limitation in the granularity of output link capacities can yield underutilized bandwidth. For example, a 100-Mbps Fast Ethernet connection will be allocated a 155 Mbps STS-3c container, and a Gigabit Ethernet link will be assigned the 2.5-Gb STS-48c capacity resulting in significant underutilization. Using VCAT, the Fast Ethernet connection can be assigned two STS-1 channels, and Gigabit Ethernet can be carried on seven STS-3s or twenty-one STS-1s, all of which can be combined in a single *virtual concatenation group* (VCG). An important feature is that each path in the VCG can be transported independently of others in the group, and VCG members can occupy noncontiguous time slots. Only the initiating and terminating equipment need to be aware of the VCAT functionality. VCAT will also allow provisioning for fractional or subrate Ethernet services if full Ethernet capacity is not currently being utilized by the source. The link concatenation using increments of 1.5 Mbps is referred to as *low-order VCAT*, whereas concatenation using increments of 50 Mbps is the high-order VCAT. The application of VCAT to implement low-overhead protection of EoS transport is discussed in Acharya et al. (2004).

To improve the flexibility afforded by VCAT, LCAS has been proposed (ITU-T 2001 "Link"). LCAS is a signaling protocol that allows dynamic bandwidth adjustment on SONET without disrupting existing service and often takes place in real time. It can be applied to remove and add connections in a VCG and to recover failed paths while retaining end-to-end connectivity for the entire group. For the time it takes to recover the failed path, the source will experience a reduced throughput rather than a full outage. For example, on recognizing a failed member in a VCG, LCAS enables the sink network element to communicate to the source element implementing the VCG to modify its concatenation rules. The combined VCAT and LCAS functions can be utilized as an intelligent bandwidth management system for SONET-SDH. It can afford continuity in service that is set up at the access network and can integrate with IP QoS policies such as the *differentiated services* (DiffServ) architecture and the MPLS framework proposed by the Internet Engineering Task Force (IETF 1998). The GFP proposed by ITU standardization sector and ANSI (ITU-T 2001 "Generic") is an international standard in support of VCAT, providing the framing process for mapping a wide range of data streams into SONET-SDH frames. Data streams can be generated from multiple higher-layer protocols and network technologies such as IP, Ethernet, or fibre channel. In the frame-mapped GFP adaptation, the data signal frame is mapped entirely into one GFP frame. This allows transparency with data-link layer functions and parameters and can be optimized for packet switching. An Ethernet frame, for example, with size varying from 46 kbytes to 65 kbytes is encapsulated into a GFP frame consisting of an eight-byte header. In the block-code oriented or transparent GFP adaptation, GFP operates on the coded character stream rather than the protocol data units. Fixed-size GFP frames

are encapsulated on the decoded data character stream, creating efficient block codes that can be transported with minimum latency. It therefore supports delay-sensitive circuit-emulation applications and is targeted for Gigabit Ethernet and storage network protocols. The basic requirement for GFP is that upper-layer data signals must be octet-aligned, and lower layers such as SONET-SDH must also provide an octet-synchronous path.

As packet traffic continues to consume network bandwidth, retaining packet awareness at all levels of network hierarchy becomes an important design feature. The concept of a packet-aware metro transport network is discussed in Afferton et al. (2004). They propose deployment of Ethernet switching and transport at the metro level and consider the RPR protocol for carrying packet traffic over the access rings. RPR is configured above GFP and provides a medium access-level protection scheme. SONET rings typically consist of a fully configured backup ring that is utilized if the primary ring experiences a failure. RPR can eliminate the need for such redundancy at the physical layer while offering network availability that is comparable with the sub-50-millisecond resiliency of SONET-SDH ring architecture. By removing the need for a second physical circuit, bandwidth utilization can be effectively doubled. RPR also supports three QoS classes—A, B, and C—where class A is highest priority with bandwidth and jitter guarantees; class B is intermediate level, requiring bandwidth guarantee; and class C refers to best effort traffic. RPR applies admission control schemes to enforce the quality requirements.

The aforementioned protocol enhancements are designed to improve the multiplexing flexibility of conventional time division multiplexing systems. The objective of making optical transport networks packet aware is also important when viewed from the perspective of improved traffic-engineering methodologies that have been implemented in traditional packet-switching networks. In this context, *multiprotocol label switching* (MPLS) (Adwuche 1999; Rosen, Viswanathan, and Callon 2001) and its extension GMPLS are among the protocols proposed by the IETF for controlling QoS on Internet paths. MPLS is designed to emulate the circuit-switched flow transfer of telephone networks. Edge routers implementing MPLS attach labels to packets identifying them as belonging to a particular *label-switched path* (LSP). At each label-switching router in the transmission path, an outgoing label is placed on the packet, based on which packets are routed. Forward equivalent classes are generated based on packets with the same labels, and they may represent flows with common service class, source-destination endpoints or other service criteria. MPLS allows the integration of link layer parameters such as the link capacity and latency into labels that are accessible at the higher IP layer. These labels serve to generate a constraint-based routing paradigm. MPLS is used in conjunction with the *resource reservation protocol* to implement traffic engineering and QoS service on the network. To implement MPLS, routers must map the QoS parameters in the labels through an appropriate admission control and queueing process that preserves the service constraints. The method for implementing these features at required Gigabit rates is not specified under any standards but rather implemented as

proprietary algorithms in switches and routers currently installed. However, they follow the general recommendations of the DiffServ architecture (IETF 1998) in which traffic is aggregated and provided differentiated service quality on a hop-by-hop basis.

GMPLS allows the extension of MPLS into the optical physical layer, supporting optical label-switched paths using *wavelength division* or *time division multiplexing* (WDM and TDM). At the physical transport layer, GMPLS-enabled routers and network elements set up optical label-switched paths between the nodes of the core transport network. The IP network affords many levels of granularity in capacity for creating label-switched paths, whereas a limited set of capacities is available on SONET or WDM physical layers. Therefore, multiple label-switched paths generated on IP paths must be appropriately multiplexed to maximize the utilization of WDM or TDM paths on the optical channel (Zhang and Qiao 2000).

CONCLUSION

The need for statistical multiplexing will continue increasing in proportion with the increasing traffic generated by variable and intermittent rates of packet-switched voice, video, and data sources. In support of this, network architects are expanding the role of traditional local access network multiplexing technologies such as Ethernet to the level of metro and core transport networks. To better utilize the significant widespread optical transport infrastructure that exists worldwide, SONET-SDH transport systems are being provided with the capability to implement more flexible forms of traffic aggregation and bandwidth management. As optical networks become more data-centric, network elements that support multiple services and new protocols to enforce service level agreements are under development. Multiservice networks will require interfaces that can function both as packet switches and optical cross connects and support hybrid packet and wavelength multiplexing for high-capacity demands. The design objective of such systems is to seamlessly integrate into the optical plane the multiple capacity demands of traffic flows routed using MPLS label-switched paths on the IP segment of the transmission path. The traditional manual management of path connectivity is being updated through the development of a distributed optical control plane that will facilitate adaptive traffic management, signaling, routing and recovery from faults. Protocols such as generalized MPLS are configured to distribute information on bandwidth availability, topology, and network status that will help network nodes configure constraint-based traffic aggregation and route selection.

The problems of packet traffic characterization and prediction of performance of statistical multiplexers continue to be challenging issues in network design. The current understanding of traffic patterns suggests that traffic descriptors must be considered at multiple time scales and that traffic features are significantly influenced by transport and control protocols and the queueing experienced during transmission. In general, traffic models applied for analyzing multiplexers can change from hop to hop and must be derived after taking into consideration system issues such as buffer size, link capacity, and system

utilization. At the access to the optical network, traffic models for aggregation must address the issues of how best to maximize the utilization of the optical capacity. A suite of protocols for virtual concatenation, link capacity adjustment, and generic framing are being applied to increase the flexibility of the optical plane while retaining the robustness and security of SONET-SDH networks.

GLOSSARY

Add-drop multiplexer (ADM): Technique for demultiplexing a high-rate signal into its lower-rate components so as to multiplex another low-rate signal.

Asynchronous transfer mode (ATM): A switching and multiplexing technique that operates on fixed-length 53-byte cells and provides a virtual connection-oriented delivery while controlling packet delay, jitter, and loss. Applies traffic parameters such as peak and average rates for controlling performance.

Broadband integrated services digital network: Standards for switching, multiplexing, and transporting integrated voice, video, and data sources using ATM. Transmission rates are higher than 1.544 Mbps.

Digital cross connect (DCS): System for switching and multiplexing low-speed voice and data signals onto high-speed lines and for demultiplexing high-speed signals into their lower-rate components.

Digital loop carrier: System that multiplexes low-rate signals from end users onto high-speed digital lines such as T1 and performs the reverse operation for transmission to end users' telephone or computers.

Digital signal (DS- N) hierarchy: Standard signal rates for time division multiplexed systems, where $N = 0, 1, 2, 3, 4$ represent 64 kbps and 1.544, 6.312, 44.736, and 274.176 Mbps, respectively.

Fast Ethernet: An enhanced version of standard Ethernet that can transfer data at a rate of 100 Mbps.

Fibre channel: Storage and networking interface technology capable of transmitting data between computers at rates as high as 10 Gbits per second.

High-level data link control: Format for delimiting frames in a packet multiplexing scheme.

Integrated services digital network (ISDN): A flexible telephone service that allows digital voice and data communications using multiple bidirectional bearer channels, each with capacity as high as 64 kbps.

Kronecker sum: Sum of two matrices A and B of dimension N and M , respectively, is given by $A \oplus B = A \otimes I_{M \times M} + I_{N \times N} \otimes B$, where the symbol \otimes represents the Kronecker or tensor product. The Kronecker product of two matrices $C_{N \times N} \otimes D_{M \times M}$ replaces each element of C by the product of the element and the matrix D , resulting in a matrix of dimension $N \times M$.

Long-range dependence (LRD): The process autocorrelation function decays hyperbolically rather than exponentially.

Open systems interconnect (OSI): Standard for data communications over a network. Consists of seven layers of protocols starting from the lowest physical or data transport layer and moving up in sequence to the data-link layer, network or Internet protocol layer,

transport layer, session, presentation, and application layers.

Optical carrier: Standardized transmission speeds in SONET-SDH fiber-optic networks.

Plesiochronous digital hierarchy: Signals are not exactly synchronized to a standard rate but operate with some variation around the nominal value.

Point-to-point protocol: Standard for serial communications over the Internet; defining protocol for the modem to transfer and receive data packets with other systems.

Self-similar: Property exhibited by fractals and chaotic systems in which certain statistical or deterministic properties remain invariant with scale.

Synchronous digital hierarchy (SDH): International networking standard with a base transmission rate of 155 Mbps.

Synchronous optical network (SONET): ANSI standard for synchronous data transmission on optical media.

Tributary: The lower-rate signal forming an input to a multiplexer.

Virtual circuit (VC): A communications channel that provides sequential transport of ATM cells between two ATM end stations.

Virtual path (VP): A logical association or a bundle of virtual circuits.

Wavelength division multiplexing (WDM): Multiplexing data sources using multiple wavelengths and transmission over a single optical fiber.

INTRODUCTION

Orthogonal frequency division multiplexing (OFDM) is a special form of *multicarrier modulation* (MCM), the purpose of which is to split a high-rate data stream into a number of lower rate data streams that are transmitted simultaneously over a number of subcarriers. The first systems using MCM were military high-frequency (HF) radio links in the late 1950s (Mosier and Clabaugh 1958) and early 1960s (Zimmerman and Kirsch 1967). OFDM, which was patented in the United States in 1970 (Chang 1970), then abandoned the use of analog steep bandpass filters that completely separated the spectrum of individual subcarrier and instead chose time domain waveforms such that mutual orthogonality was ensured even though the spectra overlapped. Such a waveform can be easily generated and detected using the *inverse discrete Fourier transform* (IDFT) and *discrete Fourier transform* (DFT) at the transmitter and receiver, respectively (Weinstein and Ebert 1971). However, for a relatively long time, implementation aspects of OFDM such as the computational complexity of the DFT appeared prohibitive, not to speak of other problems such as the stability of oscillators at transmitter and receiver, the linearity required in radio-frequency power amplifiers, and the power backoff associated with it. After many years of intensive research and development for mobile communications, digital audio broadcasting, and data transmission over telephone lines in the 1980s; for *asymmetric digital subscriber line* (ADSL), *power line communications* (PLC), digital broadcasting, and wireless *local area networks* (LANs) in the 1990s; and for wireless broadband access in the early 2000s, many of the major implementation problems have been solvable and OFDM has become part of several worldwide standards (Cimini 1985; Alard and Lassalle 1989; Bingham 1990; ANSI 1998; Lin et al. 2002; Dambacher 1996; European Telecommunications Institute 1996; Association of Radio Industries and Businesses 2000; IEEE 1999, 2003, 2006).

This chapter is organized as follows. The next section provides an overview of OFDM, including its origin, the use of DFT, the insertion of cyclic prefix, and the use of channel coding to combat frequency-selective fading. The third and fourth sections present drawbacks related to OFDM transmitters and receivers, respectively. The fifth section addresses resource allocation in OFDM. The last section before the conclusion introduces applications of OFDM in several standards of digital broadcasting, wireless LANs, and broadband wireless access, among others.

PRINCIPLES OF ORTHOGONAL FREQUENCY DIVISION MULTIPLEXING

This section will revisit the principle of OFDM and its history from its origin to current coded OFDM.

Origins

Figure 1 compares a conventional *single-carrier modulation* (SCM) and a MCM, where f_c denotes the carrier frequency (Hara and Prasad 2002). At the transmission side, $S_{SCM}(f; t)$, $S_{MCM}(f; t)$, B_{SCM} , and B_{MCM} denote the frequency spectra and bandwidths of the SCM and MCM signals, respectively. Furthermore, for MCM, f_k , $F_k(f; t)$, N_{SC} , and Δf denote the frequency of the k th subcarrier, the frequency spectrum of pulse waveform of the k th subcarrier, the total number of subcarriers, and the subcarrier separation, respectively. The frequency spectrum of the MCM signal is written as

$$S_{MCM}(f; t) = \sum_{k=1}^{N_{SC}} F_k(f; t)$$

(See Figure 1a.)

If the impulse response of a channel has a delay spread because of multipath propagation, then the channel

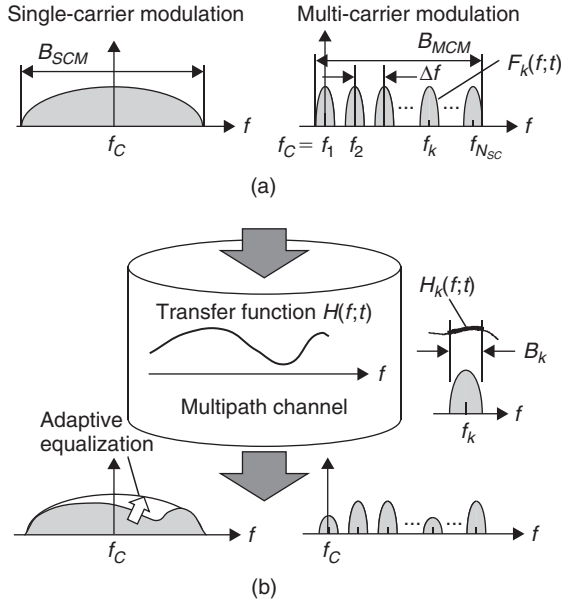

Figure 1: Comparison of SCM and MCM—(a) frequency spectra of transmitted signals and (b) frequency spectra of received signals

response in the frequency domain, which is called the *transfer function*, has a large variation, as shown in Figure 1. Such a channel is called a *multipath channel*, and the channel model is true for wired channels such as metallic cables and power lines and wireless channels in urban, rural, and indoor environments. In general, a multipath channel has a bandwidth where channel variations are highly correlated; it is called the *coherence bandwidth*. When a signal is transmitted through a multipath channel, if the coherence bandwidth is small compared with the bandwidth of the transmitted signal (i.e., the delay spread is not negligibly small as compared with the information symbol period), the channel is said to be *frequency-selective* because different spectral components of the transmitted signal experience different attenuations through the channel.

On the other hand, in general, the channel state in telephone systems does not change often, whereas the channel state in wireless systems, especially in mobile systems, always changes because of Doppler frequency spread. Such a channel with a time-varying nature is called a *multipath fading channel*; it is more hostile to information transmission, because the receiver needs to track the variation of the channel to successfully recover the transmitted data.

Through a frequency-selective multipath channel characterized by the transfer function $H(f; t)$, the frequency spectra of the SCM and MCM signals at the receiver side are written as

$$R_{SCM}(f; t) = H(f; t)S_{SCM}(f; t)$$

and

$$R_{MCM}(f; t) = H(f; t)S_{MCM}(f; t) = \sum_{k=1}^{N_{SC}} H_k(f; t)F_k(f; t)$$

respectively (see Figure 1b), where $H_k(f; t)$ denotes the channel transfer function corresponding to B_k , which is the frequency band occupied by the k th subcarrier. For SCM, because of the multipath propagation, the received signal is rich in *intersymbol interference* (ISI), so adaptive equalization in the time or frequency domain is required to reject or effectively combine intersymbol interferers. On the other hand, for MCM, when the number of subcarriers is large, the amplitude and phase response of $H_k(f; t)$ can be assumed to be constant over B_k , so $R_{MCM}(f; t)$ can be approximated as

$$R_{MCM}(f; t) \cong \sum_{k=1}^{N_{SC}} H_k(t)F_k(f; t)$$

where $H_k(t)$ denotes the complex-valued pass loss for the k th subcarrier. Therefore, the receiver requires no equalization or, at most, one-tap equalization for each subcarrier (see “Insertion of Cyclic Prefix” below for details).

The first systems employing MCM were military HF radio links in the late 1950s and early 1960s, such as Kineplex (Mosier and Clabaugh 1958) and KATHRYN (Zimmerman and Kirsch 1967), where nonoverlapped, band-limited orthogonal signals were used because of difficulty in precisely controlling the frequencies of subcarrier local oscillators and detecting subcarrier signals with analog filters.

The concept of MCM employing time-limited orthogonal signals, which is almost the same as the current OFDM, dates back to 1960 (Marmuth 1960). Defining the symbol period at subcarrier level as T_s , the mathematical expression of the transmitted signal $s(t)$ is written as

$$s(t) = \sum_{i=-\infty}^{+\infty} \sum_{k=1}^{N_{SC}} c_{ki} e^{j2\pi f_k(t-iT_s)} f(t-iT_s) \quad (1)$$

where c_{ki} denotes the i th information symbol at the k th subcarrier, and $f(t)$ denotes the pulse waveform of the symbol. When the rectangular pulse waveform is used, $f(t)$ is given by

$$f(t) = \begin{cases} 1, & (0 < t \leq T_s) \\ 0, & (t \leq 0, t > T_s) \end{cases} \quad (2)$$

so f_k and Δf are respectively written as

$$f_k = f_c + \frac{(k-1)}{T_s} \quad (3)$$

$$\Delta f = \frac{1}{T_s} \quad (4)$$

Figure 2 compares baseband data transmissions ($f_c = 0$) with a serial rectangular pulse waveform (Figure 2a) and with parallel sinusoidal waveforms resulting in an OFDM waveform (Figure 2b). Here the subscript i is dropped in Equation 1 for the sake of simplicity. Note

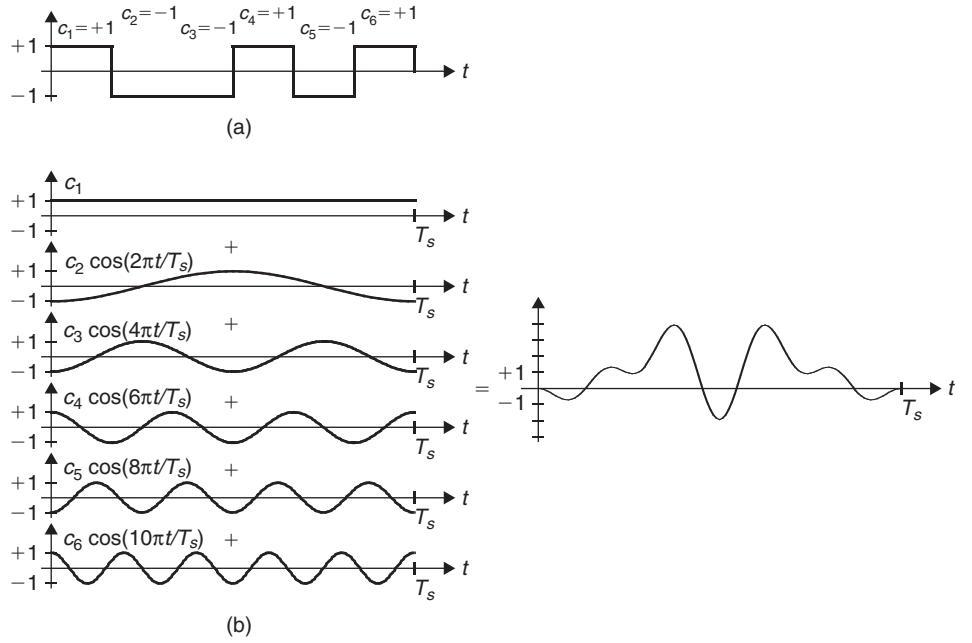

Figure 2: Comparison of transmitted waveforms—(a) rectangular pulse waveform for baseband serial data transmission and (b) baseband parallel data transmission with sinusoidal waveforms and resulting OFDM waveform

that the name *OFDM* appeared in the U.S. patent issued in 1970 (Chang 1970).

Use of the Discrete Fourier Transform

Sampling $s(t)$ ($iT_s < t \leq (i+1)T_s$) with sampling period of $t_{spl} (=T_s/N_{SC})$, the transmitted signal in a discrete form is written with a column vector ($N_{SC} \times 1$) as

$$\mathbf{s}_i = [s(iT_s + t_{spl}), \dots, s(iT_s + qt_{spl}), \dots, s(iT_s + N_{SC}t_{spl})]^T = \mathbf{W}^{-1}(N_{SC})\mathbf{c}_i \quad (5)$$

where $(*)^T$ denotes the transpose of $(*)$, and $\mathbf{W}^{-1}(N_{SC})$ and \mathbf{c}_i denote the N_{SC} -point IDFT matrix ($N_{SC} \times N_{SC}$) and the i th symbol (column) vector ($N_{SC} \times 1$), respectively:

$$\mathbf{W}^{-1}(N_{SC}) = \{w_{qk}^{-1}\} \quad (6)$$

$$w_{qk}^{-1} = \frac{1}{\sqrt{N_{SC}}} e^{j2\pi \frac{(q-1)(k-1)}{N_{SC}}}$$

$$\mathbf{c}_i = [c_{1i}, c_{2i}, \dots, c_{N_{SC}i}]^T \quad (7)$$

Equation 5 shows that the transmitted symbol vector is recovered at the receiver by means of the DFT:

$$\hat{\mathbf{c}}_i = \mathbf{W}(N_{SC})\mathbf{s}_i \quad (8)$$

where $(\hat{*})$ is used to distinguish the recovered symbol vector from the transmitted symbol vector and $\mathbf{W}(N_{SC})$ denotes the N_{SC} -point DFT matrix given by

$$\mathbf{W}(N_{SC}) = \{w_{qk}\} \quad (9)$$

$$w_{qk} = \frac{1}{\sqrt{N_{SC}}} e^{-j2\pi \frac{(q-1)(k-1)}{N_{SC}}}$$

Figure 3 shows the discrete representation of a baseband OFDM system. As we can see, the use of IDFT and DFT totally eliminates the bank of subcarrier oscillators at the transmitter and receiver (Weinstein and Ebert 1971). The N_{SC} -point IDFT and DFT requires the number of complex multiplications of N_{SC}^2 , but if the number of DFT points is selected as the power of 2, it can be replaced by the N_{SC} -FFT (fast Fourier transform), which requires a number of complex multiplications of $(N_{SC}/2)\log_2 N_{SC}$ (Mittra and Kaiser 1993). This results in reduced computational complexity and thus power consumption at the transmitter and receiver, so in OFDM systems the number of DFT points is usually chosen as the power of 2. Note that the number of subcarriers is not always chosen as the power of 2. For example, both the edge subcarriers are often not used for data transmission to reduce adjacent channel interference.

Besides its military application, OFDM's use in mobile communications was first suggested by Cimini (1985), and a telephone modem based on OFDM was developed

Figure 3: Discrete representation of a baseband OFDM system—(a) transmitter and (b) receiver

Figure 4: An instantaneous impulse response of a multipath channel

as the first commercial product in the late 1980s (Bingham 1990).

Insertion of Cyclic Prefix

As mentioned earlier in the discussion of OFDM's origins, a multipath channel can be characterized by an impulse response with delay spread in the time domain. Figure 4 shows an instantaneous impulse response of a multipath channel only with two paths, where τ_{max} denotes the time delay between the first and second paths (Hara and Prasad 2002).

After an OFDM signal goes through the channel, the receiver receives two signals. In the following, we deal with the first arrival signal as the desired one in the sense that the receiver is synchronized to it, whereas the second arrival signal is a delayed one. Figure 5 shows three

Figure 5: Transmitted signals—(a) no guard time interval insertion, (b) guard time interval insertion, and (c) cyclic prefix insertion

Figure 6: Received signals—(a) no guard time interval insertion, (b) guard time interval insertion, and (c) cyclic prefix insertion

transmitted signals, whereas Figure 6 shows the corresponding three received signals. Note that here we pay attention only to waveforms at a certain subcarrier ($f_c = 0$, $k = 2$).

Without a guard time interval between successive OFDM symbols, ISI from the $(i-1)$ th symbol gives a distortion to the i th symbol (compare Figures 5a and 6a and see the thick line in Figure 6a). If we employ a guard time interval (no signal transmission) with length of $\Delta_G > \tau_{max}$, we can perfectly eliminate ISI. This scheme is called *zero-padded OFDM*, and it was first suggested in Weinstein and Ebert (1971). However, in this scheme, the sudden change of waveform contains higher spectral components, so they result in *inter(sub)carrier interference* (ICI) (compare Figures 5b and 6b and see the thick line in Figure 7b).

Figure 5c shows the cyclic prefix insertion technique to perfectly eliminate ICI, where the OFDM symbol is cyclically extended in the guard time interval (Alard and Lassalle 1989; Peled and Ruiz 1980). Paying attention to the i th DFT window with width of t_s in Figure 6c, we can see two sinusoidal signals with full width, so it results in no ICI.

For more general multipath channels, the effect of cyclic prefix can be mathematically explained as follows. Assume that a multipath channel has an impulse response with a length of L paths (samples) h_1, \dots, h_L . To eliminate the ISI resulting from the multipath propagation, the length of the inserted cyclic prefix M should be

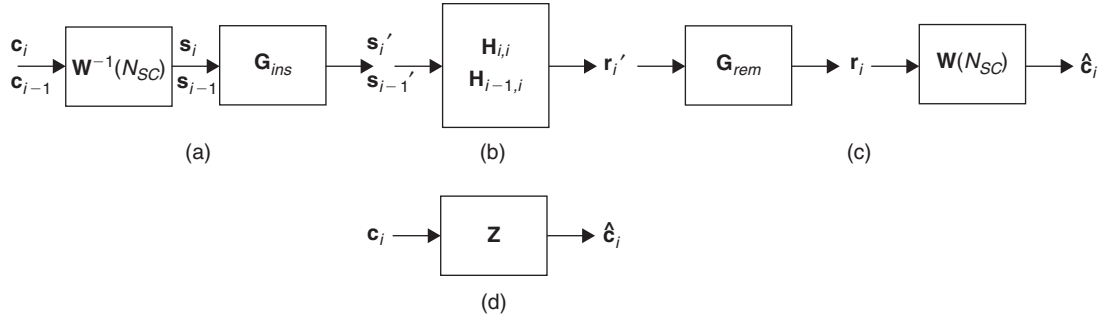

Figure 7: Matrix and vector representation of OFDM system—(a) transmitter, (b) channel, (c) receiver, and (d) input/output relationship

greater than or equal to $L - 1$, namely, $M \geq L - 1$. The i th cyclically prefixed signal is written in a vector form as

$$\mathbf{s}'_i = \mathbf{G}_{ins} \mathbf{s}_i \quad (10)$$

where \mathbf{s}'_i and \mathbf{G}_{ins} denote the i th cyclically prefixed signal vector $((N_{SC} + M) \times 1)$ and the cyclic prefix insertion matrix $((N_{SC} + M) \times N_{SC})$, respectively:

$$\mathbf{s}'_i = [s_{1i}, s_{2i}, \dots, s_{(N_{SC}+M)i}]^T \quad (11)$$

$$\mathbf{G}_{ins} = \begin{bmatrix} \mathbf{0}_{M \times (N_{SC}-M)} & \mathbf{I}_{M \times M} \\ \mathbf{I}_{N_{SC} \times N_{SC}} & \end{bmatrix} \quad (12)$$

where $\mathbf{0}_{\alpha \times \beta}$ and $\mathbf{I}_{\alpha \times \alpha}$ denote the zero matrix with size of $\alpha \times \beta$ and the identity matrix with size of $\alpha \times \alpha$, respectively.

Through the channel, the i th received signal contains contributions from not only the i th transmitted signal but also the $(i - 1)$ th transmitted signal. Assume that the receiver has been synchronized to the received signal—that is, it has accurately known the boundary between the i th and $(i - 1)$ th signals. In this case, neglecting the channel noise, the received signal vector $\mathbf{r}'_i = [r'_{1i}, r'_{2i}, \dots, r'_{(N_{SC}+M)i}]^T$ $((N_{SC} + M) \times 1)$ is written as

$$\mathbf{r}'_i = \mathbf{H}_{i,i} \mathbf{s}'_i + \mathbf{H}_{i-1,i} \mathbf{s}'_{i-1} \quad (13)$$

where $\mathbf{H}_{i,i}$ and $\mathbf{H}_{i-1,i}$ denote the i th impulse response matrices $((N_{SC} + M) \times (N_{SC} + M))$ contributed from the i th and the $(i-1)$ th transmitted signal, respectively:

$$\mathbf{H}_{i,i} = \begin{bmatrix} h_1 & 0 & \dots & \dots & \dots & 0 \\ \vdots & h_1 & \ddots & \ddots & \ddots & \vdots \\ h_L & \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & h_L & \ddots & h_1 & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & \ddots & \vdots \\ 0 & \dots & 0 & h_L & \dots & h_1 \end{bmatrix} \quad (14)$$

$$\mathbf{H}_{i-1,i} = \begin{bmatrix} 0 & \dots & 0 & h_L & \dots & h_2 \\ \vdots & \ddots & \ddots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & \ddots & h_L \\ \vdots & \ddots & \ddots & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & \ddots & \vdots \\ 0 & \dots & \dots & \dots & \dots & 0 \end{bmatrix} \quad (15)$$

The receiver removes the cyclic prefix from the received signal before demodulation. The received signal vector after the cyclic prefix removal $\mathbf{r}_i = [r_{1i}, r_{2i}, \dots, r_{N_{SC}i}]^T$ $(N_{SC} \times 1)$ is written as

$$\mathbf{r}_i = \mathbf{G}_{rem} \mathbf{r}'_i \quad (16)$$

where \mathbf{G}_{rem} denotes the cyclic prefix removal matrix $(N_{SC} \times (N_{SC} + M))$:

$$\mathbf{G}_{rem} = [\mathbf{0}_{N_{SC} \times M} \quad \mathbf{I}_{N_{SC} \times N_{SC}}] \quad (17)$$

Taking into consideration for $M \geq L - 1$

$$\mathbf{G}_{rem} \mathbf{H}_{i-1,i} = \mathbf{0}_{N_{SC} \times (N_{SC} + M)} \quad (18)$$

Substituting Equations 13 and 17 into Equation 16 leads to

$$\begin{aligned} \mathbf{r}_i &= \mathbf{G}_{rem} (\mathbf{H}_{i,i} \mathbf{s}'_i + \mathbf{H}_{i-1,i} \mathbf{s}'_{i-1}) \\ &= \mathbf{G}_{rem} \mathbf{H}_{i,i} \mathbf{s}'_i \\ &= \mathbf{G}_{rem} \mathbf{H}_{i,i} \mathbf{G}_{ins} \mathbf{s}_i \\ &= \mathbf{D} \mathbf{s}_i \end{aligned} \quad (19)$$

where

$$\mathbf{D} = \mathbf{G}_{rem} \mathbf{H}_{i,i} \mathbf{G}_{ins} \quad (20)$$

Equation 19 clearly shows that the cyclic prefix perfectly eliminates the ISI resulting from the $(i - 1)$ th transmitted signal. Furthermore, direct calculation of Equation 20

reveals that with the impulse response vector $\mathbf{h} = [h_1, \dots, h_L, 0, \dots, 0]^T$ ($N_{SC} \times 1$), \mathbf{D} can be written as

$$\mathbf{D} = [\mathbf{h}^0, \mathbf{h}^1, \dots, \mathbf{h}^v, \dots, \mathbf{h}^{N_{SC}-1}] \quad (21)$$

where \mathbf{h}^v denotes the v -cyclic shifted channel impulse response vector. \mathbf{D} is called a *circulant matrix* ($N_{SC} \times N_{SC}$), and with the DFT and IDFT matrices, it can be diagonalized (Davis 1979) as

$$\mathbf{D} = \mathbf{W}^{-1}(N_{SC}) \mathbf{Z} \mathbf{W}(N_{SC}) \quad (22)$$

where \mathbf{Z} is defined as

$$\mathbf{Z} = \text{diag}[\mathbf{W}(N_{SC}) \mathbf{h}^0] = \text{diag}[\mathbf{z}] \quad (23)$$

where $\mathbf{z} = [z_1, \dots, z_{N_{SC}}]^T$ denotes the frequency response vector of the channel ($N_{SC} \times 1$) and $\text{diag}[\mathbf{z}]$ denotes the diagonal matrix ($N_{SC} \times N_{SC}$) with main diagonal elements of $z_1, \dots, z_{N_{SC}}$. Consequently, inserting a cyclic prefix replaces the convolution of the channel impulse response by its circular convolution, which is equivalently expressed in the discrete frequency domain as multiplication of the channel frequency response. Defining the DFT output vector $\mathbf{W}(N_{SC}) \mathbf{r}_i$ as $\hat{\mathbf{c}}_i = [\hat{c}_{i1}, \dots, \hat{c}_{iN_{SC}}]^T$ ($N_{SC} \times 1$) with Equations 5, 19, and 22, it can be written as

$$\begin{aligned} \hat{\mathbf{c}}_i &= \mathbf{W}(N_{SC}) \mathbf{r}_i \\ &= \mathbf{W}(N_{SC}) (\mathbf{W}^{-1}(N_{SC}) \mathbf{Z} \mathbf{W}(N_{SC})) (\mathbf{W}^{-1}(N_{SC}) \mathbf{c}_i) \\ &= \mathbf{Z} \mathbf{c}_i \end{aligned} \quad (24)$$

Taking into consideration that \mathbf{Z} is the diagonal matrix with elements of $z_1, \dots, z_{N_{SC}}$, finally we have

$$\hat{c}_{ik} = z_k c_{ik} \quad (k = 1, \dots, N_{SC}) \quad (25)$$

Equation 25 clearly shows that, through the channel, the symbol transmitted over the k th subcarrier is multiplied by its frequency response. In other words, if the receiver estimates the frequency response of the channel, then it can easily recover the transmitted data. Figure 7 shows the matrix and vector representation of a baseband OFDM system.

Before finishing this discussion on the effect of cyclic prefix, note that the cyclic prefix insertion technique is applicable not only to OFDM but also to SCM. Indeed, an SCM system, with DFT processing and the use of cyclic prefix for frequency domain equalization, has essentially the same performance and complexity as an OFDM system (Sari, Karam, and Jeanclaude 1994).

Now let us come back to the analog representation of OFDM signal. Modifying Equations 1 through 4, the transmitted signal with the cyclic prefix is written as

$$s(t) = \sum_{i=-\infty}^{+\infty} \sum_{k=1}^{N_{SC}} c_{ki} e^{j2\pi f_k(t-iT_s)} f(t-iT_s) \quad (26)$$

$$f(t) = \begin{cases} 1, & (-\Delta_G < t \leq t_s) \\ 0, & (t \leq -\Delta_G, t > t_s) \end{cases} \quad (27)$$

$$f_k = f_c + \frac{(k-1)}{t_s} \quad (28)$$

$$\Delta f = \frac{1}{t_s} \quad (29)$$

where T_s , Δ_G and t_s denote the OFDM symbol period, cyclic prefix length, and observation period (often called the *useful symbol length*), respectively, and they satisfy the following equation:

$$T_s = \Delta_G + t_s \quad (30)$$

The OFDM waveform is expressed by Equations 26 through 30 in the sense that it is transmitted and received with the IDFT and DFT and that it has a cyclic prefix. Now we have reached the “current form” of OFDM. Figure 8 shows the cyclic prefix insertion technique, the frequency spectrum of the pulse waveform, and the frequency spectrum of the transmitted signal in the current form of OFDM.

Before moving on to the next section, note that the cyclic prefix also gives OFDM signal a drawback. Remember that the subcarrier separation of the OFDM signal

Figure 8: Current form of OFDM—(a) cyclic prefix extension technique, (b) frequency spectrum of the pulse waveform, and (c) frequency spectrum of the OFDM signal

without the cyclic prefix is $1/T_s$ (see Equation 4), whereas that with the cyclic prefix is $1/t_s$ (see Equation 29). T_s is larger than t_s , so $1/T_s$ is smaller than $1/t_s$. This means that inserting the cyclic prefix makes the subcarrier separation a bit larger. For example, the bandwidth in terms of the mainlobe is calculated as $B_{OFDM} = 2/T_s + (N_{SC} - 1)/[(1 - \alpha_G)T_s]$, where α_G is the cyclic prefix factor defined as $\alpha_G = \Delta_G/T_s$. If the number of subcarriers is large, then the bandwidth of the OFDM signal normalized by total symbol transmission rate $R = N_{SC}/T_s$ is written as $B_{OFDM}/R = 1/(1 - \alpha_G) \approx 1 + \alpha_G$. This means that the cyclic prefix insertion widens the bandwidth of the OFDM signal by Δ_G .

Coded OFDM

To show that channel coding gives OFDM more robustness against frequency-selective fading, this subsection will demonstrate the *bit error rate* (BER) performance of a coded OFDM system by computer simulation (Hara and Prasad 2002). As shown later in the third and fourth sections of this chapter, OFDM has some drawbacks, such as sensitivity to nonlinear amplification at the transmitter and sensitivity to carrier frequency offset and difficulty in DFT window synchronization at the receiver. However, here we assume that such drawbacks have been overcome—that is, we assume linear amplification, no carrier frequency offset, and perfect DFT window synchronization.

When an OFDM signal is transmitted through a frequency-selective fading channel, some subcarriers experience high attenuation whereas others experience low attenuation. We can imagine that if we employ a channel coding scheme over subcarriers, we can improve the BER by means of a frequency diversity effect.

Error-correcting codes such as convolutional codes are often designed for channels where the errors are random. However, in a frequency-selective fading channel, signal fade causes bursty errors, because the time-varying nature of the channel makes the level of the received signal fall below the noise level and the fade duration contains several transmitted data. To make such codes work well even in a frequency-selective fading channel, an interleaving technique is commonly used to transform the bursty channel into a channel with random errors by reordering the encoder outputs at the transmitter.

Figure 9 shows the block diagram of a bit-interleaved coded OFDM system to investigate the BER performance, where *quadrature phase shift keying* (QPSK) and coherent detection and a half-rate convolutional code are assumed with constraint length of 7 and bit interleaving

depth of 8 within one OFDM symbol. Note that the subcarrier arrangement of the physical layer standard (IEEE 802.11a PHY) is used (IEEE 1999). In addition, two kinds of Rayleigh fading channels are assumed. One is a frequency-nonselective Rayleigh fading channel in which a single Rayleigh-distributed path is in the multipath delay profile. The other is a frequency-selective Rayleigh fading channel in which there are three independent and identical Rayleigh-distributed paths with the identical average power in the multipath delay profile (Proakis 2001). For both channels, a quasi-static fading is assumed in which the temporal variation is negligibly small over one OFDM symbol whereas it is independent symbol by symbol.

Figure 10 shows the BER performance against the average E_b/N_0 (the ratio of signal energy per bit to spectral density of noise) in the frequency-nonselective and quasi-static Rayleigh fading channel (see Figure 11a) and in the frequency-selective and quasi-static Rayleigh fading channel (see Figure 11b), respectively. Each figure contains a theoretical result as well as a computer simulation result, and the theoretical derivation on the BER is given in Proakis (2001). In Figure 11a, there is no diversity effect even if the channel coding is employed because all of the subcarriers are subject to the same attenuation at one time. On the other hand, in Figure 11b, the third-order diversity effect is obtained. It is well known that the degree of freedom in the time domain is the same as that in the frequency domain, because they are related to each other through a linear transform of DFT (Monsen 1973). Therefore, in this case, through the channel coding, the third-order gain is obtained as a frequency diversity effect instead of as a path diversity effect.

TRANSMISSION OF OFDM SIGNALS

Figure 12 shows the block diagram of an OFDM transmitter, where the blocks for interleaving and channel coding are omitted. This section will discuss the issues related to two blocks in the figure: the *digital-to-analog* (D/A) converter and a power amplifier.

Resolution of Digital-to-Analog Converter

Equation 26 shows that the OFDM signal is composed of a number of sinusoidal signals, each one independently modulated by information data to transmit. Therefore, by the central limiting theorem, the signal becomes like a Gaussian noise; more precisely, its amplitude becomes complex-valued and Gaussian-distributed, thus its

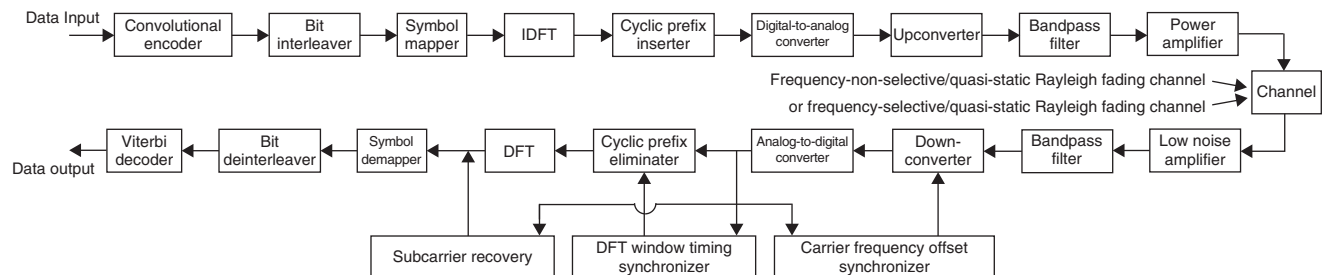

Figure 9: A bit-interleaved, convolutionally encoded OFDM system

Figure 11: Comparison of envelope variation between an OFDM signal and a SCM signal

Figure 12: Block diagram of an OFDM transmitter

envelope becomes Rayleigh-distributed. Figure 12 compares the envelope variation between an OFDM signal and an SCM signal, where the QPSK with $N_{SC} = 53$ and $\Delta_G/T_s = 0.2$ is assumed for the OFDM signal whereas the QPSK with root Nyquist filter (roll-off factor = 0.5) is assumed for the SCM signal. It can be seen from the figure that the OFDM signal has a large envelope variation, whereas the values of the SCM envelope concentrate on a certain level. Figure 13 compares the probability density functions of the envelope level between the two signals, which more clearly highlights the difference. A large variation in the envelope level also means a large difference between peak and average powers, so it is said that OFDM has a high *peak-to-average-power ratio* (PAPR).

In the transmitter, the signal generated in a digital domain is D/A-converted before upconversion. The dynamic

range of the input amplitude determines the resolution of the D/A converter, so a high resolution is required for the D/A converter in the OFDM transmitter.

Power Amplification of OFDM Signals

In general, a highly efficient power amplifier is preferable at the transmitter, especially in a mobile terminal that is driven by a battery. However, such a highly efficient power amplifier has a nonlinear characteristic that clips the amplitude of input signal. The sudden clips of the input amplitude generate higher spectral components in the power spectrum of the signal, so it results in a spectrum spreading.

As mentioned above, the OFDM signal is like a Gaussian noise with a large envelope variation, so even if we

Figure 13: Probability density functions of the envelope for the OFDM and SCM signals

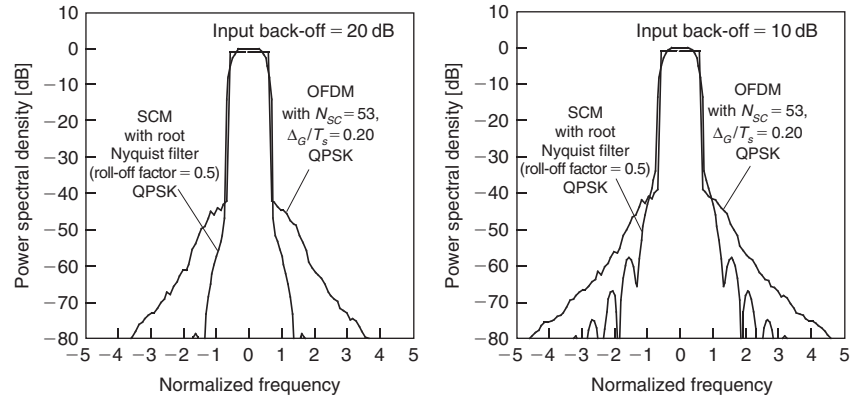

Figure 14: Power spectral densities of the OFDM and SCM signals after a nonlinear amplification

try to reduce the spectrum spreading with a large input backoff to a nonlinear amplifier, we cannot perfectly eliminate sudden inputs of the larger amplitudes beyond the saturation point of the nonlinear amplifier. Furthermore, the outband radiation generated by a subcarrier also becomes ICI for its neighboring subcarriers. Therefore, the severe ICI drastically deteriorates the transmission performance.

Figure 14 compares the power spectral densities of the OFDM and SCM signals after a nonlinear amplification. Here the horizontal axis denotes the frequency normalized by the data transmission rate, and a European Telecommunications Standards Institute (ETSI) BRAN high-power amplifier model (Johansson and Potsher undated) is assumed with input backoffs of 20 dB and 10 dB. As compared with the SCM signal, the OFDM signal has a large outband radiation even for the large input backoff of 20 dB. The sensitivity to nonlinear amplification is often pointed out as one of major drawbacks of OFDM.

There are mainly two methods to increase the power efficiency when amplifying OFDM signals. One method is to reduce the PAPR of the OFDM signal. For example, *selected mapping* (SLM) (Bauml, Fischer, and Huber 1996) multiplies an input symbol sequence by each of the phase sequences to generate alternate input symbol sequences. After applying the IDFT to all of the alternative symbol sequences, SLM selects the one with the lowest PAPR. On the other hand, *partial transmit sequence* (PTS) (Muller and Huber 1997) partitions an input symbol sequences into a number of disjoint symbol subsequences. Applying the IDFT to each symbol subsequence and then summing

the resulting signal subsequences multiplied by a set of distinct rotating vectors, PTS selects the one with the lowest PAPR. Another method is to improve the power efficiency of the amplifier even for varying-envelope input signals. For example, a dynamic biasing method (Saleh and Cox 1983) dynamically controls the direct current voltage with the envelope value of the input signal. On the other hand, *linear amplification with nonlinear components* (LINC) (Cox 1974) is based on the fact that any bandpass signal can be represented by two constant-envelope phase-modulated signals. In addition to these, it is known that some block codes can limit the PAPR within a certain level (Jones, Wilkinson, and Barton 1994).

All of the techniques shown in the above are old. Now, in the early 2000s, to improve the power efficiency of amplifier for the OFDM signal, several variants related to those techniques are now being widely discussed in the research communities on signal processing, wireless communications, and microwave technology.

RECEPTION OF OFDM SIGNALS

Figure 15 shows the block diagram of an OFDM receiver, where the blocks for deinterleaving and channel decoding are also omitted. Here we can easily imagine that, similar to the D/A converter in an OFDM transmitter, a high resolution is required for the analog-to-digital converter in the OFDM receiver.

This section will discuss the issues related to the lower blocks in the figure, such as DFT window timing and

Figure 15: Block diagram of an OFDM receiver

carrier frequency offset synchronization and subcarrier recovery.

DFT Window Timing and Carrier Frequency Offset Synchronization

Equation 25 shows that if it correctly estimates the channel responses for the subcarriers, the receiver can recover the transmitted data. This is true when the receiver has been synchronized to the received signal. Here synchronization at the receiver has two tasks. One is *DFT timing synchronization*—that is, finding a correct timing of the DFT windowing for the received signal. This is extremely difficult, because the OFDM signal is like a Gaussian noise with no distinct boundary between successive OFDM symbols. The second task is *carrier frequency offset synchronization*. There is always a mismatch between the carrier frequencies of local oscillators between a transmitter and receiver. The spectra of subcarriers are densely overlapped in an OFDM signal, so if there exists a carrier frequency offset between a transmitter and receiver, the DFT outputs at the receiver are rich in ICI, resulting in worse transmission performance. Therefore, the receiver needs to accurately estimate and compensate for the carrier frequency offset.

For burst mode transmission in wireless LAN applications, Schmidl's method can jointly accomplish DFT window timing and carrier frequency offset synchronization (Schmidl and Cox 1997). In this method, a pilot OFDM symbol that has two identical halves in the time domain is added at the head of a data burst. Then with the correlation and angle between the first and second halves of the received pilot OFDM symbol, a correct DFT timing and a carrier frequency offset are estimated, respectively.

On the other hand, for continuous mode transmission in digital broadcasting—for example, in *terrestrial integrated services digital broadcasting* (ISDB-T) (Association of Radio Industries and Businesses 2000), two kinds of pilot symbol patterns are used for DFT window timing and carrier frequency offset synchronization: (1) a continuous pilot pattern on the subcarrier with the highest frequency and (2) the scattered pilot pattern in which pilot symbols are inserted at certain subcarriers and certain OFDM symbols.

SUBCARRIER RECOVERY

For OFDM, carrier recovery—namely, generation of a reference signal point—is needed for each subcarrier, so it gives an impression that the complexity of coherent detection is magnified by the number of subcarriers. However, in wired systems, the channel state does not

change often, so coherent detection is not so difficult. For example, coherent detection was employed even by the telephone modem developed in the late 1980s (Bingham 1990) and then by the *discrete multitone* (DMT) receiver for ADSL (Chow, Tu, and Cioffi 1991).

On the other hand, in wireless systems, the channel state always changes, so until the late 1980s, coherent detection was considered to be difficult for OFDM especially in frequency-selective fading channels. Indeed, the *digital audio broadcasting* (DAB) system specified in the late 1980s was based on differential encoding and differential detection that required no subcarrier recovery (Dambacher 1996).

In the early 1990s, discussion of coherent detection of the OFDM signal in the broadcasting system began (Helard and Le Floch 1991) because, to support a higher data transmission rate in a limited frequency bandwidth, higher multilevel modulation techniques such as 16-QAM (quadrature amplitude modulation) and 64-QAM were required with coherent detection. For example, to support coherent detection, the use of scattered pilot symbols was discussed in a frequency-selective fading channel, where a two-dimensional interpolating filter was employed in the frequency domain to estimate the channel response over the subcarrier where the pilot symbol was not available and in the time domain to track the temporal variation of the channel.

Compared with the SCM signal, because of its long symbol period, the OFDM signal is not robust to the temporal variation of channel, the rate of which is determined by a Doppler frequency spread in mobile systems. Therefore, accurately tracking the temporal variation of the channel for subcarrier recovery is one of the most important receiver's tasks in mobile systems. Now in the early 2000s, subcarrier recovery as well as DFT timing and carrier frequency offset synchronization in frequency-selective fading channels is a hot OFDM topic in the research communities of signal processing and wireless communications (Hara and Prasad 2002; Fazel and Kaiser 2003; Hanzo and Keller 2006).

RESOURCE ALLOCATION

In terms of the number of connections in a channel, a system can be categorized as one of two types: single-user or multi-user. A single-user system is one in which there is only a point-to-point connection in a channel, whereas a multi-user system is one in which there are point-to-multipoint connections in a channel.

In wired telephone systems, the channel state does not change often, so the transmitter can easily know the channel state from the receiver through feedback. Indeed, to

Table 1: DAB Parameters

Parameter mode	Mode 1	Mode 2	Mode 3
Bandwidth	1.536 MHz	1.536 MHz	1.536 MHz
Number of subcarriers	1,546	768	384
Modulation and demodulation		DEQPSK/Differential	
Useful symbol length (t_s)	1 ms	250 μ s	125 μ s
Subcarrier separation (Δf)	3.968 kHz	1.984 kHz	0.992 kHz
Cyclic prefix length (Δ_G)	$t_s/4$ (250 μ s)	$t_s/4$ (62.5 μ s)	$t_s/4$ (31.25 μ s)
FEC	Convolutional code		
Information transmission rate	2.4 Mbps		

maximize the data transmission rate satisfying a certain BER, the telephone modem developed in the late 1980s (Bingham 1990), which is a typical example of a single-user system, adaptively allocated an adequate power and modulation level to each subcarrier. This is called *adaptive power and bit loading*, and, in wired systems, ADSL and PLC transceivers have used the adaptive power and bit loading (Chow, Tu, and Cioffi 1991; Lin et al. 2002).

On the other hand, in mobile wireless communication systems, the channel state changes often, so introducing an adaptive mechanism into a system requires a high rate of adaptation. For example, a frame-by-frame adaptive bit loading was proposed in a multi-user OFDM *time division multiple access* (TDMA) system in which subcarriers with large gains are assigned to higher modulation levels to convey more information per OFDM symbol; subcarriers in deep fade, on the other hand, are assigned to lower modulation levels or are not used for information transmission (Rohling and Grunheid 1996).

Resource allocation is now one of the hot research topics in multi-user OFDM systems. It can offer a multi-user diversity effect by dynamically allocating subcarrier, bit, and power to different users according to their instantaneous channel conditions (Wong et al. 1999). The optimal allocation algorithm is given by the solution of a nonlinear optimization problem, but it is impractical because of its high computational complexity. To reduce the complexity, several algorithms with modification and approximation have been proposed.

APPLICATIONS OF OFDM

The previous sections have given all of the materials required for understanding current OFDM-based systems along with advantages and drawbacks still to be overcome. This section will show several applications of OFDM in already-existing systems.

Digital Broadcasting

Digital audio broadcasting was specified between 1988 and 1992, with its introduction in Europe scheduled in the late 1990s (Dambacher 1996). Table 1 shows the three modes defined in EUREKA 147 DAB, where *differentially*

encoded quadrature phase shift keying (DEQPSK) and differential detection was employed with a convolutional code as a *forward error correction* (FEC).

Based on the successful results from the OFDM-based DAB field trials and measurements in Europe, *terrestrial digital video broadcasting* (DVB-T), with the use of OFDM, was standardized by ETSI in 1996 (European Telecommunications Institute 1996). The United Kingdom first put it into commercial service with multifrequency network use in 1998.

On the other hand, in Japan, the Association of Radio Industries and Businesses (ARIB) standardized ISDB-T in June 2000 (Association of Radio Industries and Businesses 2000). Table 2 shows the three modes defined in the ISDB-T for television. Commercial service successfully began in 2003. The ISDB-T employs QPSK to 64-QAM with coherent detection and DEQPSK with differential detection for mobile reception.

The difference between the DVB-T and the ISDB-T is that the former supports only stationary reception, whereas the latter supports not only stationary but also mobile receptions. In 2004, *handheld digital video broadcasting* (DVB-H), also with the use of OFDM, was standardized for battery-powered handheld receivers by ETSI (2004).

Wireless Local Area Networks

In 1998, the Institute of Electrical and Electronic Engineers (IEEE) 802.11 standardization group decided to select OFDM as a basis for its new 5-GHz wireless LAN standard, which supports data transmission rate from 6 Mbps to 56 Mbps with *binary PSK* (BPSK) to 64-QAM (IEEE undated "Working group"). In the DVB-T and ISDB-T (mentioned in the previous section), OFDM is used in continuous transmission mode for the purpose of broadcasting. On the other hand, this standard—IEEE 802.11a—is the first to use OFDM in packet transmission mode (IEEE 1999). Now there is also the IEEE 802.11g standard based on OFDM, which is available in the 2.4-GHz frequency band (IEEE 2003), and the frequency arrangement of which is the same as that of the IEEE 802.11a standard. Table 3 summarizes the IEEE 802.11a parameters (Van Nee and Prasad 2000).

Table 2: ISDB-T Parameters

Parameter mode	Mode 1	Mode 2	Mode 3
Bandwidth	5.575 MHz	5.575 MHz	5.575 MHz
Number of subcarriers	1405	2809	5617
Modulation	QPSK, 16-QAM, 64-QAM, coherent and DEQPSK, differential		
Useful symbol length (t_s)	252 μ s	504 μ s	1008 μ s
Subcarrier separation (Δf)	3.968 kHz	1.984 kHz	0.992 kHz
Cyclic Prefix Length (Δ_c)	$t_s/4$ (63 μ s)	$t_s/4$ (126 μ s)	$t_s/4$ (252 μ s)
	$t_s/8$ (31.5 μ s)	$t_s/8$ (63 μ s)	$t_s/8$ (126 μ s)
	$t_s/16$ (15.75 μ s)	$t_s/16$ (31.5 μ s)	$t_s/16$ (63 μ s)
	$t_s/32$ (7.875 μ s)	$t_s/32$ (15.75 μ s)	$t_s/32$ (31.5 μ s)
FEC (inner code)	Convolutional code (coding rate = 1/2, 2/3, 3/4, 5/6, 7/8)		
FEC (outer code)	Reed-Solomon code (204, 188)		
Interleaving	Time-frequency domain bit interleaving		
Information transmission rate	3.65–23.2 Mbps		

Table 3: IEEE 802.11a Parameters

Channel spacing	20 MHz
Bandwidth	16.56 MHz (–3 dB bandwidth)
Number of subcarriers	52
Number of pilot subcarriers	4
Useful symbol length (t_s)	3.2 μ s
Subcarrier separation (Δf)	312.5 kHz
Cyclic prefix length (Δ_c)	800 ns
FEC	Convolutional code
Interleaving	Frequency domain bit interleaving (within 1 OFDM symbol)
Information transmission rate	6 Mbps (BSPK, coding rate = 1/2)
(modulation, coding rate)	9 Mbps (BSPK, coding rate = 3/4)
	12 Mbps (QSPK, coding rate = 1/2)
	18 Mbps (QSPK, coding rate = 3/4)
	24 Mbps (16-QAM, coding rate = 1/2)
	36 Mbps (16-QAM, coding rate = 3/4)
	48 Mbps (64-QAM, coding rate = 2/3)
	54 Mbps (64-QAM, coding rate = 3/4)
Multiple access method	CSMA/CA (carrier sense multiple access with collision avoidance)

Broadband Wireless Access

The IEEE 802.16 standard defines the WirelessMAN air interface specification for *metropolitan area networks* (MANs); it attempts to replace the “last mile” of wired access with cable modem and digital subscriber line by broadband wireless access (IEEE undated “802.16”). The IEEE 802.16a standard especially defines the air interface as the 2 GHz to 11 GHz band, including both licensed and license-exempt spectra. In the standard, WirelessMAN-OFDM

employs an OFDM format with 256 subcarriers with TDMA, whereas WirelessMAN-OFDMA employs an OFDMA (OFDM access) with 2048 subcarriers, where the system performs multiple access by allocating a subset of the multiple subcarriers to an individual receiver. This system also uses frequency hopping spread spectrum for interference suppression.

The IEEE family has been extended to mobile access through the 802.16e standard of December 2005 (IEEE 2006). The IEEE 802.16e has drawn much attention now

Table 4: IEEE 802.16e Parameters

Bandwidth	1.25, 5, 10, and 20 MHz
Number of FFT points	128 (1.25 MHz), 512 (5 MHz), 1024 (10 MHz), and 2048 (20 MHz)
Cyclic prefix length (Δ_c/t_s)	1/4, 1/8, 1/16, and 1/32
FEC	Reed Solomon code
	Convolutional code (coding rate = 1/2, 2/3, and 3/4)
	Convolutional turbo code (optional)
	Block turbo code (optional)
	Low-density parity check
	Code (optional)
Modulation	BPSK (pilot), QPSK, 16-QAM, 64-QAM
Information transmission rate (modulation, coding rate)	1.04 Mbps (1.25 MHz, QPSK, coding rate = 1/2) to 74.81 Mbps (20 MHz, 64-QAM, coding rate = 3/4)
Multiplexing and multiple access	OFDM and OFDMA

because it has been adopted as the physical and medium access control layers protocol in the WiMAX system (WiMAX Forum undated), providing better data handling capability in all-IP services such as video, music streaming, and so on before fourth-generation (4G) cellular systems arrive. Table 4 summarizes the IEEE 802.16e parameters.

MIMO Transmission

In wireless communications, *multiple-input, multiple output* (MIMO) transmission uses multiple antennae at both the transmission and receiver sides (Foschini and Gans 1998). It can increase the data transmission rate or achieve better error-rate performance without increasing the required frequency bandwidth of the transmitted signal, so it is considered to be a promising technique in future wireless communication systems. In MIMO transmission, frequency-nonspecific fading needs to be guaranteed in a channel between any pair of transmission and reception antennae. Therefore, to adopt MIMO transmission in a frequency-selective fading channel, its combination with OFDM is suitable. For example, now in the early 2000s, the IEEE 802.11n standard is being finalized (IEEE undated "802.11"). It employs OFDM with four more subcarriers, a short cyclic prefix length, and 2×2 MIMO transmission to support much higher data-transmission rates compared with the IEEE 802.11a standard. In addition, MIMO transmission is optionally adopted in IEEE 802.16e (IEEE 2006).

Fourth-Generation Mobile Communication Systems

The introduction of service of 4G mobile communication systems is scheduled around 2010 to 2020, and it will support more than 100 Mbits/sec data rates even for high-speed cruising mobile users. Intensive research on 4G mobile communication systems and related topics are now of great interest to researchers in universities and laboratories all over the world, with OFDM promising to

play a key role in the systems with MIMO transmission (Hara and Prasad 2002; Fazel and Kaiser 2003; Hanzo and Keller 2006).

CONCLUSION

Now in the early 2000s, we are using several standards based on OFDM—for example, DMT for ADSL; European DAB, DVB-T, and DVB-H and Japanese ISDB-T for broadcasting; IEEE 802.11a and IEEE 802.11g for wireless LANs; and IEEE 802.16e for mobile broadband wireless access. OFDM fundamentally has never changed its form since the use of cyclic prefix was proposed in the late 1980s. In this sense, we can doubtlessly say that the technique of OFDM has been matured, although there are still drawbacks to overcome in implementation of OFDM transceivers, such as efficient power amplification in conjunction with reducing the PAPR and the DFT window timing and carrier frequency offset synchronization and subcarrier recovery. Looking at current discussions on OFDM, we can say that OFDM probably will continue to be a promising transmission technique. Because we desire to enjoy more broadband services in wireless systems, OFDM is suitable to combat frequency-selective fading with MIMO transmission.

GLOSSARY

Cyclic prefix: A signal extended in the guard time interval to cyclically and continuously extrapolate signals over subcarriers.

Guard time interval: A time interval inserted between successive symbols to avoid intersymbol interference because of time dispersion of channel.

Inter(sub)carrier interference (ICI): Interference among subcarriers.

Multicarrier modulation: A parallel data transmission method to split a high-rate data stream into a number of lower-rate data streams that are transmitted simultaneously over a number of subcarriers.

Multiple-input, multiple-output (MIMO) transmission: A technique to use multiple antennae at both the transmission and receiver sides to improve data transmission rate or quality without increasing the required bandwidth.

Multi-user diversity: In a large network, at any time there is a user whose channel condition is good with high probability. Multi-user diversity is a technique to improve the overall network capacity by allowing such a user to transmit data at that time. A technique to improve the overall multi-user capacity in a large network where there is a user at any time with high probability whose channel condition is good is to allow such a user to transmit data at that time.

Orthogonal frequency division multiplexing (OFDM): A kind of multicarrier modulation that allows subcarrier overlapping.

Useful symbol: A part of the OFDM symbol that corresponds to the DFT window.

INTRODUCTION

In recent years, the increasing popularity of the Internet has resulted in a rapidly growing demand for network bandwidth. It is expected that traditional networks will not be able to support the massive traffic resulting from emerging high-bandwidth applications. The demand of multimedia applications is creating an incredible pressure on existing telephony infrastructures that are designed to handle predictable connection-oriented voice traffic. Users are already seeing reduced performance of the Internet, including high delays and network failures. Hence, new technologies were needed to support the bandwidth requirements of subscribers and provide support for new services. Optical fiber technology is becoming the dominant factor for meeting these demands because of its potential capabilities: huge bandwidth, low signal attenuation, low power requirement, low material usage, small space requirement, and low cost. With optical technology, these networks are becoming the appropriate infrastructure for Internet transport. Given the large difference between optical transmission capacity (in tens of Tbps) and electronic data rate (several Gbps), it is expected that optical fibers can scale the increasing volume of information (Papadimitriou et al. 2003).

Currently, links in long-life networks consist almost entirely of optic fibers, with hundreds of thousands of miles of new fiber being deployed every year. Optic fiber offers increased capacity by allowing higher transmission rates over longer distances as compared to copper wires. However, the bandwidth is still limited by the electronic processing and switching speeds at the communication nodes. Three technologies are available in an optical network: *time division multiplexing* (TDM), *synchronous*

optical network (SONET), and *synchronous digital hierarchy* (SDH). Currently, the SONET-SDH layer has been used with many traditional networks to offer mechanisms for efficient bandwidth utilization and to provide protection. The SONET-SDH framing structure is widely used in voice transmission in optical networks but is considered to be cumbersome for high-speed links. A new flexible framing scheme is required for next generation optical network to support multiprotocol encapsulation, virtual links, *quality of service* (QoS) differentiation, and link management (Papadimitriou et al. 2003; SONET overview, undated).

The fiber bandwidth can be further exploited by dividing the bandwidth into a number of channels of different wavelengths and by operating each channel at peak electronic rate. This technique is known as *wavelength division multiplexing* (WDM). A WDM network not only provides a huge amount of bandwidth but also may offer data transparency in which the network may carry signals of arbitrary format. Data transparency may be achieved through all-optical transmission and switching of signals without electronic conversions at the intermediate nodes. The major challenge in deploying WDM is to develop architectures and protocols that take full advantage of the benefits offered by WDM. At the same time, the proposed architectures must consider the limitations imposed by current optical device technology. Also, these architectures must support critical services such as bursty traffic while efficiently utilizing the network resources. There are several optical technologies, namely, *wavelength routing* (WR), *optical packet switching* (OPS), *optical label switching* (OLS), and *optical burst switching* (OBS). In WR, end users communicate with one another via all-optical WDM

channels, which are referred to as *lightpaths*. An OPS is capable of dynamically allocating network resources with fine packet-level granularity while offering high scalability. An OLS network is proposed to provide a fast switching process based on a set of labels built during the signaling step. An OBS is designed to achieve a balance between the coarse-grained WR and the fine-grained OPS.

In this chapter, we investigate the optical components, optical multiplexing techniques, network architectures, and protocols for WDM networks with the goal of addressing the different issues related to the existing approaches and developed architectures that provide improved performance as well as support for QoS.

This chapter is organized into eight sections. The next section discusses optical multiplexing techniques and major trends in optical components. The third section presents the basic concepts of the WDM technology, as well as its advantages and limitations. The fourth section addresses the different techniques used by optical switching in the WDM networks. The fifth section presents several signaling schemes used by WDM. The sixth section provides a survey of the basic WDM architectures such as broadcast and select and WR networks. The seventh section discusses the QoS models adopted in WDM networks. Finally, the last section before the conclusion gives several critical issues related to the provision of the Internet protocol over WDM.

OPTICAL MULTIPLEXING TECHNIQUES

Bandwidth requirements are expected to increase with time. Therefore, research in optical fiber networks is directed toward achieving high-capacity optical networks. High capacities in optical networks can be achieved by using various optical components and multiplexing techniques. In all-optical networks, concurrency can be provided through time slots (TDM or optical TDM), SONET-SDH, and WDM. In this section, we present an overview of the major optical multiplexing techniques.

Major Optical Components

To transmit data across an optical fiber, the information must first be encoded, or modulated, onto the laser signal (the optical carrier). Analog techniques include amplitude modulation, frequency modulation, and phase modulation. Digital techniques include amplitude shift keying, frequency shift keying, and phase shift keying (Brackett 1990). To enable the operation of the new, vast, and versatile wavelength dimension, new technologies have to be developed. New components that can exercise selection, switching, and routing based on wavelengths were also needed, including optical transmitters, optical receivers, optical amplifiers, *optical cross-connects* (OXC) and *optical add-drop multiplexers* (OADMs).

Optical Fiber

Before describing the optical components, it is essential to understand the characteristics of the optical fiber itself. An optical fiber consists of a central core that is surrounded by a cladding layer whose refractive index is lower than the index of the core. An optical fiber acts as

Figure 1: The low-attenuation regions of an optical fiber

a dielectric waveguide to confine light within its surfaces and to guide it in a direction parallel to its axis. The confinement of light is achieved using the so-called total internal reflection, which is done when the angle of incidence of light is greater than the critical angle. Fiber possesses many characteristics that make it an excellent medium for high-speed networking. Figure 1 shows the two low-attenuation regions of optical fiber. The figure also shows the loss attenuation for an optical fiber in two regions centered at approximately 1300 nanometers (nm) and 1550 nm, respectively, where the attenuation is less than 0.5 dB per kilometer. The total bandwidth for each region is approximately 25 THz.

By using these attenuation areas for data transmission, the signal loss can be made extremely small, thus reducing the number of needed amplifiers and repeaters. Besides its enormous bandwidth and low attenuation, fiber also offers low error rates. Fiber-optic systems typically operate at *bit error rates* (BERs) of less than 10^{-10} to 10^{-11} . Also, fiber transmission is immune to electron magnetic interference and does not cause interference. Naturally, the fiber also has some weaknesses, such as dispersion, nonlinear refraction, and attenuation (when signal attenuation is higher than 0.2 dB/km).

The major forms of dispersion are modal, polarization-mode, and chromatic. *Modal dispersion* occurs only in multimode fibers in which a signal propagates at different speeds. A single mode fiber carries two polarization modes that are indistinguishable in an ideal fiber because of the cylindrical symmetry of the core. However, real fiber deviates from cylindrical symmetry to a more elliptical shape because of the manufacturing process, mechanical stress applied to the fiber, or both. This accidental loss of symmetry results in two distinct polarization modes with different propagation modes. *Polarization mode dispersion* occurs because two polarization modes arrive at different times at the receiver. *Chromatic dispersion* is the consequence of two contributing factors: material dispersion and waveguide dispersion. The first results from the refractive index of silica, which is a function of the spectral components of the signal. The second factor occurs

because part of the signal's power propagates on the core and part in the cladding, and they have different refractive indexes.

Optical Transmitter

Optical transmitters can be either tunable or fixed. Tunable lasers can be characterized by the tuning range, tuning time, and information about whether the laser is continuously tunable or discretely tunable. The tuning range is the range of wavelengths over which the laser may be operated. The tuning time is the time required for the laser to tune from one wavelength to another. The most popular tunable lasers are mechanically tuned lasers: acousto-optically and electro-optically tuned lasers or injection current-tuned lasers. Mechanically tuned lasers use a Fabry-Perot cavity that is adjacent to the lasing medium to filter out unwanted wavelengths. They can be tuned by physically adjusting the distance between two mirrors on either end of the cavity so that only the desired wavelength interferes with its multiple reflections in the cavity. A major drawback of mechanically tuned lasers is the tuning time. Because of the mechanical nature of tuning and the length of the cavity, the tuning time is on the order of milliseconds.

In acousto-optically and electro-optically tuned lasers, the index of refraction in the external cavity is changed by using sound waves and electrical current, respectively. The change in the index of refraction results in the transmission of light at different frequencies. In tuned lasers, the tuning time is limited by the time required for light to get back in the cavity at the new frequency (Brackett 1990). Injection current-tuned lasers allow wavelength selection via diffraction grating. Normally, the grating consists of a waveguide in which the index of refraction alternates periodically between two values. The wavelengths that match the period and indexes of the grating are constructively reinforced and propagated through the waveguide, whereas the other wavelengths are not propagated. Depending on the placement of the grating, a laser can be either *distributed feedback* (DFB) or *distributed Bragg reflector* (DBR) laser. In DFB, the grating is placed in the lasing medium, whereas in DBR it is placed outside of the lasing medium. The tuning time for the DBR laser is less than 10 ns.

Optical Receiver

An optical receiver can be either tunable or fixed. The most popular tunable filters are Etalon, acousto-optic, electro-optic, and liquid crystal (LC) Fabry-Perot ("Intellilight dedicated SONET ring," undated). The Etalon comprises a single cavity formed by two parallel mirrors. A signal from an input fiber enters the cavity and reflects a number of times between the two mirrors. A single wavelength can be chosen for propagation through the cavity by adjusting the distance between the mirrors, which can be done mechanically or by changing the index of the material within the cavity. An example of a mechanically tuned Etalon is the Fabry-Perot Etalon receiver (Brackett 1990). In acousto-optic filters, radio frequency waves are passed through a transducer, which is a piezoelectric crystal that converts sound waves to mechanical movement. The sound waves change the crystal's index of refraction

and enable the crystal to act as a grating. By changing the radio waves, a single optical wavelength can be chosen to pass through the filter. The tuning range for acousto-optic receivers covers the spectrum from 1300 nm to 1560 nm and allows approximately one hundred channels. The tuning time of the filters is approximately 10 ms (Yao et al. 2003; Papadimitriou et al. 2003). Electrodes located in the crystal are used to supply current to the crystal. The current changes the crystal's index of refraction, which in turn allows some wavelengths to pass. The tuning time and tuning range of these filters are 10 ns and 16 nm, respectively.

In LC Fabry-Perot filters, the cavity consists of a liquid crystal. Electrical current is used to change the refractive index of the liquid crystal to allow some wavelengths to pass, just as in electro-optic filters. The tuning time of these filters is on the order of a few microseconds while tuning ranges in the order of 30 nm to 40 nm. Fixed receivers use fixed filters or grating devices to filter out wavelengths from a set of wavelengths in a single fiber. The most popular filters or grating devices are diffraction grating, fiber Bragg grating, and thin-film interference filters.

The *diffraction grating* is typically a flat layer of transparent material such as glass or plastic with a row of parallel grooves cut into it. The grating separates light into its component wavelengths by reflecting it with the grooves at all angles. At certain angles, only one wavelength adds constructively while all other wavelengths interfere destructively. Thus, a desired wavelength can be selected by tuning the filter to that wavelength.

In *fiber Bragg grating*, a periodically variable index of refraction is directly photoinduced into the core of an optical fiber. The Bragg grating reflects a given wavelength of light back to the source and passes the other wavelengths. There are two major drawbacks of this method: (1) It induces a grating directly into the core of a fiber, which leads to low insertion loss; and (2) the refractive index in the grating varies with temperature (e.g., an increase in temperature reflects longer wavelengths) (Simmons, Goldstein, and Saleh 1999; Yao et al. 2003; Papadimitriou et al. 2003).

Thin-film interference filters are similar to fiber-grating devices, but they are made by placing alternate layers of low-index and high-index materials onto a substrate layer. Major disadvantages of these filters are their poor thermal stability, high-insertion loss, and poor spectral profile.

Optical Amplifier

Optical amplifiers are important components in the fiber links. They are used to compensate for the attenuation in fibers and for insertion loss in passive optical components such as OXC and OADM. The amplification is usually achieved using *erbium-doped fiber amplifiers* (EDFAs). An EDFA basically consists of small-length optical fibers doped with erbium; they range in length from a few meters to 10 meters. The erbium atoms in the fiber are pumped from their ground state to an excited state at a higher-energy level using a pump source. An incoming signal photon triggers these atoms to come down to their ground state. Thus, incoming signal photons trigger the additional photons, resulting in optical amplification (Brackett 1990).

An optical amplifier is used to amplify a weak or distorted signal with the aim of generating a better optical signal quality. It operates in the optical domain without converting the signal into electrical pulses. It is usually used in long-haul networks where the cumulative loss is large. Current amplifier systems provide extremely low noise and flatter gain, which is advantageous to the optical system. The amplifier output power has steadily increased to nearly +20 dB, which is many times more powerful than the primitive models. A major advantage of EDFAs is that they are capable of amplifying signals with many wavelengths simultaneously. This has provided another way of increasing the capacity: Rather than increasing the bit rate, the bit rate is kept the same and more than one wavelength is used (Yao et al. 2003).

Optical Cross-Connect

A fiber-optical cross-connect element switches optical signals from input ports to output ports. The basic OXC element is the 2×2 cross-point element. It routes optical signals from two input ports to two output ports and has two states: cross state and bar state. In the cross state, the signal from the upper input port is routed to the lower output port, and the signal from the lower input port is routed to the upper output port. In the bar state, the signal from the upper input port is routed to the upper output port, and the signal from the lower input port is routed to the lower output port. Optical cross-point elements have been used in two technologies: (1) the generic directive switch, in which light is physically directed to one of two different outputs; and (2) the gate switch, in which optical amplifier gates are used to select and filter input signals to specific output ports (National Communications System 2002).

Directive switches can be viewed as directional couplers with no gap between the waveguides in the interaction region. When properly fabricated, both cross and bar states can be electro-optically achieved with good cross-talk performance. Cross talk is caused by interference of signals between different wavelengths (interband cross talk) or by interference on the same wavelength on another fiber (intraband cross talk). Interband cross talk must be considered when determining channel spacing where intraband cross talk occurs in switching nodes in which multiple signals on the same wavelength are being switched from different inputs to different output ports. Other types of switches include the mechanical-optical fiber switch and the thermo-optic switch. These devices offer slow switching (in milliseconds) and may be employed in circuit-switched networks. Thermo-optic waveguide switches are operated by the use of the thermo-optic effect. Gate switches operate around 1300 nm and have an optical bandwidth of 40 nm, low polarization dependence (1 dB), and fairly low cross talk (below 40 dB).

Optical Add-Drop Multiplexers

Optical add-drop multiplexers (OADM) are devices that are used to add or remove single wavelengths from a fiber without disturbing the transmission of other signals (see Figure 2). OADM is required for WDM ring and bus networks in order to link the network with local transmitters and receivers. OADMs provide interconnection between network structures. They are generally evaluated in terms

Figure 2: Optical add-drop multiplexer

of performance through cross-talk measurements. Optical cross talk at the same wavelength as the transmitted signal is generally referred to as *homodyne* or *in-band cross talk*. It is particularly serious because it cannot be removed by filtering and has been shown to severely limit network performance (Simmons, Goldstein, and Saleh 1999).

Within homodyne cross talk, incoherent cross talk causes rapid power fluctuations, while coherent cross talk changes the optical power of the signal. Incoherent cross talk occurs in ring and bus networks when the signal and interferer are from different optical sources. It causes power variations at the receiver, resulting in BER degradation. Coherent cross talk in these networks results from multiple paths between ports within OADM. It causes variable attenuation levels between OADM ports. There is no accompanying power penalty because the BER is measured against the optical power at the receiver. Incoherent and coherent cross talk together give a range of possible power penalties, because coherent cross talk can cause variation in both signal and incoherent cross-talk powers at the receiver. The combination of coherent and incoherent cross talk leads to a range of possible BER and power penalties for OADM deployed in a network link.

Optical Multiplexers and Demultiplexers

Optical multiplexers and demultiplexers are used to combine multiple wavelengths onto a single fiber and allow all of the signals to be transferred using the same fiber. These optical components can increase the offered fiber capacity without adding more fibers. They also can receive an optical composite signal that consists of multiple optical frequencies from a fiber and separate it into its frequency components, which are directed to separate fibers. In addition, they can serve as an access point to the optical layer in many more aspects, including other optical devices such as OADM and OXC.

Optical Multiplexing

The need for multiplexing is driven by the fact that it is much more economical to transmit data at higher rates over a single fiber than it is to transmit at lower rates over multiple fibers. Multiplexing and demultiplexing aim to transmit multiple signals over a single communication

channel. The two common multiplexing techniques are FDM, which separates signals by modulating the data onto different carrier frequencies, and TDM, which separates signals by interleaving bits, one after another. There are three possible multiplexing techniques: (1) time division multiplexing, (2) SONET-SDH and (3) wavelength division multiplexing. TDM is a scheme that combines numerous signals for transmission on a single communications line or channel. Each communication channel is divided into many time segments, each having extremely short duration. A multiplexer at the source of a communication link accepts the input from each individual end user, divides each signal into segments, and assigns the segments to time slots in a rotating sequence.

Optical TDM (OTDM) is a promising multiplexing technique. It is similar to the electronic TDM. The only difference is that OTDM is faster and the devices used have an optical nature ("IP-over-SONET configuration" 2002). The operational principle of OTDM is to interleave several signals in time and then direct them to the same fiber. The main advantages of multiplexing are the facts that only one source is required and that the node equipment is simpler in the single channel architecture. In OTDM, many lower-speed data channels each transmit in the form of ultrashort-duration optical pulses that are time-interleaved to form a single high-speed stream. The resulting data stream is then transmitted over an optical fiber. Special considerations are required to generate ultrashort-duration optical pulses. In particular, gain-switched semiconductor lasers and mode-locked lasers are currently used to generate such optical pulses. However, a gain-switched semiconductor laser has limitations such as the spectral spread, which results from high chirp rates and non-negligible levels of timing jitter. These limitations can be overcome by using optical fibers with appropriate dispersion compensation and optical filtering.

Synchronous Optical Network Technique

SONET is a standard for optical telecommunications transport as defined by the American National Standards Institute. The standard has also been integrated into

the synchronous digital hierarchy recommendations of the International Telecommunications Union (ITU) (formerly Consultative Committee on International Telegraph and Telephone, or CCITT) ("IP-over-SONET configuration" 2002). In SONET, the basic signal rate is 51.84 Mbps. This rate is known as the synchronous transport *signal level 1* (STS-1) rate. Similar to other physical-layer transport, SONET describes transmission speed, line encoding, and signal multiplexing. SONET defines this as *optical carrier* (OC) signals, frame format, and *operations, administration, maintenance, and provisioning* (OAM&P) protocol. The fiber-optic transmission rates from OC-1 through OC-192. They are shown in Table 1.

SONET divides a fiber path into multiple logical channels called *tributaries*. A tributary's basic unit of transmission is an STS-1 or OC-1 (optical carrier level 1) signal. Both operate at 51.84 Mbps; STS describes electrical signals, and OC refers to the same traffic when it is converted into optical signals. SONET also allows channels to be multiplexed. Therefore, an OC-12 circuit, for instance, carries traffic from four OC-3 links. A circuit also can carry a single channel. To further understand the elements of SONET, key concepts need to be discussed. Frame format structure is based on the STS-1 equivalent to 51.84 Mbps. Higher levels of signals are integer multiples of the base rate, 51.84 Mbps (Papadimitriou et al. 2003; "IP-over-SONET configuration" 2002; "SONET graphical overview," undated). The STS-1 signal is divided into two main areas: transport overhead and *synchronous payload overhead* (SPE). The SPE is further divided into two overheads: the *STS path overhead* (POH) and the payload. The payload is the data being transported and switched through the SONET network without being demultiplexed at the terminating locations.

STS-1 has a sequence of 810 bytes (6480 bits), which includes overhead bytes and the envelope capacity for transporting payload. The frame consists of a 90 column by 9 row structure with a frame length of 125 ms. This means that 8000 frames are sent per second, because $9 \times 90 \text{ bytes/frame} \times 8 \text{ bits/byte} \times 8000 \text{ frames/s} = 51.84 \text{ Mbps}$. The order of transmission of bytes is row-by-row from top to bottom and from left to right.

Table 1: Fiber Optical Transmission Rates

OC level	Bit rate (Mbps)	S0 Number	DS-1 Number	DS-3 Number
1	51.84	672	28	1
3	155.52	2016	84	3
6	311.04	4032	168	6
9	466.56	6048	252	9
12	622.08	8064	336	12
18	933.12	12096	504	18
24	1244.16	16128	672	24
36	1866.24	24192	1008	36
48	2488.32	32256	1344	48
96	4976.00	64512	2688	96
192	9952	129024	5376	192

The STS payload pointer provider contained in the transport overhead designates the location of the byte where the STS-1 SPE begins. The STS POH is used to communicate various data such as the pickup and dropoff points. The higher STS- N signals are accomplished through byte interleaving of STS-1 modules. SONET provides overhead information that allows simpler multiplexing and greatly expanded operations, administration, maintenance, and provisioning capabilities.

Synchronous Digital Hierarchy

The deployment of synchronous transmission systems is characterized by their ability to interwork with existing plesiochronous systems. Advances in these systems have lead to *plesiochronous digital hierarchy* (PDH), which is a multiplexing technique that allows for combining slightly nonsynchronous rates. PDH has evolved in response to the demand for basic voice telephony and, as such, is not suited for the efficient delivery and management of high-bandwidth connections. For this reason, synchronous transmission has been introduced to overcome these limits ("Synchronous optical network," undated). Synchronous digital hierarchy defines a structure that enables plesiochronous signals to be combined together and encapsulated within a standard SDH signal. The CCITT recommendations defined a number of basic transmission rates within SDH. The first of these is 155 Mbps, normally referred to as STM-1 (where STM stands for synchronous transport module). Higher transmission rates of STM-4, STM-16 and STM-64 (622 Mbps, 2.4 Gbps, and 10 Gbps, respectively) are also defined. The recommendations also define a multiplexing structure whereby an STM-1 signal can carry a number of lower rate signals as payload, thus allowing existing PDH signals to be carried over a synchronous network ("SONET graphical overview," undated).

SDH defines a number of *containers*, each corresponding to an existing plesiochronous rate. Information from a plesiochronous signal is mapped into the relevant container. Each container then has some control information known as the *path overhead* added to it. The path overhead bytes allow the network operator to achieve end-path monitoring such as error rates. Together, the container and the path overhead form a *virtual container* (VC), which has its own frame structure made of nine rows and 261 columns. The first column is called *path overhead*. The payload container, which can itself carry other containers, follows it. Virtual containers can have any alignment within the administrative unit; the pointer in row 4 indicates this alignment. Within the section overhead, the first three rows are used for the regenerator section overhead, and the last five rows are used for the multiplex section overhead. Earlier SDH supports a concept called *virtual containers* ("SONET graphical overview," undated; "Synchronous optical network," undated). Through the use of pointers, VCs can be carried in the SDH payload as independent data packages.

In a synchronous network, all equipment is synchronized to an overall network clock. Notice, however, that the delay associated with a transmission link may vary slightly with time. As a result, the location of virtual containers within an STM-1 frame may not be fixed.

Associating a pointer with each VC accommodates these variations. The pointer indicates the position of the beginning of the VC in relation to the STM-1 frame. It can be incremented or decremented if needed to accommodate the position of the VC. There are different combinations of virtual containers that can be used to fill up the payload area of an STM-1 frame. The process of loading containers and attaching overhead is repeated at several levels in the SDH, resulting in the aggregation of smaller VCs within larger ones. This process is repeated until the largest size of VC is filled. When filled, the large VC is loaded into the payload of an STM-1 frame. When the payload area of the STM-1 frame is full, control information bytes are added to the frame to form the *section overhead*. The section overhead bytes remain with the payload for the fiber section between two synchronous multiplexers. Their purpose is to provide communication channels with alignment and a number of other functions. A higher transmission rate, when required, is achieved by using a relatively straightforward byte-interleaved multiplexing scheme.

Finally, let us notice that under OTDM, each end user should be able to synchronize with one time slot. The optical TDM bit rate is the aggregate rate over all TDM channels in the system, while the optical SONET-SDH rate may be higher than each user's data rate. As a result, the TDM bit rate and the SONET-SDH rate may be much higher than electronic processing speed. Thus, TDM and SONET-SDH are relatively less attractive than WDM, because WDM, unlike TDM or SONET-SDH, has no such requirement. Specifically, WDM is the current favorite multiplexing technology for long-haul communications in optical communication networks because all of the end-user equipment needs to operate only at the bit rate of a WDM channel, which can be chosen arbitrarily.

WAVELENGTH DIVISION MULTIPLEXING TECHNOLOGY

Wavelength division multiplexing divides the large bandwidth of a fiber into many nonoverlapping wavelength bands that can operate simultaneously with the fundamental requirement that each channel operate at a different wavelength. In this section, we introduce basic definitions of WDM and describe its technological evolution. We also highlight its advantages and limitations. We then present different protection schemes used in WDM networks.

Basic Concepts

WDM has been defined as "a technique used in optical fiber communications, by which two or more optical signals having different wavelengths may be combined and simultaneously transmitted in the same direction over one fiber. These signals are then separated, by wavelength, at the distant end." In other words, WDM is a technology that levels optical-fiber cable in ways that allow us to have multiple available bandwidths rather than a single wavelength fiber. As illustrated in Figure 3, optical signals with wavelengths λ_1 , λ_2 , λ_3 , and λ_4 are multiplexed and simultaneously transmitted in the same direction over a single optical fiber cable. The basic idea is based on

Figure 3: WDM transmission system

simultaneously transmitting several signals using different wavelengths per fiber. This way, WDM provides many virtual fibers on a single physical fiber. Today, WDM can exploit the huge optoelectronic bandwidth difference by requiring that each end user's equipment operate only at electronic rate, although multiple WDM channels from different end users may be multiplexed on the same fiber. Under WDM, the optical transmission spectrum is structured into a number of nonoverlapping wavelength bands, each supporting a single communication channel.

WDM Evolution, Advantages, and Limits

Recently, it has become apparent that the major part of future network traffic will be IP-based. The evolution will go toward IP-over-WDM networks, where several approaches have already been proposed (Chlamtac, Ganz, and Karmi 1992). Each additional layer naturally brings extra overhead to the transmission. Hence, the standard IP over ATM over SONET-SDH over WDM mapping can be considered as an inefficient solution. The other extreme is a direct IP or MPLS over WDM solution: so called λ -labeling or optical label (lambda) switching. It is anticipated that the next generation of the Internet will employ WDM-based optical backbones. Current development activities indicate that WDM networks will be deployed mainly as backbone networks for smaller and larger regions, as well as for metropolitan areas. End users to whom the backbone will be transparent (except for significantly improved response times) will be attached to the network through a wavelength-sensitive switching and routing node.

The evolution of WDM technology has far outpaced the development of applicable standards. This has created a global concern regarding interoperability. Recently, the ITU-T has recommended that vendors use wavelengths in the spectrum range of 1520 nm to 1565 nm, although such a wide range allows for hundreds of system and product variations. Even when vendors agree to use the same wavelengths, there are still the problems of switching channels between networks. There are no immediate standards that take into account such factors as fault management, or power levels, for WDM networks (National Communications System 2002). WDM's main advantages include signal transparency, scalability, flexibility, and ability to upgrade fiber bandwidth. The transparency property makes it possible to support various data formats and services simultaneously. In addition to this great flexibility, transparency protects the investments with respect to future

developments. WDM can support a variety of future protocols without making any changes to the network infrastructure.

As networks migrate from simple point-to-point WDM to optical rings with optical add-drop multiplexers covering applications that span from metropolitan area to ultralong haul, it becomes increasingly more important to also migrate core metroregional transport infrastructures into reconfigurable, manageable, and cost-effective architectures. WDM network components such as reconfigurable OADM and OXC can be used to create WDM networks that can be operated in provisioned mode (wavelength routing) or in switched mode (packet switching, label switching, and burst switching).

Because of their obvious advantages, WDM networks are rapidly deployed in long-distance carriers, local carriers, and enterprise networks. However, there are still a few limitations to be considered for WDM networks. One limitation is the nonlinearity characteristics of fiber optics. Optical fiber nonlinearities will significantly affect the performance of WDM networks. Unless corrected, these nonlinearities will lead to attenuation, distortion, and cross-channel interference. They also place constraints on the spacing between adjacent wavelength channels, reduce the maximum power of the channel, and limit the maximum bit rate. Another limiting factor is the use of wavelength converters. Wavelength conversion has been proposed for use in multihop WDM networks to improve efficiency. Wavelength converters are expensive and may not be economically justifiable because the cost is directly proportional to the number of nodes in the network. Also, several switch architectures have been proposed to allow sharing of converters among various signals at a single switch. However, experiments have shown that the performance of such a network saturates when the number of converters at a switch increases beyond a certain threshold. In addition, a certain type of converter is known to generate significant signal degradation when the output signal is converted to a higher (upconverted) signal. This produces devastating effects when a signal of a transmitted packet passes through multiple converters. However, this type appears to produce desirable results when the output signal is downconverted.

WDM Survivability

A fiber failure in a WDM optical network causes the failure of all of the connections that traverse the failed fiber, resulting in a significant loss of bandwidth and

revenue. Thus, the network designer must provide a fault-management technique and also protect against fiber-amplifier malfunction.

Protection Schemes

There are essentially two types of fault-management techniques to combat fiber failures in WDM networks: protection and restoration. In protection, additional capacity is reserved during connection setup, and it is used when the primary connection fails. In restoration, no extra capacity is made available during connection setup; instead, the disrupted connections are rerouted using whatever capacity is available after the fault has occurred. In this subsection, we will discuss these two fault-management strategies in WDM networks.

Protection can be classified into two groups: path protection and link protection. In *path protection*, the traffic is rerouted through a link-disjoint backup route when a link failure occurs on its active path. In *link protection*, the traffic is rerouted only around the failed link. Path protection usually has fewer resource requirements and lower end-to-end propagation delays for the recovered route. In path protection, for each lightpath that is set up, there are two disjoint paths: a primary path and a backup path. The lightpath is set up on the primary path. In case of a link failure, the lightpath is switched to the prereserved backup path. The primary and the backup paths are link-disjoint, whereas the backup paths of different connections may share wavelengths on common links (Chiu and Modiano 2000). The switches on backup paths can be configured at the beginning—that is, when the lightpath is set up on the primary path. No switch configuration is then necessary when the failure occurs. This type of recovery can be extremely fast, but the resources are not utilized efficiently.

Because a protection route for each active route is preplanned, rerouting is faster and simpler than a restoration, which is usually performed in a distributed manner. Based on the availability of a dedicated protection versus a shared-protection scheme, three types of protection techniques are used in WDM: 1+1 protection, 1:1 protection, and 1:N protection.

In *1+1 protection*, traffic is transmitted on both paths from the source to the destination. The destination receives data from the primary path first. If there is a failure on the primary path, the destination switches over to the backup path and continues receiving. In *1:1 protection*, data are normally not transmitted on the backup path. Thus, we can use the backup path to carry low-priority pre-emptable traffic. If there is a failure on the primary path, the source node is notified (by some protocol) and switches over to retransmit on the backup path. Hence, some data may be lost and the source must be able to retransmit those data. If sharing among backup paths is allowed, the switches on the backup paths cannot be configured until the failure occurs. The recovery time in this scheme is longer, but the overall resource utilization is better than the previous protection. This scheme is called *1:N protection*.

Restoration Schemes

Restoration can be used to provide more efficient routes after the protection has been completed or additional resilience against further faults before the first fault is

fixed. Usually, the restoration mechanism is slow (seconds to minutes) and can be computed on the fly by a centralized management system. There are two kind of restoration: link restoration and path restoration. With *link restoration*, all of the connections that traverse the failed link are rerouted around that link. The source and destination nodes of the connections traversing the failed link are unaware of the link failure. The end nodes of the failed link dynamically discover a route around the link for each wavelength in the link. On the occurrence of a failure, the end nodes of the failed link may participate in a distributed procedure to build new paths for each active wavelength on the failed link. When a new route is discovered, the end nodes of the failed link reconfigure their cross-connects to reroute that channel onto the new route. If no new routes are discovered, the relevant connection is blocked.

With *path restoration*, when a link fails, the source node and the destination node of each connection that traverses the failed link are informed about the failure (possibly via messages from the nodes adjacent to the link failure). The source and the destination nodes of each connection independently discover a backup route on an end-to-end basis (possibly using a different wavelength channel). When a new route and wavelength channel are discovered for a connection, network elements such as wavelength cross-connects are reconfigured appropriately, and the connection switches to the new path. If no new routes (and associated wavelength) are discovered for a broken connection, that connection is blocked.

Dense WDM

The WDM network provides the backbone to support existing and emerging technologies with almost limitless amounts of bandwidth capacity. With today's expansion of online services (e.g., the Internet), mobile telephony, and the anticipated emergence of multimedia services, traffic demand will grow quickly, requiring a huge increase in the transport capacity of public networks. WDM and its improvement—*dense wave division multiplexing* (DWDM)—have since proven to be the most promising technology to satisfy the capacity demand in the core network by multiplexing hundreds of Gigabit channels in one fiber. The multiplexing is performed by different lasers emitting light at different wavelengths to form signals that are multiplexed onto a single fiber. A single optical fiber is capable of carrying 10 Terabits per second when DWDM technology is used (Papadimitriou et al. 2003; Brackett 1990).

DWDM has been proposed and deployed in many telecommunication backbones to support growing needs. DWDM systems can upgrade the channel number in optical fibers by using more power or additional signal to noise margin. Technically, WDM and DWDM are similar, but as the name implies, DWDM supports many more wavelengths. The number of wavelengths that a DWDM system can support depends on the ability of the system to accurately filter and separate them. Initial implementations of DWDM systems support either eight or sixteen wavelengths. However, current DWDM systems are capable of supporting thirty-two or sixty-four wavelengths. An end terminal with an ITU-T-compliant wavelength transmitter

is directly connected to the DWDM system. An optical amplifier with a gain flatness of ± 1 dB and a maximum total output power of +21.5 dBm is a key component in the DWDM system, in which the optical power of each wavelength is kept at the same level by using EDFA at the input ports of the DWDM system. The next generation of DWDM will have 128 wavelengths, a total capacity of 1.28 Tbps and even more, and networking functions such as OXC and OADM (Zang et al. 2001).

WDM SWITCHING TECHNIQUES

Four major switching techniques have been proposed in the literature for transporting IP traffic over WDM-based optical networks. Accordingly, IP over WDM networks can be classified as WR networks, OPS networks, OLS networks, and OBS networks.

Wavelength Routing

WR networks carry data between access stations in the optical domain without any intermediate optical to and from electronic conversion. This is realized by assigning a path in the network between the two nodes and allocating a free wavelength on all links on the path. Such an all-optical path is commonly referred to as a *lightpath* and may span multiple fiber links without any intermediate electronic processing.

Lightpath Establishment

A lightpath is used to support a connection in a WR network and may span multiple fiber links. In the absence of wavelength conversion, it is required that the lightpath use the same wavelength on all fiber links of the path it uses. This requirement is referred to as the *wavelength continuity constraint*. Continuity may result in an inefficient utilization of WDM channels. Alternatively, when the routing nodes have limited or full conversion capability, it is possible to allocate different wavelengths on the links of the assigned path. Given a set of connections, the problem of setting up lightpaths by routing and assigning a wavelength to each connection is called the *routing and wavelength assignment* (RWA) problem. To establish a lightpath from source to destination, one has to determine a route along which the lightpath can be established and then assign a wavelength to the selected route. Typically, connection requests may be of two types: static and dynamic.

In a *static lightpath establishment* (SLE) problem, the entire set of connections is known in advance and the problem is then to set up lightpaths for these connections while minimizing the usage of network resources (such as the number of wavelengths or the number of fibers). In SLE algorithms, the routing procedure does not vary with time, and the routes for given source-destination pairs are predetermined based on the topology and policies criteria but independent of the current traffic condition in the network.

In *dynamic lightpath establishment* (DLE), a lightpath is set up for each connection request as it arrives, and the lightpath is released after a small period of time. In DLE, a routing algorithm can vary with time and be adaptive

in the sense that it can select a route based on the current network conditions. DLE considers alternate routing, where each source-destination pair is associated with a set of routes. If resources along one route are not available, then another route in the set is examined. When there are multiple routes to choose, the routing algorithm first tries to establish the primary path among the shortest possible routes and then tries to establish its corresponding backup paths also on the shortest possible route.

The objective in dynamic traffic cases is to set up lightpaths and assign wavelengths in a manner that minimizes the amount of connection blocking or maximizes the number of connections that are established in the network. There have been extensive studies to solve both the static and the dynamic RWA problems ("Intellilight dedicated SONET ring," undated). Wavelength-routed connections are fairly static, and they may not be able to accommodate the highly variable and bursty nature of Internet traffic in an efficient manner.

Traffic Grooming

The important advances of high-speed transmission technology creates a large gap between the capacity of an optical channel and the bandwidth requirements of a typical connection request, which can vary in range from tens or hundreds of Mbps up to the full-wavelength capacity. Furthermore, the amount of wavelength channels available for most of the networks of practical size is lower than the number of source-destination connections that need to be made. Traffic grooming poses the problem of how to multiplex (and demultiplex) a set of low-speed traffic streams onto high-capacity channels and switch them at intermediate cross-connects (Chiu and Modiano 2000).

The performance of WR networks depends on the efficient merging of the fractional wavelength link of the nodes into a full or almost full wavelength requirement. This merging of traffic from different source-destination pairs is called *traffic grooming*. Nodes that can groom traffic are capable of multiplexing and demultiplexing lower-rate traffic onto a wavelength and switching it from one lightpath to another. The grooming of traffic can be either static or dynamic. In *static* traffic grooming, the source-destination pairs, whose requirements are combined, are predetermined. In *dynamic* traffic grooming, connection requests from different source-destination pairs are combined, depending on the existing lightpath at the time of request arrival (Zhu and Mukherjee 2001). Even though WR networks have already been deployed, they may not be the most appropriate for the Internet because, for example, it takes at least a round-trip delay to establish a lightpath. This leads to poor wavelength utilization if the connection holding time is especially short. The bursty nature of the data traffic also leads to poor wavelength utilization. Therefore, to fully utilize the wavelength, a sophisticated traffic-grooming mechanism is needed to support statistical multiplexing of data from different users. The objective of traffic grooming is either to maximize the network throughput or to minimize the connection-blocking probability and improve the wavelength utilization, whereas a strategic network design problem is to minimize the total cost (Papadimitriou et al. 2003; Chlamtac, Ganz, and Karmi 1992; Chiu and Modiano 2000).

The following are the four basic grooming options.

1. Single-hop grooming on existing lightpath: The connection is assigned to one existing direct lightpath.
2. Multihop grooming on existing lightpath: Routing takes place on the electrical layer by using more than one existing lightpath and switching the connection in the electrical cross-connect of intermediate nodes.
3. Single-hop grooming on new lightpath: A new lightpath is set up between the source and the destination node. The connection request is routed on the optical layer via this new lightpath.
4. Combined multihop grooming on new and existing lightpath: This is a combination of options 1 and 3. The connection request can be routed on both the electrical and optical layer by using a series of existing and new lightpaths.

Although nonintegrated routing schemes are only capable of grooming on either existing or new lightpaths, integrated routing is able to perform the combined grooming described in option 4.

Optical Packet-Switching Technique

In OPS, a data flow is broken into packets of small size before being transmitted. Routing information is added to the overhead of each packet so that intermediate switches between the source and destination are able to forward the arriving packet. An OPS is capable of dynamically allocating network resources with fine packet-level granularity while offering excellent scalability (O'Mahony 2001). In OPS networks, bit-level synchronization and fast clock recovery are required for packet header recognition and packet delineation. In general, all-optical packet-switched networks can be divided into two categories: *slotted* (or synchronous) and *unslotted* (or asynchronous).

OPS Synchronization

The need for a synchronizer in an optical switch results from delay variations between nodes. These variations are caused by the distance the packet travels in the fiber, chromatic dispersion, and temperature variations. Figure 4 shows a block diagram of the synchronization procedure in a node. An optical splitter directs a small amount of power from the incoming packets into a header-reading circuit. The reading circuit recognizes a special bit stream

pattern and prepares to read the header information. Also, the timing information is read and passed to the control unit to configure the synchronization stages and switch fabric. The input synchronization stage aligns the packets into fixed time slots before they enter the switch fabric. The output synchronization stage is used to compensate for any timing drift that occurs during the switching. The required accuracy of synchronization in a system depends on the size and position of the header, payload, and guard time (Yao et al. 2003).

OPS Slotted Network

In slotted networks, packets have fixed size. Slot size is larger than the packet size to allow guard time before and after each packet. Because a node has input fibers from different upstream nodes, the slot boundaries on these fibers are not synchronized. There will be time variation of these boundaries because of different propagation distances and temperature changes. Some synchronization mechanisms need to be implemented to align the slots before the packets enter the space switch. Such mechanism can be realized by using switched *fiber delay lines* (FDLs) of different lengths to create the desired delays with limited resolution. Slotted networks have fewer contentions than unslotted networks because the packets are of the same size and are planed in a joint manner.

OPS Unslotted Network

In an unslotted network, packets may not have the same size and can arrive and enter the switch without being aligned. Therefore, the packet-by-packet switch action could take place at any point in time (Qiao and Yoo 1999). This can lead to contention of different incoming packets for the same outgoing resource. The chance for contention is high because the behavior of the packets is more unpredictable and less regulated. The unslotted networks are easier and cheaper to build, more robust, and more flexible compared to slotted networks. IP traffic is processed and switched at every IP router on a packet-by-packet basis when each contains a payload and header. The header carries the information required for packet routing, whereas the payload carries the actual data. The future and ultimate goal of OPS networks is to process the packet header entirely in the optical domain. With the current technology, it is not possible to do such a task optically. Instead, the header is processed in the electronic domain, and the payload is kept in the optical domain.

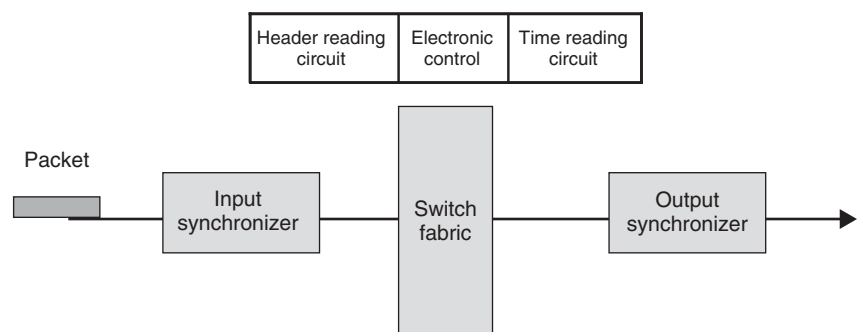

Figure 4: Synchronization of packets

Many technical challenges need to be addressed for this solution to be efficient.

OPS Switching Issues

Optical packet switching is a promising technology as it offers high capacity and data transparency. It is currently in an experimental stage and is not implemented commercially because of the lack of optical buffering. The network control and routing is performed electronically, and the routing information from the packet header has to be converted to electrical form. This problem was solved by transferring the payload and the header with different transmission rates. The header can be transmitted at a relatively slow rate so that it is possible to read the header in an electronic form, whereas the data can be transmitted fast in order to benefit from the transmission media. The data rate can be increased by compressing more data into the same time slot. The header and the data can be sent consecutively, separated by a guard time. In OPS networks and photonic slot-routing networks, headers are sent in their own channels. The main idea in these approaches is based on the fact that the headers are sent slowly enough to allow the control information to be read. Higher throughput is accomplished by compressing the payload and increasing the data rate (O'Mahony 2001).

A second issue in OPS networks is synchronization. Most of the optical switches proposed are synchronous and use constant-length packets, meaning that the networks are slotted. This makes controlling and managing the switch easier and facilitates routing and buffering. On the other hand, careful synchronization is required. This synchronization is usually managed using FDL, whereas the issue in OPS networks is the regeneration of optical signal. Optical regenerators are divided into three classes: 1R regenerators are capable of amplification, 2R regenerators can both amplify and reshape signal, and 3R regenerators can amplify, reshape, and retune signals. In recent research efforts, a 3R regenerator was implemented, but using such a regenerator in a network is expensive.

Today's OPS networks are not entirely optical. The signals are converted to electrical form before switching and processing. This means that the major advantages of optical packet switching, (e.g., speed and efficiency) are lost because of the increased delays. All-OPS networks are not coming to commercial use in the few coming years. The biggest problem currently is the lack of optical buffering needed for buffering the packets. In addition, the extremely high switching rates needed in packet networks cause problems. In the near future, the development seems to lead to the integration of optical and electronic networks and the use of optical burst switching.

Optical Burst-Switching Technique

Optical burst switching has received a great attention in recent years as one of the most promising technologies to carry the next-generation optical Internet. OBS combines the advantages of optical circuit switching and optical packet switching while reducing their shortcomings. In OBS networks, the control plane and the data plane are separated, and the signaling is performed out of band

(Qiao and Yoo 1999). Although the control plane is done electronically, the data plane is all-optical.

Burst Assembly

One solution, used by OBS, is to aggregate or assemble packets into bursts at ingress nodes in order to keep switching time and associated guard band inefficiencies negligible with respect to the burst sizes. The two main burst assembly algorithms are threshold-based and timer-based.

The Threshold-Based Burst Assembly. This technique requires a single and configurable parameter that corresponds to the burst length (set of packets) stored in the input queue. If the arriving packet reaches this size, the active burst is scheduled to be sent, and its packets are immediately removed from queue. The method offers no delay guarantees under low-input offered load. It may need to wait for a long period of time until this length is reached. However, under high-input offered load, the threshold will be quickly reached, minimizing delay.

Timer-Based Burst Assembly. This method requires a single and configurable parameter that is a time period corresponding roughly to the interdeparture times of the bursts. A time period for each queue is started at the initialization of the system after a burst for that queue is scheduled to be sent immediately when the first packet arrives after the appropriate queue has been emptied. At the expiration of the timer, the burst assembler generates a burst containing all the packets in the buffer at that point. Under low-input load conditions, it guarantees a fixed minimum delay. However, under high-input offered load, it may generate bursts that are extremely large.

Hybrid Burst Assembly. The threshold-based and timer-based algorithms can be used simultaneously to benefit from the advantages of both schemes. In this hybrid system, the burst is sent when one of the constraints is reached (Vokkarane and Jue 2003). For periods of low input load, the timer would expire first, resulting in deterministic burst spacing but randomly sized bursts. For periods of high-input load the threshold would be reached first, resulting in randomly spaced but constant-sized bursts.

OBS Network Architecture

An OBS network consists of optical switches interconnected with WDM links. An optical burst switch transfers a burst coming from an input port to its destination output port. A control message is transmitted ahead of the burst in order to configure the switches along the burst's path. The burst follows the header without waiting for an acknowledgment that resources have been reserved and switches have been configured along the lightpath. The control packet associated with a burst may be transmitted in-band over the same channel as data or on a separate control channel. The source edge nodes are referred to as *ingress nodes* and the destination edge nodes are referred to as *egress nodes*. The ingress edge node assembles incoming packets from client terminals into bursts. The assembled bursts are transmitted completely optically over OBS core nodes without any intermediate storage.

The egress edge node, upon receiving the burst, disassembles the bursts into packets and forwards the packets to destination terminals (Vokkarane and Jue 2003; Qiao and Yoo 1999).

Edge nodes perform the functions of presorting packets, buffering packets, aggregating packets into burst and de-aggregating bursts into their constituent packets. Different burst assembly policies can be used to aggregate data packets into optical bursts. Core routers primarily contain an OXC and a *switch control unit* (SCU). The SCU creates and maintains a forwarding table and is responsible for configuring the OXC (Qiao and Yoo 1999). When the SCU receives a BHP, it identifies the intended destination and consults the router signaling processor to find the intended output port. If the output port is available when the data burst arrives, the SCU configures the OXC to let the data burst pass through. If the port is not available, then the OXC is configured depending on the contention-resolution policy implemented in the network.

Optical Label-Switching Technique

OLS offers seamless integration of data and optical networking while supporting circuit, burst, and packet switching using the optical labels. It provides diverse QoS, class of service (CoS), and type of service. OLS networks separate the control plane and the data plane to facilitate protocol and format independence for data payloads. Interoperability with IP, *multiprotocol label switching* (MPLS), *multiprotocol lambda switching* (MPλS), and other client networks can be achieved with a *generalized MPLS* (GMPLS) extension. In this subsection, we discuss the architecture of OLS networks in light of interoperability and seamless network upgrades in the context of MPLS, MPλS, and GMPLS.

Optical Label-Switching Concept

In OLS networks, the key concept is an efficient and transparent packet-forwarding method using an OLS mechanism that can coexist with legacy WDM technology on the same fiber. New signaling information is added in the form of an optical label that is carried in-band within each wavelength in a multiwavelength transport environment. The optical label, containing routing and control information such as the source, destination, priority, and packet length, will propagate through the network along with the data payload. Each OLS router will read the optical label, look up to the forwarding table, and take the necessary steps to forward the packet. During the optical label-processing stage, the corresponding packet is delayed by an FDL at the input interface before entering the OLS switch fabric. The goal is to reduce the need to manage the delay separating the optical label and its payload. If a packet is to be routed to a wavelength and path where there is already another packet being forwarded, the OLS router will attempt an alternate path.

Label-Switching Structure

The OLS label-encoding method for packet-based networks attaches a label header. This label is four octets long and is segmented into four parts. Figure 5 depicts the label structure in which the first twenty bits contain

Figure 5: Label structure

an unsigned integer value that distinguishes the specific traffic route. The next three bits are deemed experimental and are used primarily to provide a means to determine a CoS to relay information to the network routers about how to handle the traffic. The next bit provides a hierarchical label stack function. Finally, the last eight bits represent a conventional time to live that provides network elements with the ability to disregard a packet after a certain length of time to prevent endless recirculation loops through the network (Papadimitriou et al. 2003; Gallaher 2002).

Label-Switching Procedure

The following is a list of commonly used terms and their acronyms that represent the components of an OLS network.

Forwarding equivalence class (FEC): A class or group of traffic based on common parameters such as class of service. It defines a common set of packet-handling parameters.

Label-switched path (LSP): A determined traffic path through the OLS network, from ingress to egress, with the same FEC and intended destination.

Label edge routers (LERs): Routers that are OLS-aware. They are located at the ingress and egress of the OLS network and perform the following functions: (1) computing the LSP through the OLS network, (2) determining an appropriate FEC, (3) appending the OLS label at the ingress of the OLS network, and (d) removing the OLS label at the egress of the OLS network.

Label-switched router (LSR): This is an intermediate router located along the LSP. It inspects the optical label and forwards traffic accordingly. When the LER receives a standard packet containing information destined to traverse the OLS network, it attaches the OLS label. OLS-aware LSR provides high-speed traffic routing by only inspecting the OLS label. The OLS label directs traffic to specific predetermined LSPs, which are FEC-based, aggregate, multipoint-to-point traffic paths through the OLS network. Further packet inspection is not performed until the packet exits the OLS network through the egress LER. Once the egress LER receives the packet, the OLS label is removed and the traffic is routed through the non-OLS destination network without the OLS label (Gallaher 2002). Figure 6 depicts IP traffic traversing an OLS network.

Label stack: The desire to maintain SLA between two networks that are disjoint across a third network results in the implementation of *label stacking*. Label stacking is a hierarchy-based implementation of OLS that helps to provide QoS across multiple third-party networks such as those of an ISP backbone. Additional OLS labels are pushed onto the protocol stack as the packet enters the

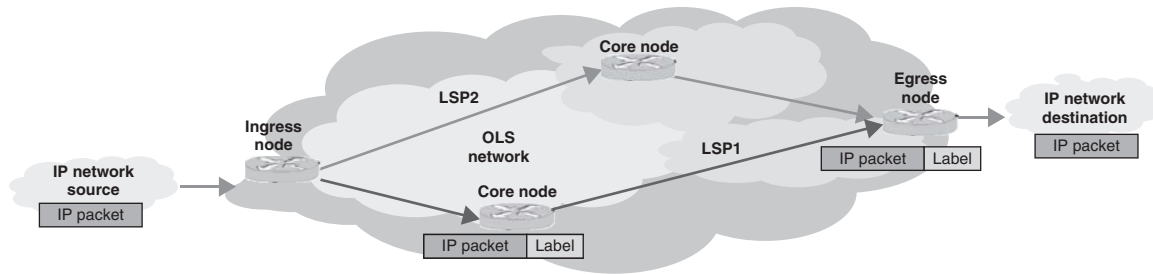

Figure 6: OLS network

intermediate network and are popped off at the egress of the intermediate network. The traffic across the intermediate network is classified as *tunneled traffic*. Label stacking provides a means for best-effort traffic to be marked, classified, and policed to achieve end-to-end QoS (Gallagher 2002).

WDM SIGNALING PROTOCOLS

The signaling technique aims first at constructing routes and scheduling traffic on particular wavelengths. Several signaling techniques have been proposed for WDM networks. Several signaling protocols have been proposed for WDM. In addition to just-in-time, just-enough-time, tell-and-wait, and tell-and-go protocols, an ATM-like protocol has been considered to provide some sort of efficiency in terms of network resources utilization and QoS support (Khelifi et al. 2005). It requires that the transmission of packets is preceded by the setup of a virtual optical communication circuit. It also defines a route between the source and destination composed by an association of fiber links and wavelengths along the chosen route and passing through the FDL (Khelifi et al. 2005). In this section, we present signaling schemes adopted in OBS and OLS techniques.

OBS Signaling Schemes

Signaling and reservation represent fundamental criteria by which OBS can be differentiated from other optical transport technologies. OBS adopts an out-of-band signaling technique in which the header is sent ahead of the burst by a time offset. When a burst is transported over the optical core, a signaling scheme must be implemented in order to allocate resources and configure intermediate switches. Signaling may be implemented in-band, in which a header is transmitted on the wavelength used to transmit the burst, or out-of-band, in which the burst header is transmitted on a separate wavelength. Typically, the connection setup phase of an OBS signaling technique can be one-way or two-way based. In the *one-way scheme*, the source sends out a control packet requesting the intermediate nodes on the path to allocate the necessary resources for the data burst. The primary objective of the one-way based signaling is to minimize the end-to-end delay. Unfortunately, this objective leads to high data loss because of contention of data bursts. In the *two-way scheme*, the request for a resource is sent, and an acknowledgment message confirming a successful assignment of the requested resources is sent back by the destination to the

source. The burst is transmitted only after a connection is established successfully. If any intermediate node in the path is busy, then the request is blocked and the intermediate node takes suitable actions to release any and all of the previously reserved links. The source can choose to retry or drop the request. Therefore, the primary objective of the two-way based techniques is to minimize packet loss, but such an objective leads to high delays.

Just-Enough-Time Scheme

In the *just-enough-time* (JET) technique, a source node first sends a *burst header packet* (BHP) on a control channel toward the destination node. The BHP is processed at each subsequent node in order to establish an all-optical data path for the corresponding data burst. If the reservation is successful, the switch will be configured before the burst arrival. Meanwhile, the burst waits at the source in the electronic domain. After a predetermined offset time, the burst is sent optically on the chosen wavelength (Qiao and Yoo 1999). The offset is computed based on the number of hops from source to destination and the switching time of a core node.

Just-in-Time Scheme

The *just-in-time* (JIT) signaling technique uses immediate reservation, whereas JET signaling adopts delayed reservation. In general, *immediate reservation* is simple and practical to implement but incurs higher blocking because of inefficient bandwidth allocation. On the other hand, implementation of *delayed reservation* is more involved but leads to a higher bandwidth utilization. Delayed reservation and immediate reservation can be incorporated into any signaling technique if the underlying node maintains the relevant information. JIT is similar to JET except that JIT employs immediate reservation and explicit release instead of delayed reservation and implicit release.

Tell-and-Wait Scheme

In the *tell-and-wait* (TAW) technique, a "SETUP" BHP is sent along the burst route to collect channel availability information at every node along the path. At the destination, a channel-assignment algorithm is executed, and the reservation period on each link is determined based on the earliest available channel times of all of the intermediate nodes. A "CONFIRM" BHP is sent in the reverse direction to reserve the channel for the requested duration at each intermediate node. At any node along the path, if the required channel is already occupied, a "RELEASE" BHP is sent to the destination to release the previously reserved resources. If the CONFIRM packet reaches the

source successfully, then the burst is sent into the core network (Qiao and Yoo 1999). In the TAW scheme, resources are reserved at any node only for the duration of the burst. Also, if the duration of the burst is known during reservation, then an implicit release scheme can be followed to maximize bandwidth utilization.

Tell-and-Go Scheme

In the *tell-and-go* (TAG) technique, a source first sends a control packet on a separate control channel to reserve bandwidth (and set switches) along a path for the following data that, unlike in circuit switching, can be sent on a data channel without having to receive an acknowledgment first. This implies that the offset time T can be (much) less than the circuit setup time or even zero as in packet switching. After the burst is sent, another control signal (similar to a circuit teardown signal) is sent to release the bandwidth. In this scheme, the burst is transmitted immediately after the control packet (Qiao and Yoo 1999). When arriving at an intermediate node, the control packet attempts to reserve the necessary resources to schedule the burst. Meanwhile, the burst is typically delayed in the optical domain using input FDL.

OLS Signaling Schemes

To reserve resources and manage LSP over the OLS network, it is necessary for the network to have a signaling plane. Two methods have been investigated to provide this plane: *resource reservation protocol with traffic engineering extensions* (RSVP-TE) and *label distribution protocol with constraint-based routing* (CR-LDP). Both methods provide label distribution and LSP creation. The two signaling protocols perform similar functions in OLS networks (Chen, Thomas, and Wu 2000). The main difference between the two is the direction in which the resources are allocated during the signaling process and the transport protocol used. The following subsections summarize these OLS signaling protocols.

RSVP-TE

Resource reservation protocol with traffic engineering extensions operates by providing resources in the reverse direction along the LSP and uses raw IP as an exchange protocol of information. Figure 7 depicts the major steps of RSVP-TE.

The source sends an RSVP-TE *path message* to the receiver to establish the connection. When the ingress LER receives the path message, it injects a *label request* into the path message to request a label binding. The modified path message is then forwarded to the adjacent LSR. The forwarding continues until the path message is received by the egress LER.

When the egress LER receives the path message, it generates an *resv message* that includes a *label object*. The egress LER then propagates the resv message back to adjacent LSRs. When the adjacent LSRs receive the resv message, they will reserve the necessary resources, enter the new LSP label into their forwarding tables, and forward the resv message onto the next adjacent LSR and back toward the source. If, however, a LSR does not accept the resv message for reasons such as unavailability of resources, the LSR will respond to the egress LER with a request to terminate signaling.

Once the ingress LER receives the resv message, it will append the label to the data packets and forward the traffic through the network along the predetermined LSP. Each intermediate LSR along the LSP will inspect only the label, compare it to its forwarding table, and deliver the packet to the next LSR in the LSP.

When the egress LER receives the OLS packets, it will remove the label and deliver the packets to the destination (Awduche, Hannan, and Xiao 2001).

CR-LDP

Label distribution protocol with constraint-based routing operates by allowing resources in the forward direction and uses TCP as its transport protocol. Resources are allocated along each segment of the network in turn. Several methods of label distribution can be implemented with CR-LDP. Downstream-unsolicited and hop-by-hop, explicit-route, downstream-on-demand label distribution can be implemented. Figure 8 depicts downstream-unsolicited label distribution utilizing CR-LDP signaling. The distribution is accomplished when the egress LER advertises without a label request:

1. The egress LER sends out a label-mapping message advertisement to its adjacent LSR.
2. The adjacent LSR then reserves the resources for that egress LER and forwards the message onto its adjacent LSR.

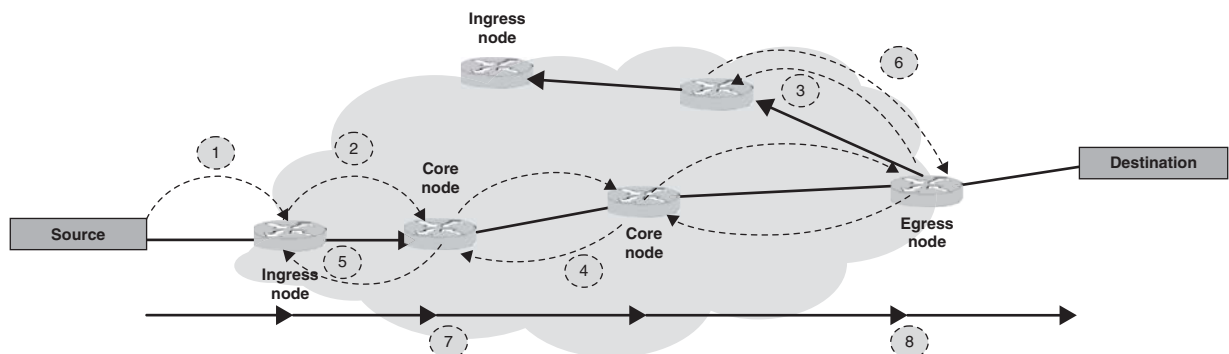

Figure 7: RSVP-TE OLS signaling

Figure 8: CR-LDP downstream-on demand label distribution OLS signaling

3. Once the ingress LER receives this message, the LSP is established.

Downstream-on-demand label distribution can occur by explicit routing or hop by hop. Whereas the former involves the pre-establishment of an intended LSP path before signaling, the latter operates by reserving the resources in the forward direction, one segment at a time, toward the destination. The latter operates as follows (Chen, Thomas, and Wu 2000):

1. The source attempts to send traffic to the destination through the ingress LER.
2. The ingress LER generates a label request and distributes it to the adjacent LSR.
3. If an adjacent LSR accepts the label request and can allocate the requested resources, then it forwards the label request to its adjacent LSR in the direction of destination.
4. Once the label request is accepted by the egress LER, the latter generates a label mapping and sends it back. When an LSR receives the label mapping, it checks the label ID with the one occurring in the label request message. If it matches, the LSR adds the label to its forwarding table and forwards the label mapping to the next adjacent LSR in the direction of the source.
5. When the ingress LER receives the label mapping, it checks the label ID and adds it to the forwarding table.
6. The label is attached to the packets and the traffic is forwarded through the OLS network along the pre-defined LSP without deep packet inspection.
7. Finally, when the traffic reaches the egress LER, the label is removed.

WDM NETWORK ARCHITECTURES

The commonly used architectural forms for WDM networks are *broadcast and select networks* (BSNs), and *wavelength routing networks* (WRNs). In a BSN (Zang et al. 2001), each transmitter broadcasts its signal on a

different channel, and receivers can tune to receive the desired signal. Generally, these networks are based on a passive star coupler. This device is connected to the nodes by fibers in a star topology. It consistently distributes the signals received to the output ports. The main networking problem for these networks is the coordination of pairs of stations in order to agree and tune their systems to transmit and receive on the same channel. Therefore, BSNs are suitable for local area networks and are not scalable. WRNs are composed of one or more wavelength-selective nodes called *wavelength routers* and fibers interconnecting these nodes. Each wavelength router has a number of input and output ports. Signals routed to the same output port should be on different wavelengths. As long as any two channels do not share the same fiber link anywhere on the network, they can use the same wavelength. The wavelength reuse feature results in an interesting reduction in the number of wavelengths required for building a wide network.

Broadcast and Select Networks

Broadcast and select networks are based on the simplest all-optical organization that enables WDM. In this organization, the network infrastructure is entirely composed of glass material that acts as a propagation medium that broadcasts individual transmissions. The network model is illustrated in Figure 9, where the transmitters transmit signals on distinct wavelengths, and the network combines these signals and distributes the aggregate signal to the receivers. The figure shows only the transmitters and receivers. For proper network operation, each end node is able to make connections with any other end node. For this reason, each end node should have access to multiple WDM channels. This can be accomplished by making the transmitters or receivers or both tunable over multiple channels, or having a multiple fixed tuned transmitters or receivers; each is assigned to a different channel on an end node. To avoid interchannel interference, the transmitters are assigned narrow line widths and receivers can filter each channel individually (i.e., narrow bandwidth filters are required). In addition, to improve efficiency, tunable components should cover all of the channels.

Figure 9: Broadcast and select network

Let us assume that there are W channels, each running at a rate of C bits/sec. The broadcast and select organization supports at most W concurrent connections and has a total capacity that is equal to $W \times C$ bits/sec. It is possible to increase the channel bit rate C up to peak electronics rate. It is also possible to have a large aggregate capacity without forcing the limits of electronics on end nodes. Therefore, the capacity of the network is directly proportional to the number of channels available in the network. On the other hand, the number of channels is directly related to the tunability range and bandwidth of lasers and transmitters. In addition, broadcasting and multicasting is possible in BSNs because the receivers have access to entire channels. In other words, it is possible to establish one-to-many and one-to-all connections. In the near future, many applications that require broadcasting or multicasting will be widespread, such as distributed computing, distributed database applications, and interactive video.

Wavelength Routing Networks

The splitting loss and lack of wavelength reuse restrict BSNs from spanning long distances and having large numbers of end nodes with large throughputs. Wavelength routing networks get around these problems by channeling the transmitted power to an appropriate lightpath between the source and destination and reusing the wavelengths in spatially disjointed areas of the network. WRNs are composed of one or more wavelength-selective elements and the fibers connecting them (Karasan and Glu 1998). The wavelength-selective elements are composed entirely of glass material (i.e., no electro-optical conversions) and are called *wavelength routers*. They are capable of routing signals individually. The output port of each signal in a wavelength router is determined by the input port it arrives through and its wavelength. Signals routed to the same output port should be on different wavelengths to avoid mixing different signals.

In WRNs, each wavelength router is connected to one or more wavelength routers or end nodes or both to define a topology in which end-to-end connections between end nodes are established using wavelength channels through one or more wavelength routers. If wavelength routers are ideal, then the connections between the end nodes do not experience any splitting loss and electro-optical conversion. Therefore, an end-to-end connection behaves like a high-speed transparent pipe between end nodes.

If two lightpaths do not share a fiber on their routes, they can be assigned to the same wavelength. Therefore, the spatial reuse of wavelengths can be achieved in WRNs.

Usually, wavelength routers are connected to each other or to end nodes with a pair of fibers. Therefore, bi-directional lightpaths can be established between the end nodes such that each connection follows the same route in the network and is assigned to the same wavelength in counterdirection fibers. To establish a lightpath between two end nodes, one of the transmitters of the source and one of the destination receivers should be tuned to the same wavelength. Therefore, the number of transmitter-receiver pairs in an end node determines the maximum number of lightpaths that can be supported by that particular end node simultaneously. Therefore, end nodes should be equipped with a multitude of tunable and fixed transmitter-receiver pairs to utilize network resources efficiently.

QOS REQUIREMENTS IN WDM NETWORKS

Basic Concepts

The huge bandwidth offered by WDM is promising to reduce the cost of core network equipment and simplify bandwidth management. However, the problem of providing quality-of-service guarantees for several advanced services, such as the transport of real-time packet voice and video, remains largely unsolved for optical backbones. The QoS problem in WDM networks has several fundamental differences compared with the QoS solutions provided in electronic switches. Currently, there is no optical memory, and the use of electronic memory in an optical switch requires *optical-to-electrical* (O-E) and *electrical-to-optical* (E-O) conversions within the switch, which tends to limit the speed of the optical switch. In addition, the use of converters loses the advantage of being bit rate transparent. Furthermore, converters increase the cost of switching significantly. Currently, the only means to provide a limited buffering capability in optical switches is the use of fiber delay lines. Unfortunately, FDLs cannot provide full buffering capabilities. In addition, the wavelength domain provides a further opportunity for contention resolution based on the use of FDL. In this section, we describe the critical issues affecting QoS in WDM based on the optical switching techniques.

Contention Resolution in OPS and OLS Networks

In OPS and OLS networks, contention occurs at a node whenever two or more packets are trying to leave the switch from the same output port on the same wavelength. The way the contention is resolved has a significant effect on the network performance in terms of packet loss ratio, average packet delay, average hop distance, and network utilization. In electrical packet-switched networks, contention is resolved using store-and-forward techniques that require the packets in contention to be stored in a memory and sent out at a later time when the related output port is free. This is possible because of the availability of electronic *random access memory* (RAM). For this, several contention-resolution schemes are explored in OPS networks such as wavelength, time, and space-based schemes (Yao et al. 2003). Three techniques can cooperate to resolve contention: wavelength conversion, optical buffering, and deflection routing.

Wavelength Conversion

Wavelength conversion offers the most effective contention resolution without incurring additional latency while it maintains the shortest path or minimum hop distance. Multiple packets can be sent simultaneously to the same output port (Papadimitriou et al. 2003; Yao et al. 2003).

Optical Buffering

In optical buffering, FDLs are typically used to delay the packets in contention and send them out at a later time. Because FDLs are simply first-in, first-out queues with fixed delays, they are less efficient than the electronic RAM. To be able to resolve contention effectively, a large number of FDLs are usually required. Handling many fibers in a node cannot be an easy task.

Deflection Routing

Packets in contention are deflected to output ports other than to the desired port. This causes part of the network to be used as buffers to store these packets. The disadvantage of deflection is that it introduces extra link propagation delays and causes packets to arrive out of order (Yao et al. 2003; Yao et al. 2000).

Contention Resolution in OBS Networks

Because OBS networks provide connectionless transport, bursts may contend with one another at intermediate nodes. Several techniques are designed to address the contention, including optical buffering, wavelength conversion, deflection routing, and burst segmentation.

OBS Buffering

In OBS networks, FDLs can be utilized to delay burst for a fixed or a variable amount of time. A FDL can be further classified into feed-forward, feedback, and hybrid architectures (Chia et al. 2001). In a *feed-forward* architecture, each FDL connects an output port of a switching element at a given stage to an input port of another switching element in the next stage. In *feedback* architecture, each FDL connects an output port of a switching element at a given stage to an input port of a switching element in the

same stage or at a previous stage. In a *hybrid* architecture, feed-forward and feedback buffers are combined. According to the position of the buffers, burst switches are essentially categorized into three major configurations: input buffering, output buffering, and shared buffering. In *input buffering*, a set of buffers is dedicated for each input port. In *output buffering*, a set of buffers is dedicated for each output port. In *shared buffering*, a set of buffers can be shared by all switch ports. Input buffering has poor performance because of head-of-line blocking. Conversely, output buffering and shared buffering can achieve good performance. However, output buffering requires a significant number of FDLs and larger switches. With shared buffering, all output ports can access the same buffers. Therefore, it can be used to reduce the total number of buffers in a switch while achieving a desired level of packet loss. In the optical domain, shared buffering can be implemented with one-stage feedback recirculation buffering (Zhang, Lu, and Jue 2004) or multistage feed-forward shared buffering (Hunter, Chia, and Andonovic 1998).

Wavelength Conversion

In OBS with wavelength conversion, a contending burst may be switched to any of the available wavelengths on the outgoing link. Although optical wavelength conversion has been demonstrated in laboratory environments, the technology is not yet mature, and the range of possible conversions are somewhat limited (Ramamurthy and Mukherjee 1998). The following are different categories of conversion.

Full Conversion

Any incoming wavelength can be shifted to any outgoing wavelength; thus, there is no wavelength continuity constraint on the end-to-end connection requests.

Limited Conversion

Wavelength shifting is restricted so that not all incoming channels can be connected to all outgoing channels. The restricting on the wavelength shifting will reduce the cost of the switch at the expense of increased blocking.

Fixed Conversion

Fixed conversion is a restricted form of limited conversion, wherein each incoming channel may be connected to one or more predetermined outgoing channels.

Sparse Wavelength Conversion

The networks may comprise a collection of nodes having full, limited, fixed, and no wavelength conversion. For this to work, many wavelength conversion algorithms are used to minimize the number wavelength converters (Xiao and Leung 1999).

Deflection Routing

In deflection routing, a deflected burst typically takes a longer route to its destination, leading to increased delay and degradation in the signal's quality. Furthermore, the burst may loop indefinitely within the network, adding to congestion. Mechanisms must be implemented to prevent excessive path lengths. These may include a maximum-hop

counter or a constrained set of deflection alternatives (Jue 2002). In JET-based OBS networks, another concern with deflection is the offset time. It is possible that, if the burst traverses a large number of hops, the burst may overtake the header. Approaches for ensuring sufficient separation include setting a higher initial offset value at the source node and using an FDL at each intermediate node to delay the burst.

Burst Segmentation

Burst segmentation is another approach proposed to reduce packet loss resulting from contention. It is the process of dropping only those parts of a burst that overlap with another burst. Then, when two bursts contend in the OBS network, only those segments of one burst that overlap with the other burst will be dropped. In burst segmentation, the important issue is the decision of which burst segments to drop when a contention occurs between the two bursts. There are two possible approaches for determining which segments to drop: tail dropping and head dropping. In *tail dropping*, the overlapping tail segments of the original burst are dropped. In *head dropping*, the head overlapping segments of the contending burst are dropped. An advantage of dropping the overlapping tail segments of bursts rather than the overlapping head segments is that there is a better chance of in-sequence delivery of packets at the destination, assuming that dropped packets are retransmitted at a later time. A head-dropping policy results in a greater likelihood that packets arrive at their destination out of order; however, the advantage of head dropping is that it ensures that, once a burst arrives at a node without encountering contention, the burst is guaranteed to complete its traversal of the node without preemption by later bursts.

QoS Parameters

Quality of service in WDM networks is characterized by a number of parameters. The following are the most important.

Control Latency

Latency is the time between sending a message from one node and receiving it by another node. This means delay in a transmission path. In a router, latency is the amount of time between receiving a data packet and retransmitting it. This is also referred to as the *propagation delay*.

Jitter

Jitter is a distortion that occurs when data are transmitted over a network and packets do not arrive at their destination in consecutive order or on a timely basis—that is, they vary in latency. In packet-switched networks, jitter is an aberration of the interpacket arrival times compared to the interpacket times of the original transmission. This distortion is particularly damaging to multimedia traffic. For example, the playback of audio or video data may have a jitter.

Bandwidth

Bandwidth is a measure of data-transmission capacity, usually expressed in kbps or megabits per second (Mbps).

Bandwidth indicates the theoretical maximum capacity of a connection, but as the theoretical bandwidth is approached, negative factors such as transmission delay can cause deterioration in quality. If bandwidth is increased, more data can be transferred. Network bandwidth can be visualized as a pipe that transfers data. The larger the pipe, the more data can be sent through it.

Packet Loss

Packet loss means the percentage value of lost packets during a time period. For example, packet loss can be expressed as a percentage.

Availability

Availability is a measure of the percentage of time that a node is in service. Equipment vendors typically claim high availability for their boxes when they attain availability levels in the region of 99.999 percent.

QoS Models

QoS support is another important issue in WDM networks. Applications with diverse requirements urge transport technologies that are carrying the next-generation optical Internet technologies (such as OLS, OPS, and OBS) to provide QoS guarantees. There are two models for QoS: relative QoS and absolute QoS. In the *relative QoS* model, the performance of each class is not defined quantitatively in absolute terms. Instead, the QoS of one class is defined relatively in comparison with other classes. For example, an entity (packet or burst) of high priority is guaranteed to experience lower loss probability than an entity of lower priority. However, the loss probability of a high-priority traffic still depends on the traffic load of lower-priority traffic, and no upper bound on the loss probability is guaranteed for the high-priority traffic.

The *absolute QoS* model provides a worst-case QoS guarantee to applications. This kind of hard guarantee is essential to support applications with delay and bandwidth constraints such as multimedia and mission critical applications. Moreover, the absolute QoS model is preferred in order to ensure that each user receives an expected level of performance. Efficient admission-control and resource-provisioning mechanisms are needed to support the absolute QoS model. QoS models can also be classified based on the degree of isolation between the different traffic classes. In an isolated model, the performance of the high-priority traffic is independent of the low-priority traffic. In a nonisolated model, the performance of the high-priority traffic depends on the low-priority traffic. The degree of isolation can be fixed ahead of time and satisfied using different techniques.

Most QoS differentiation schemes in IP networks focus on providing loss differentiation, delay differentiation, or bandwidth guarantees because IP routers have the capability to buffer packets electronically. However, optical core nodes do not have any electronic buffers, and the data follow an all-optical path from source to destination. Thus, the delay incurred from source to destination results primarily from propagation delay, and bandwidth guarantee is implicitly provided by supporting loss guarantee. Hence, the focus of QoS support in OBS networks

is to primarily provide loss differentiation, although a few papers have addressed the problem of providing delay differentiation.

QoS in OBS Networks

In OBS networks, several schemes have been proposed to support the relative QoS model. A differentiated signaling scheme may be used to provide QoS in optical burst switched networks. An additional offset-based JET scheme was proposed for isolating classes of bursts so that high-priority bursts experience less contention and loss than low-priority bursts (Yao et al. 2000). In this additional offset-based reservation scheme, higher-priority class bursts are given a larger offset time than the lower-priority class bursts. By providing a larger offset time, the probability of reserving the resources without conflict for the higher-priority class burst is increased; therefore, the loss experienced by higher-priority class traffic is decreased. The limitation of this approach is that high-priority bursts will experience higher delays; thus, the approach may be capable of satisfying loss requirements but is not capable of meeting delay requirements. Furthermore, it has been shown that this scheme can lead to unfairness, with larger low-priority bursts experiencing higher loss than smaller low-priority bursts (Yao et al. 2000).

Another approach intentionally drops low-priority bursts under certain conditions in order to reduce loss for high-priority bursts. The scheme provides a proportional reduction rather than a complete elimination of high-priority burst losses resulting from contention with low-priority bursts. This proportional QoS scheme based on per-hop information was proposed to support burst loss probability and delay differentiation. The proportional QoS model quantitatively adjusts the QoS metric to be proportional to the differentiation factor of each class. If p_i is the loss metric and s_i is the differentiation factor for class i , then, using the proportional differentiation model, the following will hold for every class: ($p_i/s_i = p_j/s_j$). To implement this model, each core node needs to maintain traffic statistics, such as the number of burst arrivals and the number of bursts dropped for each class. Hence, the online loss probability of class i , p_i , is the ratio of the number of class i bursts dropped to the number of class i burst arrivals during a fixed time interval. To maintain the differentiation factor between the classes, an intentional burst dropping scheme is employed. A limitation of the scheme is that it can result in the unnecessary dropping of low-priority bursts. Proportional QoS differentiation is also provided by maintaining the number of wavelengths occupied by each class of burst. Every arriving burst is scheduled based on a usage profile maintained at every node. Arriving bursts that satisfy their usage profiles preempt scheduled bursts that do not satisfy their usage profiles so as to maintain the preset differentiation ratio.

QoS Mechanisms

The Quality of Service Forum has defined the different mechanisms that must be carried out to ensure QoS in a network, including the following.

Admission Control

Admission control determines whether a requested connection is allowed to be carried by the network. The main considerations behind this decision are current traffic load, current QoS, requested traffic profile, requested QoS, pricing, and other policy considerations. For QoS-enabled IP networks, admission control, for example, could be performed in setting up RSVP flows or OLS paths.

Traffic Shaping and Conditioning

In QoS-enabled IP networks, it is necessary to specify the traffic profile for a connection to decide how to allocate various network resources. *Traffic shaping and conditioning* ensures that traffic entering at an edge or a core node adheres to the profile specified. Typically, this mechanism is used to reduce the burstiness of a traffic stream. This involves a key trade-off between the benefits of shaping (e.g., loss in downstream network) and the shaping delay. Leaky bucket-based traffic shaping is an example of this mechanism.

Classification and Marking

To provide the requested QoS, it is critical to classify packets so as to enable different QoS treatment. This can be done based on various fields in IP headers and higher-layer protocol headers (e.g., source and destination port numbers for TCP or UDP). Efficient and consistent packet classification is a key problem under active research. Either as a result of a traffic-monitoring mechanism or voluntary discrimination, a packet can be annotated for a particular QoS treatment in the network (e.g. high or low, loss or delay priority). IP packet marking is proposed to be done using the IP header's type of service.

Priority and Scheduling Mechanisms

To satisfy the QoS needs of different connections, nodes need to have priority and scheduling mechanisms. The *priority* feature typically refers to the capability of providing different delay treatment—for example, higher-priority packets are always served before lower-priority packets, both in the context of packet processing and transmission on outbound links. Nodes also implement different loss-priority treatment—that is, higher-loss priority packets are lost less often than the lower-loss priority ones. Nodes also need to have closely related *scheduling* mechanisms to ensure that different connections obtain their promised share of the resources (i.e., processing and link bandwidth). This mechanism also ensures that any spare capacity is distributed in a fair manner. Examples of this mechanism include *generalized processor sharing*, *weighted round robin*, *weighted fair queuing*, and *class-based queuing*. Efficient implementation of these mechanisms, their extension to include both delay and bandwidth needs simultaneously, and hierarchical scheduling are active research areas.

Signaling Protocols

To obtain the required QoS from a network, end systems need to signal the network the desired QoS as well as the anticipated offered traffic profile. This has been a fundamental part of various connection-oriented networks

(e.g. ATM). However, for connectionless networks (e.g. IP), this is relatively new. Corresponding examples are the signaling associated with the resource reservation and label distribution protocols. Implementation, scalability and the corresponding capabilities to signal different QoS needs are issues under current examination.

ADVANCED ISSUES

As the Internet continues to evolve, it will be expected to support a growing number of applications, including Internet telephony, video conferencing, and video distribution. To support these applications, the network must be capable not only of providing the required bandwidth but also guaranteeing QoS, security, and survivability. A WDM network can provide the necessary bandwidth to support a wide range of multimedia Internet services. WDM networks, however, require the development of suitable devices and network architectures, along with appropriate protocols, to enable service guarantees.

A WDM network not only can provide a huge amount of bandwidth but also may offer the benefit of data transparency in which the network may carry signals of arbitrary format. Data transparency may be achieved through the all-optical transmission and switching of signals without electronic conversions at intermediate nodes. As optical devices mature and become cost-effective and competitive, it is conceivable that, by the end of this decade, optical systems will play a much more significant role in switching technology than today, with many switching and routing functions incorporated into the optical domain.

Several technologies have been proposed to allow for the best utilization of WDM network resources such as OLS, OPS, OBS, and WR. In WR, end users communicate with one another via all-optical WDM lightpaths. WR eliminates the need for buffering in the forwarding path but is poorly suited for rapid provisioning of wide bandwidth data services. OLS provides many desirable features not readily available in conventional networks. Its capability to achieve packet switching as well as burst or circuit switching implies seamless network upgrades and network interoperability. By designing a new signaling protocol that extends GMPLS, OLS can interoperate with MPLS and MPAS networks.

Currently, OPS and OBS techniques are in the experimental stage. The lack of commercially viable optical buffering technology constrains the commercial development of optical packet switches. Also, it is not clear how such switches can be deployed to carry IP traffic. Burst switching seems to be a more commercially viable technology than optical packet switching in the near future—if it can be designed so that it will not require optical buffering. The performance of the various burst switching schemes as well as the size of burst need to be studied in the light of IP traffic. With today's networks experiencing enormous exponential growth, it is important that we develop and take advantage of recent related technologies to keep pace with these increasing demands. WDM is an extremely promising technology for supporting these needs, and by developing architectures and protocols that fully utilize the benefits of WDM, we can ensure that this tremendous growth will continue to grow in the future.

CONCLUSION

In this chapter, we discussed and justified the need for the optical technology to provide bandwidth to carry next-generation Internet. We also provided a survey of the different optical multiplexing techniques, including TDM, SONT-SDH, and WDM. We then presented WDM technology as a solution to support the increasing bandwidth demands of new applications and services. We described with sufficient details the basic concept of this technology, its evolutions, its advantages, and its limits. We also described the most optical switching technologies—OCS, OPS, OBS, and OLS—and we discussed the major signaling schemes proposed in the literature and adopted by these switching technologies. Moreover, we presented in detail the contention resolution methods and stated how to provide service differentiation in optical switched networks and discussed the parameters and models that can be implemented to provide QoS.

GLOSSARY

Dense wavelength division multiplexing (WDM): A way of increasing the capacity of the optical fiber. It carries multiple wavelengths in single strands of the fiber.

Optical burst switching (OBS): A switching technology that can aggregate or assemble packets into bursts at ingress nodes such that the switching times and associated guard band inefficiencies are negligible with respect to the burst sizes.

Optical cross-connect (OXC): An element that switches optical signals from input ports to output ports. A basic cross-connect element is the 2×2 cross-point element. It routes optical signals from two input ports to two output ports and has two states: cross state and bar state.

Optical label switching (OLS): Offers seamless integration of data and optical networking while supporting circuit, burst, and packet switching using the optical labels. The dynamic and agile characteristics of optical label switching indicate its support of diverse QoS and CoS services.

Optical packet switching (OPS): A switching technique in which a data stream is broken into packets of small size before being transmitted. Routing information is added to the overhead of each packet in order to aid intermediate switches between the source and destination nodes.

Optical time division multiplexing (OTDM): An optical multiplexing technique used to enable multiple streams of information to share the same transmission media.

Synchronous optical network-synchronous digital hierarchy (SONET-SDH): A digital transmission standard. Higher layers use optical packet switching; the optical layer is point to point.

Wavelength division multiplexing (WDM): A multiplexing technique in which two or more optical signals with different wavelengths are combined and simultaneously transmitted in the same direction over an optical fiber.

Wavelength routing (WR): Enables optical networks to carry data between access stations in the optical domain without any intermediate optical to and from electronic conversion.

INTRODUCTION

Digital communication is the process of conveying information from a transmitter to a receiver across a physical channel. Typically, information is transformed into digital bits that are processed for transmission. The origin of the binary data is known as a *source*; the destination of the binary data is known as a *sink*.

It is hard to conceive of analog communication or analog physical layer technologies that are comparable to our commonly used digital communication technology. Examples include the analog telephone and AM transmitter-receivers. In these cases, the actual signal of interest is transmitted without digitization. Because of the redundancy of the signal and the difficulty in using advanced techniques for higher data rates, these forms of transmission are not particularly efficient. This is why digital communication is used to carry the majority of information transmission.

Early forms of digital communication using electrical signals date back to the invention of the telegraph by Samuel Morse in the 1830s. The telegraph used Morse code, essentially a mapping from letters to quaternary sequences (long pulses, short pulses, letter spaces, and word spaces) to convey digital information over long distances via cable. Guglielmo Marconi patented a wireless telegraph in 1896: This is the origin of wireless digital communication. The *facsimile* (fax) machine is a sometimes surprising example of early digital communication. First patented in 1843 by Alexander Bain, the fax machine both then and now scans documents line by line and digitally encodes and conveys the presence or absence of ink.

Digital communication systems offer higher quality compared with analog systems, increased security, better robustness to noise, reductions in power, and easy integration of different types of sources such as voice, text, and video. Because the majority of a digital communication system's components are implemented using semiconductor technology, devices can take advantage of the reductions in cost and size in CMOS and other semiconductor technologies.

Digital communication technology is a mix of analog and digital components. The backbone of the Internet uses digital communication over optical fibers. So-called last-mile access technologies including voice-band modems, cable modems, and digital subscriber lines (DSLs) are all digital. Local area networks use different digital communication technologies such as IEEE 802.3 (Ethernet) for wired access or IEEE 802.11 for wireless access. Digital communication allows remote access to the Internet via cellular systems through CDPD in first-generation systems and GPRS, HDR, or EDGE in second-generation systems. Third-generation cellular systems harmonize voice and data access. Examples of upcoming wireless networks include the IEEE 802.16 standard (or WiMAX) and the evolutionary path of the *groupe spéciale mobile* developed by the 3rd Generation Partnership Project called *long-term evolution*.

This chapter presents the fundamentals of digital communication. Many topics of relevance to digital communication are treated elsewhere in this handbook. A broad description of cellular and wireless networks is contained in Volume 2, Part 3. Other modulation schemes are described more in Part 2 of this volume. Readers who are interested in only a cursory overview can read the second section of this chapter. Those who want a more thorough treatment beyond this should read the entire chapter as well as consult select references described in "Further Reading."

FUNDAMENTALS OF DIGITAL COMMUNICATION

Digital Communication System Overview

The physical layer typical of a digital communication system is illustrated in Figure 1. In some systems, various functional blocks may be combined or omitted, depending on the needs of system designers. Some critical control functions such as synchronization are not explicitly highlighted but are discussed in this chapter.

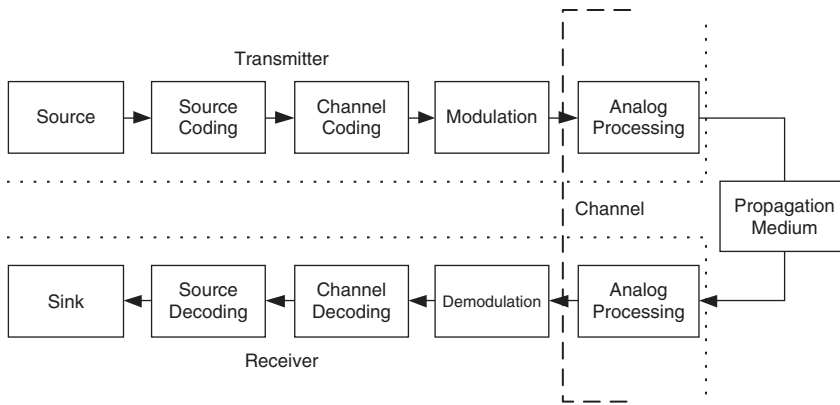

Figure 1: The components of a typical digital communication system

The physical layer is one of several layers of abstraction of a communication network, and it deals with the transmission and reception of raw data. There are several steps in the transmission and reception process, some of which involve *digital signal processing* (DSP) and some of which involve analog processing. Thus, it is important to distinguish that whereas digital communication involves the transmission of digital information, the transmission and reception process involves both digital and analog processing. In this chapter, we focus on the DSP aspects of digital communication, in particular the aspects at the physical layer where the analog waveforms are generated and processed.

The block diagram for a typical digital communication system in Figure 1 is divided into three parts: the transmitter, the channel, and the receiver. The transmitter processes a bit stream of data for transmission over a physical medium. The channel is the physical medium that adds noise and distorts the transmitted signal. It accounts for the propagation medium as well as any analog effects in the transmitter and receiver. The receiver attempts to extract the transmitted bit stream from the received signal.

The first basic transmitter block is devoted to *source encoding*. The purpose of source encoding is to compress the data by removing inherent redundancies. The input to the source encoder will be called $s[n]$, the *source sequence*. The output of the source encoder will be called $i[n]$, the *information sequence*. Source encoding includes both lossy and lossless compression. In lossy compression, some degradation is allowed to reduce the amount of data that need to be transmitted. In lossless compression, redundancy is removed, but upon inverting the encoding algorithm the signal is exactly the same. In other words, if f and g are the source encoding and decoding processes, then $\hat{s}[n] = g[i[n]] = g[f[s[n]]]$; for lossy compression, $s[n] \cong \hat{s}[n]$, and for lossless compression, $s[n] = \hat{s}[n]$. So, data from the source encoder $s[n]$ are transformed into $i[n]$, both of which are in bits. The bit rate R_b is the rate at which information bits are transmitted through the channel.

Following source encoding is *encryption*. The purpose of encryption is to make it difficult for an unintended receiver to interpret the transmitted data. Generally, encryption involves applying a lossless transformation to the information sequence $i[n]$ to produce an encrypted

sequence $e[n] = p(i[n])$. *Decryption* reverses this process by applying an inverse transform $p^{-1}(\cdot)$ to produce $i[n] = p^{-1}(p(i[n]))$. Unlike source coding, encryption does not compress the data; instead, it makes the data unintelligible to an uninformed receiver.

The next block is the *channel coder*. Channel coding adds redundancy to the encrypted sequence $e[n]$ in a controlled way to provide resilience to channel distortions and to improve overall throughput. Using common coding notation, for every k input bits, or information bits, there is an additional redundancy of r bits. The total number of bits is $n = k + r$; the coding rate is defined as k/n . Two types of channel codes are prevalent: forward error-correction codes and error-detection codes. Forward error-correction codes are used to provide redundancy that enables errors to be corrected at the receiver. They come in varieties such as *trellis codes*, *convolutional codes*, and *block codes* (Bossert 1999). Error-detection codes—*cyclic redundancy check* (CRC) codes being the most common—provide redundancy that allows the receiver to determine if an error occurred during transmission. The receiver can use this information to either discard the data in error or request a retransmission. Channel coding is discussed in more detail in other parts of this handbook.

Following channel coding, the bits are mapped to *waveforms* by the modulator. This is the demarcation point where basic transmitter-side digital signal processing for communications ends. Typically, the bits are mapped in groups to *symbols*. Following the symbol mapping, the modulator converts the digital symbols into corresponding analog waveforms for transmission over the physical link. This can be accomplished by sending the digital signal through a *digital-to-analog* (D/A) converter into a shaping filter and, if needed, mixed onto a higher-frequency carrier. Symbols are sent at a rate of R_s symbols per second (known as the *baud rate*); the symbol period $T_s = 1/R_s$ is the time difference between successive symbols.

The signal generated by the transmitter travels through a propagation medium to the receiver. The medium could be a radio wave through a wireless environment, a current through a telephone wire, or an optical signal through a fiber.

The first block at the receiver is the *analog front end* (AFE), which consists at least of filters to remove unwanted noise, oscillators for timing, and *analog-to-digital*

(A/D) converters to convert the data into the digital regime. There may be additional analog components such as low-noise amplifiers and mixers. This is the demarcation point for the beginning of the receiver-side digital signal processing for digital communication.

As illustrated in Figure 1, the channel is the component of the communication system that accounts for all of the noise and intersymbol interference introduced by the analog processing blocks, the propagation medium, and interfering signals. Noise is a random disturbance that degrades the received signal. Sources of noise include the thermal noise that results from the material properties of the receiver, the quantization noise caused by the D/A and the A/D converters, and the external interference from other communication channels. *Intersymbol interference* is a form of signal distortion that causes the transmitted signal to interfere with itself. Sources of intersymbol interference include the distortion introduced by the analog filters as well as the propagation medium.

The first digital communication block at the receiver is the *demodulator*. The demodulator uses a sampled version of the received waveform, and perhaps knowledge of the channel, to infer the transmitted symbol. The process of demodulation may include equalization, sequence detection, or other advanced algorithms to help combat channel distortions.

Following the demodulator is the *channel decoder*. Essentially, the decoder uses the redundancy introduced by the channel coder to remove errors generated by the demodulation block. The decoder may work jointly with the demodulator to improve performance or may simply operate on the output of the demodulator. Overall, the effect of the demodulator and the decoder is to produce the closest possible $\hat{e}[n]$ given the observations at the receiver.

After demodulation, *decryption* is applied to the output of the demodulator. The objective is to make the information intelligible to the receiver. Generally, decryption applies the inverse transformation $p^{-1}(\cdot)$ corresponding to the encryption process to produce an estimate of the transmitted information $\hat{i}[n] = p^{-1}(\hat{e}[n])$.

The final block in Figure 1 is the source decoder that essentially reinflates the data back to the form it was sent: $\hat{s}[n] = g(\hat{i}[n])$. This is basically the inverse operation of the source encoder. After source decoding, the digital data are delivered to higher-level communication protocols that are beyond the scope of the chapter.

For Internet traffic, common transmitter-receiver pairs include DSL modems, fiber-optic transceivers, local area networks, and even storage devices such as disk drives.

Although their physical media are diverse and the speeds at which they transmit may be significantly different, the fundamental model for each of these digital communication systems is the same.

Processing in the Digital Domain

There are three basic classes of signals in digital communication: continuous time, discrete time, and digital. *Continuous time* signals are those whose value at time t is $x(t)$, where t and $x(t)$ can take values on a continuum—for instance, the real number line or the complex plane. *Discrete time* signals take values only at integer times n , but the signal $x[n]$ takes values on a continuum. Finally, *digital* signals are those that have value at integer times and take on values on some finite (perhaps countably infinite) set.

The link between the analog and the digital domains is through the D/A and A/D converters as illustrated in Figure 2. At the transmitter, the D/A converts a digital signal $x[n]$ to an analog signal $x(t)$ essentially by letting $x(nT_s) = x[n]$ and interpolating the remaining values. At the receiver, the A/D samples the received signal $y(t)$ at some period T (typically a fraction of T_s) to produce $y[n] \cong y(nT)$, where this is approximate equality because $y[n]$ is quantized to some set of values. This new signal is called $y_d[n]$, and is the digital waveform derived from the continuous time waveform $y(t)$.

The Nyquist sampling theorem gives flexibility in the choice of whether to process $y(t)$ or $y[n]$. Ignoring quantization noise, the Nyquist sampling theorem states that if the inverse of the sample rate is greater than twice the maximum frequency in $y(t)$ (or equivalently the bandwidth), then there is no loss in the sampling process. This implies that any processing done on the continuous time waveform can be done equally well on the sampled waveform given that the conditions stated in the Nyquist sampling theorem are satisfied. Several practical considerations, however, make digital the domain of choice.

The biggest advantage of doing as much processing as possible in the digital domain is that it allows full exploitation of the benefits of digital technology. Many digital platforms exist that are highly customizable and easy to alter—for instance, field programmable gate arrays and digital signal processors. This hardware has been designed to have very good tolerances and reproducibility. As the DSP components are relatively easy to change, they are also well suited to adaptation. Analog circuitry is typically not as easy to adjust, and custom design can be expensive.

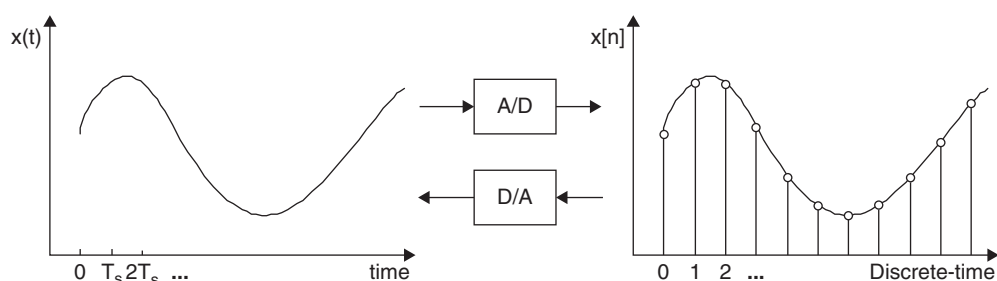

Figure 2: The relationship between a continuous time signal and a discrete time signal

Moreover, even small changes in design or specification tolerances may require wholesale redesign, which may be more costly than adjusting some parameters in a digital platform. Another advantage of processing in the digital domain is a by-product of the shrinking transistor size: It offers both dramatic increases in processing power as well as significant reductions in overall cost. Thus, doing the majority of the processing in the digital domain improves cost, performance, and flexibility. For these reasons, doing processing in the digital domain has become highly relevant to digital communication.

Key Resources: Power and Bandwidth

The two primary resources in any communication system, both digital and analog, are power and bandwidth. Systems whose performance is limited by the available power are *power-limited*, whereas those that are limited by bandwidth are *bandwidth-limited*. Most practical systems are both power- and bandwidth-limited.

The power of a signal is roughly defined as the average energy over time. Mathematically, this is often written as $P = \lim_{T \rightarrow \infty} (1/T) \int_{-T/2}^{T/2} |x(t)|^2 dt$. Power may be measured in watts but is more often measured in decibels relative to one watt (dB) or one milliwatt (dBm). The decibel is a relative measure that is defined as $(P/Q)_{dB} = 10 \log_{10}(P/Q)$. When used to measure the power of P in dB, Q is assumed to be 1 watt, whereas to measure the power of P in dBm, Q is assumed to be 1 milliwatt. Sometimes the notation *dBW* and *dBmW* are used when measuring dB in terms of watts.

There are two different but related notions of power in a communication system: transmit power and the received power. Naturally, the *transmit power* is the average energy over time of the transmitted signal whereas the *received power* is the average energy over time of the received signal.

The transmitted power in a communication system is limited by the maximum power available to transmit a signal. Generally, system performance will be better if there is high transmitted power (and thus received power). Practical constraints on cost, properties of the transmission medium, battery life (in mobile systems), or regulatory constraints generally motivate having a low transmitted power.

Because propagation media are lossy and dispersive, the received power is a function of the transmit power and the channel. In all media, the loss resulting from the

channel increases as some function of the distance between the transmitter and receiver. Thus, the larger the distance, the smaller the received power.

The minimum received power required at the receiver, known as the *receiver sensitivity*, is determined by the parameters of the system, the quality of the hardware, as well as the desired operating characteristics. The range of the system can be inferred from the ratio of the maximum transmit power to the minimum received power. Generally, increased data rate in a given bandwidth or lower *bit error rates* (BERs) increase the required minimum received power.

Besides power, *bandwidth* is the other design constraint in a communication system. Unfortunately, there are many definitions of bandwidth and different notions are used in different systems. The most generic definition of the bandwidth of a signal $x(t)$ is the portion of the frequency spectrum $X(f) = \int_{-\infty}^{\infty} x(t)e^{-j2\pi ft} dt$ for which $X(f)$ is nonzero. Because the true bandwidth of a finite duration signal is infinite, systems often use the “3-dB bandwidth,” which is the contiguous range of frequencies over which the power spectrum is at least 50 percent of the maximum value. Other definitions of bandwidth are also possible (see Couch 2001 for details).

Note that the definition of bandwidth differs depending on whether the communication system is *baseband* or *bandpass*. Baseband communication systems operate at DC, whereas bandpass communication systems convey information at some carrier frequency f_c . Figure 3 illustrates the different bandwidth notions of absolute and 3-dB bandwidth in each of these types of systems.

The bandwidth available in a communication system depends on the transmission medium. In wireless systems, bandwidth is a precious and expensive commodity that is regulated by the government. Thus, although the theoretical bandwidth of the wireless medium is significant, only a fraction is available to a given communication system. In wireline systems, the bandwidth is determined by the type and quality of the cable and the interconnects. Generally, the larger the bandwidth, the larger the potential data rate that can be supported. Exploiting larger bandwidths, however, typically requires more sophisticated receiver processing algorithms and more expensive analog components.

Bandwidth and power are related through the concept of the *power spectral density* (PSD). The PSD is a measure of the power in a signal as a function of frequency. The integral of the PSD is hence the power of the signal.

Figure 3: Illustration of two different notions of bandwidth in baseband and bandpass signals

Measures of Performance

There are many potential measures that are used to evaluate the performance of a digital communication system. The choice of a performance measure depends significantly on the application of the system. Broad classes of performance measures include the probability of error, the outage probability, and the capacity. In this chapter, we will discuss the probability of error and the capacity. The *probability of error* is a measure of the rate at which errors occur, whereas the *capacity* is a measure of the maximum data rate that can be supported by a channel with a given *signal-to-noise ratio* (SNR) and an arbitrarily small probability of error.

Of the two measures, the probability of error is the more pragmatic indicator of system performance. There are various flavors of the probability of error, including the probability of bit error, the probability of symbol error, and the probability of frame error. Equivalently, these measures are known as the *bit error rate*, the *symbol error rate* (SER), and the *frame error rate* (FER). In simple transmission mediums, SER and the FER can be determined from the BER; therefore, the BER is a generically studied performance metric.

Essentially, the BER provides the average number of bit errors. For example, a BER of 10^{-2} means that on average approximately one bit out of every one hundred will be in error. The BER can be measured at various places in the receiver but is typically most meaningful after demodulation (the uncoded BER) and after error correction (the coded BER).

The performance needs of the application determine the required BER. For example, voice communication in cellular systems might require a coded BER of 10^{-2} , whereas data communication in the same system might require a coded BER of 10^{-5} . In most communication systems, the uncoded BER is a function of the data rate and the modulation scheme and can be readily related to the signal-to-noise ratio. The SNR is essentially the ratio of the received signal power to the noise power in the signal bandwidth. Thus, the BER is a function of both the received power and the bandwidth of the signal, although more generally the channel model will also play a role.

The fundamental limit to data communications can be most simply described by the so-called capacity of a channel, C , which is the maximum average number of bits that can be supported by a channel with a given SNR at an arbitrarily small probability of error. The capacity is measured in units of bits per second and is essentially a bound on the achievable data rate. Often the capacity is normalized by the bandwidth. The normalized capacity C/B measures the bits per channel use in units of bits per second per hertz. Unlike the BER, the capacity provides an upper bound (instead of the actual performance) of a communication system because it is optimized over all possible modulation and coding schemes. Like the BER, the capacity is typically a function of the SNR, the bandwidth, and the channel.

The capacity is a measure for determining the fundamental limit on the data rate imposed by the given communication channel. The BER is more useful for evaluating the performance of an actual coding and modulation scheme. Typically, a target BER will be defined

and a coding and modulation scheme will be proposed to achieve the largest data rate possible, R . Naturally, it should be the case that $R < C$. Spectrally efficient digital communication systems have a rate R that closely approaches the capacity C for the desired operating point.

IMPORTANT CONCEPTS IN DIGITAL COMMUNICATION

Modulation

The modulator in a digital communication system maps binary data onto waveforms for transmission over the physical channel. The modulator maps a group of bits (or symbols) onto a finite number of waveforms each symbol period. Binary modulations map each bit to one of two possible waveforms, whereas M-ary modulations map each group of $\log_2 M$ bits to one of M possible waveforms. The analog waveforms are designed with the constraints of the channel such as the bandwidth or the carrier frequency in mind.

There are two basic forms of modulation: linear modulation and nonlinear modulation. *Linear modulation* schemes are typically more spectrally efficient—that is, they are able to come closer to the capacity. *Nonlinear modulations* typically have other properties, such as constant envelope, that make them easier to implement and less susceptible to various impairments in the channel. The choice of a modulation scheme depends on the desired throughput, the target BER, the spectral efficiency of the modulation scheme, the power efficiency of the modulation scheme, robustness to impairments, and the implementation cost and complexity.

Modulations may also have memory or they may be memoryless. When a symbol is only a function of the bits from the current symbol period, then it is said to be *memoryless*. When a symbol is a function of the bits from previous symbols periods, the modulation is said to have *memory*. Having memory in the modulation scheme may have practical advantages such as reducing the peak-to-average ratio of the transmitted signal or simplifying noncoherent detection at the receiver. Modulations with memory can also provide additional resilience to errors; thus, they are sometimes called *coded* modulation schemes.

To illustrate the concept of modulation—in particular, linear modulation—let us first define the concept of signal space and then relate that to common modulation formats found in practice. A *vector space* is defined to be a set of vectors (in this case, continuous signals), $\{\phi_i(t)\}$, with two operations: (1) addition of those vectors (i.e., $\phi_i(t) + \phi_j(t)$ is defined and is an element of the vector space) and (2) multiplications of those vectors by a scalar (i.e., $k\phi_i(t)$ is defined and is an element of the vector space). Other technical rules for being a vector space can be found in Anton and Rorres (1991). In communications, typically these vectors are orthogonal—that is,

$$\int_{-\infty}^{\infty} \phi_i(t)\phi_j(t)dt = \delta_{ij} \quad (1)$$

where δ_{ij} is 1 for $i = j$ and 0 otherwise. Because these waveform vectors are orthogonal, they are also a basis

for the vector space and are sometimes referred to as *basis functions*.

A digital communication system may be baseband or bandpass, depending on whether the symbols are conveyed at baseband (DC) or at some carrier frequency (see Figure 3). An asymmetric digital subscriber line is an example of a baseband communication system (see also “DSL (Digital Subscriber Line)”). Most digital communication systems are bandpass, including all narrowband wireless systems, optical systems, and cable modems. Although bandpass systems convey information at a carrier frequency, the modulator and demodulator do not need to generate signals at that carrier frequency. Instead, the modulator and demodulator work with the *baseband equivalent* waveform. At the transmitter, the *upconverter* in the analog processing block converts the baseband equivalent signal to the bandpass signal by shifting it to the desired carrier frequency. At the receiver, the *downconverter* in the analog processing block shifts the bandpass signal down to zero frequency. The advantage of the baseband equivalent notion is that it makes the digital operations of the communication system independent of the actual carrier frequency.

Let us first consider baseband *pulse amplitude modulation* (PAM) (see also “Pulse Amplitude Modulation”). PAM transmission is used in *high bit rate digital subscriber lines* (DSL), HDSL-II and G.SHDSL. It is a linear and memoryless modulation. An M-PAM system is a form of M-ary modulation in which $m = \log_2 M$ bits at a time are mapped to an element of the set of M possible amplitudes C_{PAM} , which is the constellation. For 4-PAM, a set of possible amplitudes is $C_{PAM} = \{-3, -1, 1, 3\}$, which are equally spaced apart. A pulse-shaping filter $\phi(t)$ with a bandwidth B is modulated to produce the transmitted waveform $x(t) = \sum_n x[n] \phi(t - nT_s)$, where $x[n] \in C_{PAM}$. So the set C_{PAM} is the constellation, $x[n]$ is the symbol transmitted starting at time nT_s , and $\phi(t)$ is the basis waveform. The spectrum of the PAM waveforms is determined by the pulse-shaping filter $\phi(t)$. The choice of pulse-shaping filter is a complicated one involving several competing requirements including resistance to timing jitter, simple implementation, and minimized spectral bandwidth.

A nice generalization of PAM that is preferable for bandpass systems is known as *quadrature amplitude modulation* (QAM). As with PAM, QAM is a linear and memoryless modulation. For simplicity, the M-QAM modulation is defined for M that is a power of four. Let $m = 1/2 \log_2 M$ and consider the same set of 2^m possible amplitudes C_{PAM} and pulse-shaping waveform $\phi(t)$. For M-QAM, at some carrier frequency f_c the transmitted waveform is

$$x(t) = \left(\sum_n i[n] \phi(t - nT_s) \right) \cos(2\pi f_c t) - \left(\sum_n q[n] \phi(t - nT_s) \right) \sin(2\pi f_c t) \quad (2)$$

where $i[n] \in C_{PAM}$ corresponds to the symbol transmitted on the in-phase component $\cos(2\pi f_c t)$ and $q[n] \in C_{PAM}$ corresponds to the symbol transmitted on the quadrature component $\sin(2\pi f_c t)$. Assuming that f_c is much greater than $1/B$, the modulated in-phase and quadrature components are orthogonal; thus, QAM has double the data

rate of a PAM system that would use only the in-phase or quadrature component. Of course, recalling the discussion about Figure 3, note that a bandpass QAM system also uses twice the bandwidth of a baseband PAM system and thus the spectral efficiency of QAM at bandpass and PAM at baseband is the same. The ordered pair $(i[n], q[n])$ is the symbol transmitted starting at time nT_s , and $\phi(t) \cos(2\pi f_c t)$ and $\phi(t) \sin(2\pi f_c t)$ are the basis waveforms. For M-QAM, the constellation C_{PAM} is composed of all possible ordered pairs that can be generated from choosing the 2^m PAM points for the in-phase and quadrature components. Thus, the M-QAM constellation has two dimensions. The baseband equivalent of the QAM signal in Equation 2 is a complex function and is given by

$$\sum_n (i[n] + jq[n]) \phi(t - nT_s)$$

where $j = \sqrt{-1}$. Quadrature modulation schemes have complex baseband equivalents to account for both the in-phase and quadrature components. The spectrum of the QAM waveform is determined by the pulse-shaping filter $\phi(t)$ and is shifted in frequency by f_c . PAM and QAM modulation are illustrated in Figure 4.

Not all bandpass systems are capable of using QAM modulation. For example, in optical transmission phase information is not available, so the constellations are defined for positive amplitudes only. If the constellation values are 0 and A, this is known as *on-off keying*.

Another common form of modulation is *multicarrier modulation* in which several carriers are modulated by QAM modulation simultaneously (see also “DMT Modulation”). These carriers can be thought of as a basis waveform modulated by sinusoids of differing frequencies. This is not easy to accomplish, so an *inverse fast Fourier transform* (IFFT) is used to approximate this operation. The IFFT of a set of constellation points is, in fact, the sum

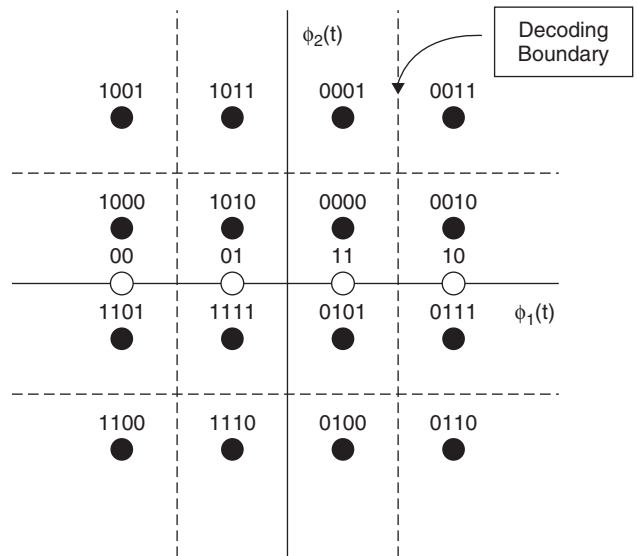

Figure 4: Signal space illustration of PAM and QAM signaling. The solid black circles are QAM, and the white circles are PAM. The numbers above the circles represent the mapping of bits to the constellation points

of a set of sampled sinusoids multiplied by the constellation points. In the digital domain, each of these waveforms can be independently demodulated. These samples are sent through a single pulse-shaping filter (basis waveform) and transmitted through the channel. The receiver samples the waveform and performs the inverse operations, a *fast Fourier transform*. Multicarrier modulation has become important because of its robustness to impulsive noise, ease of equalization, and its ability to do spectral shaping by independently controlling the carriers. *Discrete multitone* is the most common baseband version of multicarrier modulation, whereas *orthogonal frequency division multiplexing* (OFDM) is the most common band-pass version.

Intersymbol Interference Channels

After modulation, the analog waveform $x(t)$ corresponding to an input sequence of bits is transmitted over the communication medium. Communication media—whether fiber-optic cable, coaxial cable, telephone cable, or free space—generally have a dispersive effect on the transmitted signal. The effect of the medium on $x(t)$ is often modeled using a concept from signal processing known as a *linear and time-invariant* (LTI) system. The linearity implies that if $y_k(t)$ is the response to $x_k(t)$, then $\alpha y_1(t) + \beta y_2(t)$ is the response to the input signal $\alpha x_1(t) + \beta x_2(t)$. The time invariance means that the response to $x(t + \tau)$ is $y(t + \tau)$ —that is, the behavior of the channel is not a function of time. Practically all physical channels are time-varying (because of changes in environmental factors), especially wireless channels. However, over short periods of time they can be modeled as time-invariant. Optical channels can also exhibit nonlinear behavior and thus other models may sometimes be appropriate.

The LTI assumption about the communication medium allows the distortion to the input signal to be modeled using the convolution operation

$$y(t) = \int_{-\infty}^{\infty} h(\tau)x(t - \tau)d\tau$$

The function $h(\tau)$ is known as the *impulse response* of the channel and includes all of the analog effects in the normal operating regime such as filtering at the transmitter and receiver in addition to the distortion in the medium. From basic Fourier transform theory, LTI systems have the nice property that, in the frequency domain, $Y(f) = H(f)X(f)$, where $Y(f)$ is the Fourier transform of $y(t)$, $H(f)$ is the Fourier transform of $h(t)$, and $X(f)$ is the Fourier transform of $x(t)$. Essentially, the channel acts as a frequency-selective filter that operates on the input signal. LTI systems induce distortion that is multiplicative in the frequency domain.

In an ideal channel, $|H(f)| = 1$ and there is no distortion (only a delay) of the input signal. Equivalently, in the time domain, an ideal channel produces $y(t) = x(t - \tau)$, where τ is an arbitrary delay. When the channel is not ideal, a more serious problem—intersymbol interference—is encountered. To illustrate this concept, suppose that $x(t)$ is generated at baseband using PAM as described in the previous section. In the absence of a channel, ideal

sampling of $x(t)$ at the receiver at time mT_s (more details on this in the next section), results in $\sum_n x[n] \phi(mT_s - nT_s)$. The pulse-shaping filter $\phi(t)$, however, is often a Nyquist pulse shape, which means that $\phi(0) = 1$ and $\phi(nT_s) = 0$ for $n \neq 0$. Thus, sampling at time mT_s yields symbol $x[m]$. Now consider a nonideal channel. Let $\phi_{\sim}(t)$ be the convolution of $\phi(t)$ and $h(t)$. For a nontrivial channel, it will generally be the case that $\phi_{\sim}(t)$ is no longer a Nyquist pulse shape and thus $y[m] = \sum_n x[n] \phi_{\sim}((m - n)T_s)$. In this case there are multiple superpositions of symbols at each sampling instant—thus the notion of intersymbol interference. Compensating for intersymbol interference is known as *equalization* and is an important part of the receiver processing when intersymbol interference is present.

Noise and Interference

Noise and interference are the most ubiquitous forms of degradation in any communication system. Essentially, both can be modeled as random disturbances that are unrelated to the desired signal. Intersymbol interference also results in degradation, although the effect is different because it causes the signal to interfere with itself. *Noise* usually refers to the disturbances generated in the receiver as a result of the analog components, analog-to-digital conversion, and material properties of the receiver. Generally, noise can be reduced by using higher-quality materials but never eliminated. *Interference* generally refers to disturbances generated by external signals. Typically, interference has more signal structure than noise and thus it can be mitigated by more complex processing at the expense of higher cost.

There are various sources of noise in communication systems. Common examples include thermal noise, shot noise, and quantization noise. *Thermal noise* is a result of the Brownian random motion of thermally excited electrons. It is generated by resistors and the resistive parts of other devices such as transistors. *Shot noise* is more impulsive and may be more related to the signal—for example, the random arrival rates of photons in optical systems. *Quantization noise* is a result of digitizing the amplitude of the discrete time signal. Because thermal noise limits the performance in most systems (with the exception of optical system), we will focus our explanation on thermal noise.

Because noise is fundamentally not deterministic, it is often modeled as a random process. For thermal noise, the Gaussian random process has been found to be adequate for the job. When applied to model thermal noise, the process is assumed to be zero mean, uncorrelated from sample to sample, and have a variance σ^2 that is generally proportional to kBT_e , where k is Boltzmann's constant ($1.23e - 23$ J/K), B is the signal bandwidth, and T_e is the effective noise temperature of the device. The latter, T_e , is a parameter determined by the analog portion of the receiver. Essentially, for thermal noise the variance increases linearly as a function of the bandwidth. Thus, for the same transmit power, signals with larger bandwidths incur an additional noise penalty while simultaneously enjoying a higher signaling rate.

The effect of thermal noise is additive, therefore the received signal can be written $z(t) = y(t) + v(t)$, where $v(t)$

is a realization of the noise process. Because $v(t)$ is unknown to the receiver, its presence degrades the performance of subsequent processing blocks. The severity of thermal noise is quantified by the SNR.

The origin of interference is usually an undesired communication signal. Examples include adjacent channel interference, cross talk, and co-channel interference. *Adjacent channel interference* refers to the interference caused by signals operating in adjacent frequency bands. Because practical signals cannot have a finite absolute bandwidth, when the carrier frequencies of two different signals are close together, there is often leakage from one signal to the other. *Cross talk* is a form of interference in wireline systems and results from the electromagnetic coupling among the multiple twisted pairs making up a phone cable. *Co-channel interference* is the wireless equivalent of cross talk. Because of the limited availability of frequencies, wireless cellular systems reuse each carrier frequency. Essentially, co-channel interference is the interference among users sharing the same communication frequency.

Like thermal noise, interference is also additive. Thus, a signal with interference may be written $z(t) = y(t) + \sum_k y_k(t)$, where $y_k(t)$ refers to the distorted interfering signals. Performance degrades because $y_k(t)$ is both random and unknown at the receiver. More generally, noise is also present; thus,

$$z(t) = y(t) + \sum_k y_k(t) + v(t)$$

In some cases, the interference is modeled as another Gaussian noise source. Then performance is characterized by the *signal-to-interference plus noise* (SINR) ratio, which is essentially $P_y/(P_i + P_v)$, where P_y is the power in the desired signal, P_i is the power in the sum of the interfering signals, and P_v is the power in the noise. Systems for which $P_i \ll P_v$ are called *noise-limited*, whereas those for which $P_v \ll P_i$ are called *interference-limited*. If the source of the interference is cross talk or co-channel interference, then the interfering signals $\{y_k(t)\}$ all have a structure (modulation, coding, etc.) similar to the desired signal. In this case, advanced signal processing algorithms can be used to mitigate the impact of the interference. Examples of algorithms include *joint demodulation*, in which all of the signals are demodulated simultaneously; *interference cancellation*, in which the interference is partially cancelled; and *optimum filtering*, in which filters are constructed that partially eliminate the interference. Removing or mitigating interference improves performance by reducing the required transmit power to achieve a given BER for a given data rate, by allowing the data rate at a given BER to be increased for a given transmit power, and by mitigating the effect of error floors.

Timing and Synchronization

Before demodulation and symbol recovery at the receiver, several timing and synchronization tasks need to be performed, including phase synchronization, frequency synchronization, symbol timing, and frame synchronization. Synchronization is performed to ensure that the transmitter and receiver operate in a synchronous manner.

The process of synchronization typically consists of first estimating the synchronization error and then correcting this error. Typically, the processing required for synchronization is done in a mixture of the analog and digital domains.

In bandpass systems, information is modulated onto sinusoids as illustrated in the QAM example in Equation 2. To demodulate this signal at the receiver, these sinusoids must be exactly reproduced. The problem of ensuring that the phases are accurate is known as *phase synchronization*. The problem of estimating the transmitted carrier frequency is known as *frequency synchronization*. Estimating and tracking the phase of the sinusoid is typically more difficult than the frequency, although phase differences can sometimes be included as part of the channel and removed during equalization.

At the receiver, the A/D converter samples the analog waveform for subsequent digital processing. Optimal processing requires two aspects of symbol synchronization: symbol timing and sampling clock recovery. *Symbol timing* is the problem of knowing exactly where to sample the received signal. Even in systems with ideal channels, symbol timing errors can lead to intersymbol interference because of timing errors. Often the symbol timing problem is solved by oversampling the received signal and choosing the best subsample. *Sampling clock recovery* refers to the problem of ensuring that the sampling period T_s at the receiver is identical to that at the transmitter. Sampling clock recovery is typically more important in baseband systems than in bandpass systems because in bandpass systems the sampling clock can be derived from the carrier.

In systems in which the fundamental unit of information is a frame and not a symbol, an additional synchronization step is required. This process, known as *frame synchronization*, is required to determine where the beginning of the frame is located. Frame synchronization is often assisted by the presence of synchronization sequences that mark the beginning of the frame.

Demodulation

The goal of the demodulator is to convert the sampled received waveform back into a sequence of bits. Of course, demodulation is highly dependent on the modulation and the channel; therefore, this section provides only a cursory overview.

For an ideal channel, with only an additive noise source, the first step in the demodulation process is to sample the waveform. Typically, this is done via a front-end filter that filters out unwanted noise, followed by a sampler. The sampled data come from an A/D converter, so the data are in the digital domain. The sampled signal includes residual noise left after filtering, the noise from the sampling device, and the signal of interest. For example, assuming perfect timing, synchronization, and no interference, in the presence of an ideal channel the sampled PAM signal at the receiver $y(nT_s)$ is

$$y[n] = x[n] + v[n]$$

where $x[n]$ is the transmitted PAM symbol, $v[n]$ represents the sampled thermal noise and the quantization

noise. The samples $y[n]$ are sent through a decision device that processes the data to make a decision. Typically, the decision device determines the most likely symbol from the given constellation that was transmitted. An inverse symbol mapping operation then converts the symbols to bit form.

Because the noise is unknown to the receiver, the role of the decision device is to produce its best “guess” about the transmitted data. One common criterion is to find the symbol that is the most likely input given the observations. If X and Y are vectors representing the input $x[k]$ and the output $y[k]$, respectively, then

$$\hat{X} = \arg \max_X P(X|Y)$$

where $P(X|Y)$ is the probability that $x[k] = X$ given that observation of $Y = y[k]$. The maximization is taken over all possible points in the constellation to find the point with the maximum conditional probability and is called the *maximum a posteriori decision*. When the source data are equally likely, it turns out that this is equivalent to the *maximum likelihood detection rule*, which is given by:

$$\hat{X} = \arg \max_X P(Y|X)$$

In this case, the decision rule determines the symbol that was most likely to have produced the observation. For the *additive white Gaussian noise* (AWGN) channel, the above conditional probabilities have a known form.* For instance, when the input symbols are equally likely, it turns out that the detection principle is simply to minimize the Euclidean distance between the observation and the set of possible inputs

$$\hat{X}[k] = \arg \min_{x[k] \in C} \|y[k] - x[k]\|^2 \quad (3)$$

In this case, the detector is known as a *slicer*. The operation of the slicer can be described by Figure 4. For a QAM or PAM waveform, if a received sample is within a decoding boundary of a point, it is mapped to that point. Because of the simple decoding boundaries, the test is essentially a series of threshold tests and hence the name *slicer*.

Slicing is an example of what is known as *hard decoding*. In essence, this term means performing the detection operation in Figure 1 before the channel decoding. In many systems, the detection and channel decoding blocks work together to obtain a better estimate of the transmitted bit sequence. An example of this cooperative behavior is when the detector performs *soft decoding*. In this case, the output of the decoder, is bit likelihoods. Essentially, instead of outputting a 0 or 1 as performed in the slicing operation, a soft detector would output a number between $-\infty$ and $+\infty$, depending on how confident the detector is about the resulting decision. For example, a result of 0.0 might mean that the reliability of the decision is low. Advanced

error-control codes such as turbo codes and low-density parity-check codes exploit soft detection as part of their decoding processes (Wicker and Kim 2002).

In the absence of an ideal channel, even with perfect timing and synchronization, there will be intersymbol interference; thus, the sampled PAM signal may have the form

$$y[n] = \sum_{l=0}^L h[l]x[n-l] + v[n] \quad (4)$$

where $h[l]$ is the sampled equivalent channel impulse response. Optimum decoding requires considering the channel response in the decision device. Because of the memory in the channel, it is no longer possible to make a decision on a symbol-by-symbol basis. Instead, sequences must be decoded. Thus, given a sequence of observations $\{y[p]\}_{p=0}^{P-1}$, we must determine the sequence $\{x[n]\}_{n=0}^{N-1}$, that was most likely to have been transmitted. We allow for $P \geq N$ at the receiver to account for multiple observations of the received signal via oversampling or multiple antennae, for example. Clearly, the complexity of the search grows with both N and P . Using the fact that memory of the channel is finite, however, allows lower complexity approaches such as the *Bahl, Cocke, Jelenick, and Raviv* (BCJR) *algorithm* to help in maximum a posteriori decoding and the *Viterbi algorithm* for maximum likelihood decoding (see, e.g., Wicker and Kim 2002 for details).

Alternatively, to correct for intersymbol interference, many transmission systems use equalizers that attempt to remove the effect of the channel before the slicing operation. Some common equalizers are *zero-forcing equalizers* (ZFEs) that invert the channel, *minimum mean square error* (MMSE) equalizers that include the effects of noise, and *decision feedback equalizers* (DFEs) that use the detected symbols to remove some portion of the trailing intersymbol interference. Equalization generally gives inferior performance relative to sequence decoding but offers much lower complexity.

One way to simplify linear equalizers is to use orthogonal frequency division multiplexing modulation. As described earlier, OFDM is a form of digital modulation in which information is sent on different subcarriers. OFDM is the modulation scheme of choice in wireless standards such as IEEE 802.11g and IEEE 802.16e. The key concept in OFDM is to create a circular convolution using a cyclic prefix. This allows equalization to be easily performed in the frequency domain courtesy of the fast Fourier transform operations. Using OFDM modulation, it is possible (after several mathematical manipulations) to create the effective input-output relationship

$$Y[n] = H[n]X[n] + V[n] \quad (5)$$

where $H[n] = \sum_{l=0}^L h[l] \exp(-j2\pi nl/N)$ and $\{X[n]\}_{n=0}^{N-1}$ are the N symbols transmitted in the OFDM symbol. It is clear that the equalization of Equation 5 is simple, only requiring $Y[n]/H[n]$ instead of the deconvolution operation in Equation 4. An interesting aspect of OFDM is that it can be combined with adaptive modulation, by which the constellation size is varied on each n in

*In the AWGN channel, there is no intersymbol interference and the only source of degradation is uncorrelated Gaussian noise.

Figure 5: The normalized capacity of an AWGN channel as a function of the SNR

response to $H[n]$ to achieve especially high practical data rates.

A PERFORMANCE EXAMPLE

The AWGN channel provides an analytically tractable baseline case by which performance in other channels can be compared. First, consider the capacity of the AWGN channel. It can be shown in this case that the capacity expression is remarkably simple:

$$C = B \log_2(1 + \text{SNR}) \quad (6)$$

where B is the channel bandwidth. The theoretical spectral efficiency that can be achieved in this channel is thus C/B bits per second per hertz. The normalized capacity as a function of SNR is illustrated in Figure 5.

The capacity expression in Equation 6 provides an interesting means for evaluating system performance. For instance, if a coded system provides 3 dB of increased immunity to noise, then the SNR will increase by a multiple of $2(10 \log_{10} 2 \approx 3 \text{ dB})$. Hence, the amount of information that can be transmitted will increase by approximately one bit per transmission for high SNR because $\log_2(1 + 2 \cdot \text{SNR}) \approx \log_2(2 \cdot \text{SNR}) \approx \log_2(\text{SNR}) + 1$.

Unlike the capacity, the symbol error rate in an AWGN channel is a function of the modulation scheme that is employed. For uncoded M-PAM or M-QAM transmission, the probability of symbol error is given by

$$P_e = 2 \left(1 - \frac{1}{M}\right) Q \left(\sqrt{\frac{3 \text{ SNR}}{M^2 - 1}} \right) \text{ for PAM} \quad (7)$$

$$= 4 \left(1 - \frac{1}{\sqrt{M}}\right) Q \left(\sqrt{\frac{3 \text{ SNR}}{M - 1}} \right) - 4 \left(1 - \frac{1}{\sqrt{M}}\right)^2 \left(Q \left(\sqrt{\frac{3 \text{ SNR}}{M - 1}} \right) \right)^2 \text{ for QAM} \quad (8)$$

where $Q(x) = 1/\sqrt{2\pi} \int_x^\infty e^{-t^2/2} dt$ for $x = 0$ is the area under the tail of the Gaussian probability distribution function. The probability of symbol error for QAM transmission is illustrated in Figure 6 as a function of SNR. Notice how the error rate exponentially decreases as the SNR increases. Observe that for a given probability of error (at high SNR), there is approximately a 6-dB difference between the SNR required for 4-QAM and 16-QAM or between 16-QAM and 64-QAM.

By inverting the formulas in Equation 7 and Equation 8 for a target probability of error, a useful expression for the maximum spectral efficiency obtained is

$$R = \log_2 \left(1 + \frac{\text{SNR}}{\Gamma} \right) \quad (9)$$

where the gap, Γ , can be calculated as a function of M and the target probability of error. Conveniently, Equation 9 allows direct comparison with the capacity in Equation 6. The gap, Γ , effectively determines the loss in capacity—that is, the gap between the actual spectral efficiency and the maximum spectral efficiency. Coded modulation schemes generally reduce the gap (toward the ultimate limit of $\Gamma = 1$). The effect of coding is most often expressed in dB as the coding gain, Γ_{dB} making the effective gap smaller, so that $\Gamma_{\text{dB}}^{\text{new}} = \Gamma_{\text{dB}} - \Gamma_{\text{dB}}$.

PRACTICAL DISCUSSION OF WIMAX: A DIGITAL COMMUNICATION STANDARD

WiMAX is a mobile standard that supports speeds beyond 120 km/hr, based on the IEEE 802.16-2005 standard (Ghosh et al. 2005). IEEE 802.16-2005 is a broad standard for broadband cellular communication and includes

Figure 6: The symbol error rate for QAM transmission in an AWGN channel as a function of SNR

several different deployment options (fixed and mobile), different physical layer solutions, and several advanced communication techniques such as multiple antennae. WiMAX refers to a subset of IEEE 802.16-2005 functionality, agreed upon by an industry consortium known as the WiMAX Forum. WiMAX is perhaps the most cutting edge application of digital communication, at least wireless digital communication, so it is briefly summarized in this section. The purpose is to provide the reader with an appreciation of some of the advanced communication techniques that are on the verge of deployment in commercial wireless systems.

The WiMAX standard is based on the OFDM modulation and is used for reasons of ease of equalization as described earlier. The WiMAX waveform is special: It

does not simply use OFDM, it uses multiple access over the OFDM waveform. This is known as *OFDM multiple access* (OFDMA). In OFDM, the band is converted into multiple frequency bins. In OFDMA, these frequency bins are mapped to users. The fundamental frequency unit is called a *subchannel*. For WiMAX, OFDMA has many modes of operation in which the subchannels may or may not be contiguous. For the mandatory mode of operation, the subcarriers are not contiguous. This is intended to give the transmitted data packet frequency diversity. Effectively, in a frequency-selective channel, it is unlikely that many of the subcarriers will be in a notch of the channel. Frequency diversity comes from the fact that the propagation channel is frequency-selective—that is, it varies as a function of location as illustrated in Figure 7.

Figure 7: Frequency response of one realization of the ITU vehicular A channel. The stem plot illustrates OFDM subcarriers that are occupied by a given user

The standard WiMAX profile will also include many advanced features such as two-stream spatial multiplexing, beam forming, and convolutional turbo codes. *Spatial multiplexing* is a type of digital modulation used in *multiple-input, multiple-output* communication links. These are communication links with multiple transmit and multiple receive antennae. Spatial multiplexing sends independent information on different transmit antennae, effectively multiplexing the data pipes in space (Bolcskei 2006). *Two-stream spatial multiplexing* increases throughput by doubling the effective size of the constellation to a maximum of two 64-QAM symbols in one symbol period. *Beam forming* also uses multiple transmit antennae but uses them to send one data stream very reliably. Effectively, transmit beams are used to focus the energy at a desired user as a function of frequency. Beam forming can increase throughput by active interference cancellation and increasing the power at the subscriber. Finally, *convolutional turbo codes* are special error-correction codes that are extremely efficient. They use a combination of interleaving and iterative decoding to achieve extremely good error-rate performance. Convolutional coding is used to increase the overall coding gain over traditional convolutional codes.

CONCLUSION

Digital Communication plays an important role in delivering information in computer networks. The fundamentals of digital communication are easy to understand by viewing a digital communication system as a sequence of functions: encryption, source coding, channel coding, and modulation, and their inverse operations. Each forms an area of research and design in and of itself, and all are dealt with in more detail throughout this handbook. Digital communications continues to increase in relevance as our world continues to demand more computation and more information.

GLOSSARY

- Analog Front End (AFE):** The processing unit before the analog-to-digital converter.
- Analog-to-Digital (A/D) Converter:** A hardware block which converts analog signals to digital format.
- Asymmetric Key Encryption:** An encryption process that employs one key for the encryption process and a separate key for the decryption process.
- Bandpass:** A type of communication signal that has information modulated onto a carrier.
- Baseband:** A type of communication signal that does not have information modulated onto a carrier.
- Bit Error Rate (BER):** The average probability of bit error.
- Capacity:** The maximum data rate for which nearly errorless transmission can occur.
- Carrier:** Name for the high frequency sinusoid that shifts the spectrum of a baseband signal to higher frequencies, making it bandpass.
- Channel Coding:** The process of adding redundancy to the transmitted data stream for the purpose of improving resilience to errors caused by the channel.
- Ciphertext:** The information produced by the process of encryption.
- Decryption:** The process of transforming encrypted data to its original unencrypted form.
- Demodulation:** The process of extracting the transmitted digital data from the continuous waveform observed at the receiver.
- Digital Signal Processing (DSP):** A general name that includes all forms of operations on digital data.
- Digital Signature:** An encryption-based authentication method employing secret information used to affirm the origin of electronic documents.
- Digital-to-Analog (D/A) Converter:** This hardware block converts digital data into the analog domain.
- Downconversion:** Process of converting a bandpass signal to a baseband signal by removing the carrier frequency.
- Encryption:** The process of encoding data to prevent unauthorized access during transmission.
- Field Programmable Gate Array (FPGA):** A general purpose array of gates that can be configured by the end user for various applications.
- IP Security:** An Internet network layer security protocol providing authentication, confidentiality, and message integrity services.
- Message Digest Function:** An assumed one-way function whose domain is all positive integers and whose range is a set of fixed-length integers.
- Modulation:** The process of converting digital data to continuous waveforms for transmission on a communication medium.
- Orthogonal Frequency Division Multiplexing (OFDM):** A type of digital modulation scheme used to help simplify equalization in fading channels.
- Plaintext:** Information before the process of encryption.
- Private Key:** A key employed in asymmetric cryptography that is available only to its owner in the protocol.
- Public Key:** A key employed in asymmetric cryptography that is shared with all participants in the protocol.
- Pulse Amplitude Modulation (PAM):** A form of modulation in which data are encoded in the amplitude of one basis function.
- Quadrature Amplitude Modulation (QAM):** A form of modulation in which data is encoded in the amplitude of two basis functions.
- Receiver Sensitivity:** The minimum required signal level for a receiver to be able to demodulate the received signal.
- Secure Socket Layer:** An Internet application layer security protocol providing authentication, confidentiality, and message integrity services.
- Signal-to-noise ratio (SNR):** Essentially the ratio of the received signal power to the noise power.
- Source:** Generic name for the component that generates the information stream that is the input to the transmitter.
- Source encoding:** The process of removing redundancy from the information stream provided by the source.
- Symbol:** A representation of a set of bits in the digital or analog domain.
- Symmetric key encryption:** An encryption process that employs the same key for both encryption and decryption.

Synchronization: The process of ensuring that the transmitter and receiver operate in a synchronous manner.

Upconversion: Process of converting a baseband signal to a bandpass signal by increasing the carrier frequency.

FURTHER READING

Digital communications is a broad area that draws on many different but related aspects of electrical engineering. Perhaps the standard academic references for digital communication are *Digital Communications* by John G. Proakis (2001) and *Digital Communication* by Edward Lee and David Messerschmitt (1994). The text *Digital Communications* by Bernard Sklar (2000) provides an intuitive presentation of the concepts of digital communications. Good online information by John Cioffi (undated) is also available. A good technical discussion of digital communication in wireless systems is found in *Principles of Mobile Communication* by Gordon L. Stuber (2001). *Coding Theory and Cryptography: The Essentials* (2000), a reference edited by Darrel Hankerson, provides a good introduction to cryptography, which is perhaps the most relevant aspect of security for digital communications. The standard reference for digital signal processing is *Discrete-Time Signal Processing* (1999) by Alan V. Oppenheim, Ronald W. Schaffer, and J. R. Buck. For a basic reference on vector spaces, *Elementary Linear Algebra: Applications Version* (1991) by Howard Anton and Chris Rorres is a good text.

There are many advanced concepts in digital communication that were just barely covered. *Elements of Information Theory* (1991) by Thomas M. Cover and Joy A. Thomas, provides a more thorough introduction to information theory. *Synchronization Techniques for Digital Receivers* (1997) by Umberto Mengali and Aldo N. D'Andrea provides a current treatment of synchronization in digital communication systems. More detail is also available in other chapters of this handbook. Forward error correction is a topic that was only briefly mentioned yet is of significant importance. A classic reference is *Error Control Coding: Fundamentals and Applications* (1982) by Shu Lin and Dan J. Costello. A text that treats some current topics is *Fundamentals of Codes, Graphs, and Iterative Decoding* (2002) by Stephen B. Wicker and Saejoon Kim.

Current research in digital communication appears in a variety of journals, including the *IEEE Transactions on Communications* (www.comsoc.org/pubs/jrnal/transcom.html), the *IEEE Transactions on Signal Processing* (www.ieee.org/organizations/society/sp/), the *IEEE Transactions on Information Theory* (<http://www.itsoc.org/publications/journals.htm>), among others. Research in the areas of security and digital communication appears in these journals as well as the *ACM Transactions on Information and System Security* (www.acm.org/pubs/tissec/).

INTRODUCTION

Radio broadcasting in the twentieth century was one of the public's main sources of information and entertainment. However, since the widespread acceptance of the compact disc, which was developed for music storage and easy replay, people have become aware of audio quality problems with traditional analog radio broadcasting. With the technological progression of television and computer audio systems, *digital radio broadcasting* (DRB) technologies have been developed for the broadcasting industry to transmit digital audio signals.

DRB services transmit digital radio programs and data services for fixed, portable, and mobile receivers by utilizing DRB technologies to encode audio signals and modulate radio frequencies digitally. DRB has the potential to provide digital radio signals with near-CD fidelity to radio listeners. It eliminates or greatly diminishes reception problems that exist in analog *frequency modulation* (FM) transmission, such as fades and interferences caused by multipath echoes, as well as signal-to-noise ratio problems in analog *amplitude modulation* (AM) transmission. It also supports multicasting and auxiliary data services, such as texts, graphics, and images. In the 1990s, two major DRB technologies have been developed and adopted for terrestrial radio broadcasting: Eureka 147 *digital audiobroadcasting* (DAB), which has been implemented in Europe, Canada, and Australia; and *in-band on-channel* (IBOC), which has been approved by the Federal Communication Commission (FCC) and licensed by radio stations in the United States. In addition, *satellite digital audio radio services* (SDARS) and audio Webcasting became part of digital radio broadcasting.

The Need for Digital Radio Broadcasting

Radio Broadcasting in Contemporary Society

Radio Listeners. Among all types of mass media, radio is still popular in serving the needs of people for entertainment, sports, and information. According to the FCC [Federal Communications Commission (FCC) 2007a], there were 18,739 broadcast radio station totals in the United States as of the end of 2006; they break down as follows:

AM stations	4754
FM commercial	6266
FM educational	2817
FM translators and boosters	4131
Low-power FM	771
Total	18,739

The total number of stations had increased by 409 in just one year, including ninety-six new stations in a low-power FM format that was a new radio service starting in 2005.

Radio reaches 93.7 percent of people each week, and 73.4 percent of people each day, among those aged 12 and older, according to the Radio Advertising Bureau (RAB) (2005). They listen an average of 19.5 hours each week, 2 hours 54 minutes each weekday, and 5 hours each weekend. Listening to radio has become an essential activity while driving automobiles, especially because of its portability and audible nature. According to the RAB report, people aged 12 and older spend 35.7 percent of their total listening time on their home radios, 45.7 percent on their car radios, and 18.6 percent on radios at work or other places during weekdays. Advertisers often use radio to convey information to potential consumers.

According to pretesting surveys, the key messages of major product categories—such as autos, beer, direct-to-consumer medicine, fast food, health and beauty aids, Internet services, and long-distance service—delivered by radio are more communicative to consumers than those from television. The synergy of combined radio and TV advertising is more effective than dual TV commercials for autos, beer, direct-to-consumer drugs, e-business, and travel. Even during prime-time TV hours, radio still reaches 54.6 percent of the population (Radio Advertising Bureau 2005).

Technological Challenges to Analog Radio Systems. AM and FM are the most used audio systems. However, because of the limitations of amplitude modulation technology, AM radio is vulnerable to both internal and external interferences that cause amplitude changes in the AM waveform. In addition, it has particular problems with atmospheric interference, which is heard as static, hiss, and other kinds of noises. The restricted bandwidth of AM systems, approximately ± 5 kHz, further limits the quality of sound. Moreover, because AM radio signals propagate through ground waves during daytime hours, the grounded conductive structures can change the amplitude and phase of an AM waveform, degrading the AM radio signal at the reception end. The daytime coverage area for many AM stations is less than 50 miles; a few powerful AM stations may reach 200 miles. At night, because ionosphere reflectivity increases, the AM signal is transmitted primarily through the reflection of sky waves from the ionosphere. The AM radio signal can reach distant areas thousands of miles away from an AM station, thus causing co-channel interference with stations in those areas that broadcast on the same carrier frequency as the distant AM station. The FCC requires AM stations to either cease operations after sunset or reduce power to avoid such interferences (FCC 2004). To reduce existing AM-band interference, in 1996 the FCC announced an expanded AM band (between 1605 MHz and 1705 MHz) and an eighty-seven station allotment plan for new assignments in the expanded band (FCC 1996).

By comparison with AM radio, FM radio provides higher audio fidelity and is not affected by amplitude interferences. However, there are weaknesses in the FM system. The FM signal is primarily vulnerable to multipath interferences: An original signal may be interfered with by its reflected signals, which cause nulling effects when the direct and reflected signals are received with nearly equal strength in a 180-degree phase shift. Or an original signal may be interfered with by its reflected signals arriving with short delays, resulting in audible interference (FCC 2004; Pohlmann 2000).

Although radio still is a popular medium, various digital audio products such as compact discs, mp3 players, and iPods have rapidly developed and widely occupied the market since the late 1990s. Although people are accustomed to analog radio services, these digital audio devices provide high-fidelity music and have stimulated listeners' desires for high-quality radio broadcasting. Therefore, digital radio broadcasting has become an inevitable demand of radio innovation. The research project aiming to

develop DRB formats for the transition from traditional radio broadcasting to DRB began in the late 1980s and early 1990s (Pohlmann 2000).

Digital Audio Technology

Because human hearing is an analog process, analog audio signals need to be digitized for transmission in DRB, with a receiver converting the digital signals back to analog for listening. Sampling and digitizing are the principle processes involved in the conversion of a signal from analog to digital. *Pulse code modulation* (PCM) is the most widely used conversion technique (for details, see Chapter 26). PCM is a digital representation of an analog signal; only the presence or absence of a pulse is necessary to read a digital signal. By and large, a PCM signal can be regenerated without loss because any amplitude changes added on the pulse can be eliminated without affecting the presence or absence of the pulse. In addition, "depending on the sampling frequency and capacity of the channel, several PCM signals can be combined and simultaneously conveyed with time-division multiplexing" (Pohlmann 2000, 51). Along with the digital audio signal, the data for synchronization, error correction, and auxiliary data services can be multiplexed into a PCM stream for reproducing the analog audio signal in the receiver. Depending on the quality of application, the sampling rates used for digital audio are usually in a range from 8 kHz to 192 kHz.

The Development of Digital Radio Broadcasting

Digital radio technological research started in the late 1980s and early 1990s. The Eureka Project 147 was funded in 1987 by the European Commission to design a multiservice digital broadcasting system for fixed, portable, or mobile receivers using a nondirectional antenna. According to the European Telecommunications Standards Institute (ETSI), the Eureka DAB system can operate "at any frequency up to 3 GHz for mobile reception (higher for fixed reception) and may be used on terrestrial, satellite, hybrid (satellite with complementary terrestrial), and cable broadcast networks" [European Telecommunications Standards Institute (ETSI) 2000, 9]. The British Broadcasting Corporation (BBC) has adopted the Eureka 147 DAB technology to operate a *single frequency network* (SFN) digital radio broadcasting system in the United Kingdom. A 12.5-MHz band range of VHF band III spectrum from 217.5 MHz to 230 MHz has been allotted to the BBC for its DAB operations (Bower 1998; FCC 1999). Canada and other European countries are using the L band (1452 MHz to 1492 MHz) to operate Eureka digital broadcasting.

Although in the early 1990s the FCC was concerned about providing a terrestrial and satellite digital audio system in the United States, the commission did not think it was time to discuss DAB standard, testing, licensing, and policy. In 1991, USA Digital Radio Partners, L.P., was established by CBS Radio and the Gannett Co. to develop a digital radio broadcasting system. Westinghouse Electronic Corporation joined the partnership the same year. This partnership developed the IBOC DRB concept (FCC 1998). During the mid-1990s, the National Radio Systems

Committee (NRSC) in collaboration with the Consumer Electronics Manufacturers Association (CEMA, now the Consumer Electronics Association), tested several IBOC systems. However, no viable IBOC system was found not only to provide good quality audio performance but also to eliminate interferences caused by impaired signal conditions. CEMA also conducted the field test of a Eureka 147 system operating in the L band and concluded that the Eureka 147 technology was an ideal DAB system in comparison with other proposed DAB technologies. CEMA's report to the Commission states that of "all the systems tested, only the Eureka system offers the audio quality and signal robustness performance that listeners would expect from a new [DAB] service in all reception environments" (FCC 1999, 7).

However, the FCC did not have the available L-band and VHF band III spectra for implementing Eureka 147 system because L-band was "allocated for the purpose of flight test telemetry, and the spectrum around 221 MHz (in VHF band III) is allocated for the primary purposes of land mobile and amateur use" (FCC 1999, 7). In addition, the U.S. radio broadcasting industry was against adoption of a DRB system that required new spectra and preferred an "in-band" approach that would allow for a smoother transition from analog to digital services. In 1998, USA Digital Radio Partners changed its name to USA Digital Radio (USADR) and filed a petition for rule making that urged the commission to take regulatory steps toward implementing digital radio broadcasting (FCC 1998).

In November 1999, the FCC proposed criteria for evaluating and testing certain DAB systems and considering standard issues (FCC 1999). Subsequently, the DAB subcommittee of the NRSC conducted extensive laboratory tests on several IBOC DRB systems, including comprehensive field and laboratory tests of FM-band and AM-band IBOC systems.

In 2000, USADR merged with Lucent Digital Radio to form iBiquity Digital Corporation. In December 2001, the NRSC proposed that the FCC authorize iBiquity's FM IBOC system as an enhancement to FM broadcasting in the United States (National Radio Systems Committee 2006). The report suggested that the IBOC system bring "an efficient transition to digital broadcasting with minimal impact on existing analog FM reception and no new spectrum requirements" (FCC 1999, 4). In April 2002, the NRSC filed an AM IBOC report that recommended that iBiquity's AM IBOC "should be authorized as a daytime-only enhancement to AM broadcasting, pending further study of AM IBOC performance under nighttime propagation conditions" (FCC 1999, 4).

In October 2002, the FCC announced in its *Digital Audio Broadcasting Report and Order* (DAB R&O) that iBiquity's in-band on-channel technology would be adopted as the standard for DRB and authorized interim requirements for radio stations to initiate DRB voluntarily (FCC 2002b). However, the FCC restricted AM stations from nighttime IBOC operation. iBiquity launched its IBOC consumer brand, HD Radio™, and its commercial rollout to broadcasters began. In 2003, AM and FM stations licensed for HD Radio began DRB in the United States (FCC 2004). Based on iBiquity's AM nighttime IBOC tests, in 2004 the National Association of

Broadcasters (NAB) submitted a recommendation to the commission to permit nighttime AM broadcasts. In May 2007, the FCC extended the IBOC AM station operation hours to "include all hours during which a given station is currently authorized for analog operation, subject to the notification procedures established in the DAB R&O" (FCC 2007b).

The Advantages and Disadvantages of Digital Radio Broadcasting

Both digital and analog radio broadcasting methods have advantages and disadvantages.

Advantages of Digital Radio Broadcasting

- Service: DRB provides both audio and data services.
- Quality: DRB offers the potential to provide near-CD quality audio with higher interference protection.
- Economy: DRB audio and general data services can be offered for free or by subscription.
- Spectrum: DRB offers spectrum efficiency—for example, Eureka 147 allows single-frequency networks and IBOC uses existing frequency channels with the same bandwidth to provide multiple audio services per channel.
- Transmission power: DRB has improved power efficiency, requiring approximately 10 percent of the power of analog radio broadcasting.
- Compatibility: The IBOC system provides both backward and forward compatibility with existing analog broadcasting.

Disadvantages of Digital Radio Broadcasting

- Technical complications: DRB's processes for digital audio coding, modulation, radio frequency (RF) transmission coding, and decoding at the receiver require more expensive equipment for transmitting and receiving.
- Cost: Broadcasters need to invest in new equipment, and listeners need to purchase new radio sets.
- Spectrum: Eureka 147 requires new frequency allocations.
- Compatibility: Eureka 147 radio is an all-digital service. Its receivers are not compatible with analog services.

The following are reasons why listeners in the United States will adopt HD Radio while analog radio remains available.

- There is a replacement cycle. According to iBiquity studies, consumers replace radio sets every ten to fifteen years because they are either out of fashion or dysfunctional.
- Consumers desire better-quality radio programs. HD Radio AM provides near-FM quality, and HD Radio FM can provide near-CD quality. In addition, FM IBOC supports *multicasting*—that is, it allows two or more audio services per channel.
- HD Radio provides free services to listeners. Although satellite radio delivers multichannel CD-quality programs, it charges monthly fees.

- HD Radio broadcasts programs via airwaves. It is more convenient, especially in a mobile situation, than CD or DVD players or mp3 or iPod players. Listeners must carry CDs and DVDs, and mp3 and iPod players require that consumers have the skills to install files.
- HD Radio helps consumers and broadcasters transition smoothly from analog to hybrid (i.e., simulcast digital and analog) radio and finally to all-digital broadcasting.
- Professional organizations such as the HD Digital Radio Alliance provide incentive for adoption, including technical training and strong marketing support to radio stations in the transition process.

The details will be described in the relevant sections.

DIGITAL RADIO BROADCASTING

The technical processes of digital radio broadcasting include audio compression, transmission coding, modulation, and multiplexing. In this chapter, the focus is on how those technical processes are utilized to achieve the various goals of digital radio broadcasting; the detailed technical concepts are described in other chapters of this handbook. However, a few key terms such as *perceptual audio coding*, *interleaving*, *phase shift keying*, *quadrature amplitude modulation*, and *orthogonal frequency division multiplexing* are briefly reviewed before the discussion on the digital radio broadcasting systems.

Technical Foundation of Digital Radio Broadcasting

Perceptual Audio Coding

Perceptual coding of digital audio, or *psychoacoustical coding*, is used to compress the digital audio signal. This technique is based on the spectral and temporal characteristics of the human auditory system. There exists a theoretical threshold curve of human audibility responding to the audio spectrum from 20 Hz to 20 kHz and a theoretical amplitude masking effect (*psychoacoustic masking*). The amplitude masking effect occurs when a louder tone shifts the threshold upward in a frequency region surrounding this tone (see Figure 1). The louder tones

can completely block the softer tones within the range of the frequencies nearby (Bower 1998; Pohlmann 2000).

Based on perceptual coding techniques, a digital audio compression system only codes the audio signal components that the human ear is able to perceive and disregards the components that the ear does not sense, such as a frequency below the intensity threshold level or a frequency blocked by a nearby louder tone. Perceptual coding can also be tailored to the audio quality required by a specific type of audio service. Different bit rates can be used to code speech, sports, stereo music, and other kinds of music. For example, the bit rate of 6 kbps can be used for a monophonic channel and 1024 kbps for a 5.1-channel format (Pohlmann 2000). The BBC is using 192 kbps for its national network stereo radio service and 9 kbps or lower rates for BBC Radio Five Live sports commentaries and Parliament coverage (Bower 1998).

Interleaving

Interleaving is used in a predetermined manner on error corrections for transmission. The output of interleaving is structured in a matrix format. Each matrix is the combination of the audio or data service's signal and the information associated with a specific portion of the transmitted spectrum (Johnson 2000; Peyla 2000). The matrix signal is reassembled in the receiver to reproduce the digital audio. Interleaving techniques involve either dispersing data randomly or adding redundant data in both time and frequency domains. A convolutional interleaver has memory; that is, its operation depends not only on current symbols but also on previous symbols (diversity delayed symbols) (Johnson 2000; Peyla 2000; Pohlmann 2000).

Phase Shift Keying

Phase shift keying (PSK) techniques are commonly used in digital signal modulation. There are orders of PSK such as *binary phase shift keying* (BPSK), *quadrature phase shift keying* (QPSK), and higher-order PSK (8-PSK and 16-PSK), depending on the number of bits transmitted per modulation symbol. A one-bit digital signal applies a binary PSK. In BPSK, two modulation phase shifts represent two states of the PCM binary signal; a binary 0 places

Figure 1: Psychoacoustic masking (Eureka 147 Project 1997)

the carrier in phase 0 degrees, and a binary 1 places the carrier in phase 180 degrees (Pohlmann 2000). The digital symbol rate equals the transmission carrier rate. In QPSK, four phase shifts are used to represent two bits per symbol—that is, 00 places the carrier at 0 degrees, 10 at 90 degrees, 11 at 180 degrees, and 01 at 270 degrees. The digital symbol rate is one-half of the carrier rate. In many circumstances (e.g., Gaussian white noise RF environment) PSK signals generate the lowest *bit error rate* (BER) for a given signal strength (Pohlmann 2000).

QSPK is the most widely used PSK digital modulation method. A QPSK-modulated signal transmitting at 400 kbps would require a bandwidth between 200 kHz and 400 kHz. The bandwidth for a M -PSK signal is given between $D/\log_2 M$ and $2D/\log_2 M$, where D is the data rate and M is the order of PSK such as in binary ($M=2$) and in quadrature ($M=4$) (Pohlmann 2000).

Quadrature Amplitude Modulation

Quadrature amplitude modulation (QAM) is a modulation scheme that uses two orthogonal carriers of the same frequency for amplitude modulation. The phase shift between these two carriers is exactly 90 degrees. Each carrier is amplitude-modulated independently, and the two carriers are combined and transmitted before being separated by demodulation at the receiver. Similarly to PSK, there are 4-QAM (2 bits), 16-QAM (4 bits), 64-QAM (6 bits), and 256-QAM (8 bits). The most used QAMs are 16-QAM (for data) and 64-QAM (for audio signals) (ETSI 2001c; Johnson 2000).

Orthogonal Frequency Division Multiplexing

Orthogonal frequency division multiplexing (OFDM) is an aggregation of a large number of orthogonal subcarriers. The OFDM processing divides the transmitted digital signal into many low bit-rate data streams. It provides a parallel modulation scheme in which the low bit-rate data streams modulate those orthogonal subcarriers, and the modulated subcarriers are transmitted simultaneously (Johnson 2000). The individual subcarriers are typically modulated using the already mentioned PSK or QAM techniques.

Technological Approaches to Digital Radio Broadcasting

In Europe, the Eureka 147 DAB system was developed under the Eureka 147 Project and standardized by the European Telecommunications Standards Institute in 1995. The BBC is operating a single-frequency network Eureka 147 DAB to cover the entire United Kingdom. SFNs using Eureka 147 DAB can be implemented in terrestrial, satellite, or hybrid systems. The Eureka 147 DAB system has also been widely adopted by radio stations in other European countries, Canada, Australia, and several regions in Asia and Africa. The Eureka 147 DAB system is able to simultaneously broadcast five or more high-quality audio channels and various audio-based multimedia services such as text, graphics, and still pictures. It provides opportunities for listeners to receive multimedia radio with pictures and Web pages. Based on the characteristics of the European community, the Eureka 147 technology is well designed to cover a region or area

where a hybrid satellite and terrestrial system can be used for broadcast. For example, a single satellite system's footprint covers the main area, and terrestrial transmitters or repeaters operating on the same frequency are used to fill in the gaps.

Another system is a terrestrial DRB system, the IBOC system, developed in the United States. In October 2002, the FCC (FCC 2002b) approved the IBOC as the technology for U.S. digital radio broadcasting. In 2004, the FCC summarized the IBOC technology as follows:

iBiquity's IBOC DAB technology provides for enhanced sound fidelity, improved reception, and new data services. IBOC is a method of transmitting near-CD quality audio signals to radio receivers along with new data services such as station, song and artist identification, stock and news information, as well as local traffic and weather bulletins. This technology allows broadcasters to use their current radio spectrum to transmit AM and FM analog signals simultaneously with new higher quality digital signals. These digital signals eliminate the static, hiss, pops, and fades associated with the current analog radio system. IBOC was designed to bring the benefits of digital audio broadcasting to analog radio while preventing interference to the host analog station and stations on the same channel and adjacent channels. IBOC technology makes use of the existing AM and FM bands (In-Band) by adding digital carriers to a radio station's analog signal, allowing broadcasters to transmit digitally on their existing channel assignments (On-Channel). iBiquity IBOC technology will also allow for radios to be "backward and forward" compatible, allowing them to receive traditional analog broadcasts from stations that have yet to convert and digital broadcasts from stations that have converted. Current analog radios will continue to receive the analog portions of the broadcast. (FCC 2004, 2–3)

The HD Radio system (the trademark of iBiquity Digital Corporation's IBOC implementation) is suitable for independent radio stations to broadcast digital radio programs plus data services on their original licensed frequencies. Listeners receive free radio service as well. According to the FCC, as of October 1, 2003, more than 280 radio stations were licensed to iBiquity's technology, which have either begun digital audio broadcasting or were in the process of conversion (FCC 2004). As of late September 2005, 909 radio stations were licensed and 505 had implemented HD Radio on the air, with 28 stations having multiple broadcast channels. Three months later, in December 2005, the licensed stations were up to 1044, on air stations had increased to 703, and multicast stations were 202, which was almost 8 times of the number in September (refer to Table 6).

Other systems also deliver digital audio through direct broadcast satellites such as XM and Sirius in North America, WorldSpace for international satellite radio services, and over the Internet through Webcasting, mp3 and iPod players, and mobile phones.

Eureka 147 DAB System

The Eureka 147 DAB system is designed to provide all-digital audiobroadcasting for mobile, portable, and fixed receivers without the need for a directional antenna. Upon the test results, the Consumer Electronic Manufacturers Association in the United States and the European Telecommunication Standard Institute report that the Eureka 147 system offers reliable and high-fidelity audio with multiple data services. Technically, it can be operated at any spectrum allocation up to 3 GHz for mobile reception, and it can be used for broadcasting on terrestrial, satellite, hybrid, and cable broadcast networks. It can be operated as a single-frequency network in terrestrial or hybrid broadcasting. The recommended spectrums for the Eureka 147 DAB system are: 47.9 MHz to 67.0 MHz for VHF band I, 174.9 MHz to 239.2 MHz for VHF band III, and UHF L band (1452 MHz to 1492 MHz). The BBC's national digital radio services are broadcast as an SFN. This means all the DAB transmitters transmit the BBC multiplexed signals on the same frequency at 225.648 MHz (block 12B of VHF band III) with a bandwidth of 1.54 MHz [British Broadcasting Corporation (BBC) 2006a]. The Eureka DAB system is a highly spectrum- and power-efficient sound and data broadcasting system.

The BBC adopted the Eureka 147 system and began its DAB broadcasts in London in September 1995, operating from five transmitters on a single-frequency network to provide simulcasting of national services on Radio 1, Radio 2, Radio 3, Radio 4, Radio Five Live, and BBC World Service channels (BBC 2006b). In spring 1998, the BBC's national

SNF comprised twenty-seven transmitters that provided BBC's national digital radio services to more than 60 percent of the UK population and served major motorway and road routes (BBC 2006b). In February 2002, the BBC launched its first national digital only radio station, BBC Five Live Sports Extra in the United Kingdom, and subsequently added four new DAB services (1Xtra, 6 Music, BBC 7, and Asian Network) in the same year (BBC 2006d).

A Technical Diagram of Eureka 147 DAB System

A conceptual block diagram of the Eureka 147 DAB system is shown in Figure 2. The top part demonstrates the conceptual process of DAB signals. Each service signal of audio or data is encoded individually at the source level—that is, by an audio encoder or a data encoder. In the channel encoder and time interleaver, each encoded source ensemble is processed with error-correction and interference-protection techniques; the output signal of the interleaving process is a channel of either digital audio or data service. Then all of the channels are multiplexed together with associated service information in the *multiplexer* (MUX). The multiplexer output consists of frequency-interleaved audio and data signals with multiplex control and service information into the *main service channel* (MSC), which is of a predetermined but changeable service configuration. The service information of the multiplexer controller is called the *multiplex configuration information* (MCI). It travels through a *fast information channel* (FIC) that does not pass through the time interleaver in order to avoid the delay generated

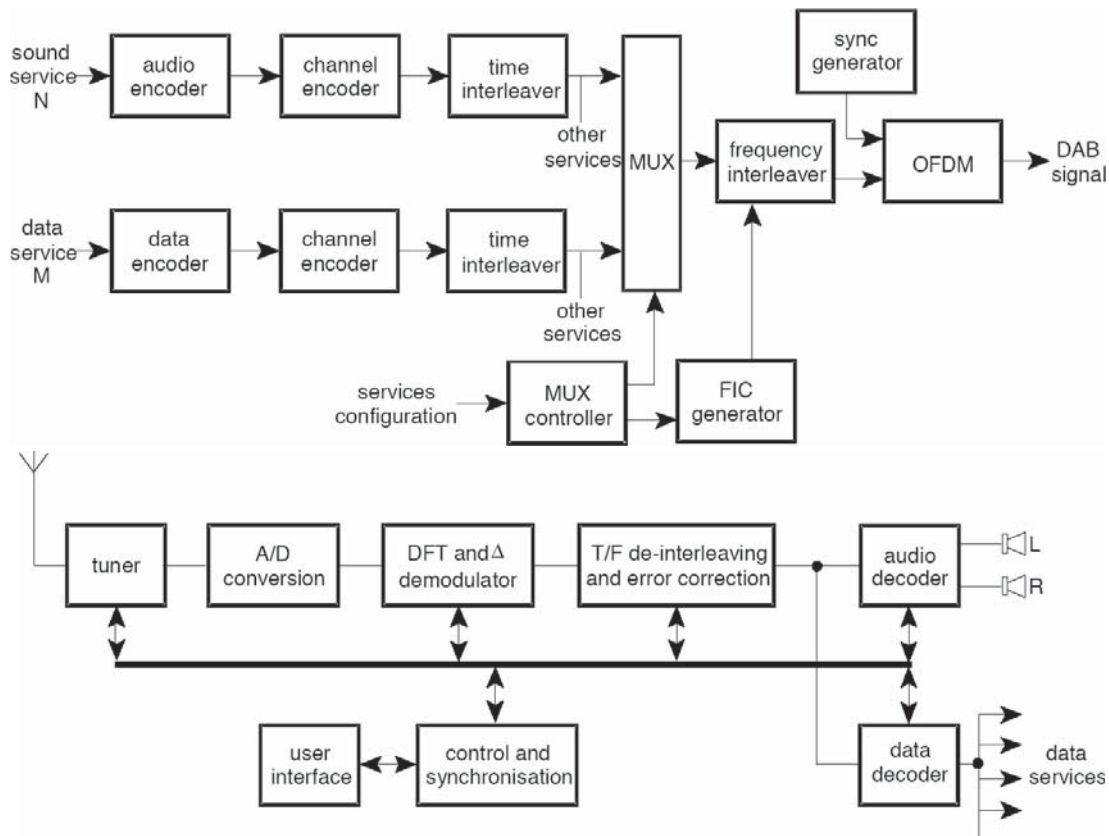

Figure 2: Eureka 147 conceptual block diagram © European Telecommunications Standards 2000. © European Broadcasting Union 2000. Further use, modification, redistribution is strictly prohibited. ETSI standards are available from <http://pda.etsi.org/pda/> and http://www.etsi.org/services_products/freestandard/home.htm

by time interleaving. The signals from the MSC and FIC channels are combined with rugged synchronization symbols to form transmission frames. Finally, the digital signals in the transmission frames are modulated with the differential QPSK scheme onto a number of orthogonal frequency division multiplexed subcarriers to generate the DAB transmission signal.

The bottom part of Figure 2 shows a conceptual receiver where the transmitted DAB signal is selected and filtered through a tuner and then downconverted to a multiplexed digital stream, including the wanted DAB ensemble, synchronization data, service information, and other data. The digital stream is then filtered and demodulated. The subsequent stages are the time and frequency de-interleaving processes and error correction used to recover the coded audio programs and service data. The system controller is connected to a user interface that processes the user's commands to retrieve the information in the FIC, which is associated with the program the user is searching. Then the data of the requested program are further processed in an audio decoder, producing the left and right audio signals of the program. The associated program data, such as lyrics and song titles, are recovered in a data decoder.

Multiple Audio and Data Services

The system supports multicasting. The transmitted DAB signal carries a multiplex of various digital services simultaneously, including multichannel radio programs and associated data and other data service. For example, the BBC's national DAB radio uses an SFN for its nationwide broadcasting. It includes eleven channels of radio programs: Radio 1, 2, 3, and 4; 1Xtra, Radio Five Live, Five Live Sports Extra, 6 Music, BBC 7, Asian Network, and World Service. The data services are provided on a small screen and include information about the current program on the radio, such as a plot summary of a play, the name of a track currently being played, e-mail addresses, up-to-the-minute sports results, and competition details. Some of the latest DAB products can pick up a broadcast electronic program guide that provides free, useful program information for as many as seven days before a broadcast, allowing users to program the receiver to record a particular program—or even an entire series of a program—automatically (BBC 2006b).

Audio Encoder. The audio coding techniques used in Eureka 147 is based on a perceptual coding principle. They use advanced digital techniques to remove redundancy and perceptually irrelevant information from the audio source signal. The low bit-rate sub-band coding system used to deliver high-quality audio signals is standardized by the International Organization for Standardization (ISO) and International Electrotechnical Commission (IEC) under the heading ISO/IEC 11172-3 (MPEG-1 audio), and ISO/IEC 13818-3 (MPEG-2 audio) layer 2. Different encoded bit-rate options (e.g., 8, 16, 24, 32, 40, 48, 56, 64, 80, 96, 112, 128, 144, 160 or 192 kbit/s per monophonic channel) are available in the system, and it is possible to provide multichannel sound. Broadcasters can take advantages of these options, depending on the intrinsic quality required

and the number of sound programs to be broadcast (ETSI 2000).

Types of Data. The MSC includes multiple audio service channels, *program-associated data* (PAD), and possible additional data. The PAD are included in each audio service channel, having a variable capacity (minimum 0.333 kbit/s for MPEG-2 audio half-sampling frequency coding or 0.667 kbit/s for full sampling frequency coding), and can be used to convey information linked to the radio program, such as program titles or lyrics, and speech or music indication, as well as text with graphics features. The PAD are incorporated at the end of a DAB audio frame and should not be subject to a different transmission delay (ETSI 2000).

The *multiplex configuration information* is the information that defines the configuration of the main service multiplex. The MCI contains current and forthcoming (in the case of an imminent reconfiguration) details about the services, service components, and subchannels and the linking between these objects. It also includes the identification of the DAB ensemble and a mark of date and time.

Service information (SI) includes data for categorizing (such as basic program service label, time and date, language, and program-type label) and data for monitoring or controlling (such as cross-reference and transmitter identification).

Data for other services, such as the traffic message channel, can be in the form of a continuous stream that can be time-interleaved with audio service data or arranged as packet data services.

Channel Coding and Time Interleaving. The data that represent each of the audio services are processed through energy dispersal scrambling, convolutional coding, and time interleaving. The convolutional encoding process involves adding redundancy to the service data. There are two kinds of error protection: *equal error protection* (EEP) and *unequal error protection* (UEP), which is done by following a preselected pattern. In DAB, for the bit rates of 8, 16, 24, 40 and 144 kbit/s that can be used by MPEG-2 audio half-sampling frequency coding, only EEP can be applied. For audio source-encoded bits that need greater protection than other signals, the UEP profiles are applied. The average code rate, defined as the ratio between the number of audio source-encoded bits and the total number of encoded bits after convolutional encoding, can take a value from 0.35 (the highest protection level) to 0.75 (the lowest protection level). Different average code rates can be applied to different audio sources, subject to the protection level required and the bit rate of the audio source-encoded data. For example, the protection level of audio services carried by cable networks can be lower than that of services transmitted in RF channels. General data services are convolutionally encoded using one of the selected uniform rates. The data carried in the FIC are encoded at a constant 1/3 rate. Time interleaving improves the ruggedness of data transmission in a changing environment (e.g., reception condition in a moving vehicle) but results in a 384 ms transmission delay (ETSI 2000).

Main Service Multiplexer. These encoded and interleaved DAB ensembles (audio programs and data services) are fed to the MUX. In each 24 ms, the data are gathered sequentially into a multiplex frame. The combined bit-stream output from the multiplexer—the MSC—has a gross capacity of 2.3 Mbit/s. Depending on the chosen convolutional code rate, the added protection redundancy can be different from one application to another. Therefore, the net bit rate ranges from approximately 1.7 to 0.6 Mbit/s, accommodated in a DAB signal with a 1.536 MHz bandwidth. At the MUX, all of the program services going through the multiplexing process are brought together and synchronized before the transmission modulation (ETSI 2000).

Fast Information Channel. The FIC is designed to carry the multiplex configuration information, which is accurate and timely information about the current and future content of the MUX. Essential SI items that are associated with the content of the MSC (i.e., for programming selection) must also be carried in the FIC.

The data carried by the FIC are not time-interleaved. It is frequency-interleaved with the MSC ensemble before combining with synchronization for the OFDM modulation. The data carried by FIC are highly protected and frequently repeated to ensure their ruggedness so that a receiver can gain access to any or all of the individual services with a minimum overall delay. When the multiplex configuration is about to change, the new information, together with the timing of the change, is sent in advance within the MCI (ETSI 2000).

Transmission

Transmission Modes. The system provides four transmission modes that allow the use of a wide range of transmitting frequencies, as high as 3 GHz, for mobile reception. These transmission modes are designed to cope with Doppler spread and delay spread for mobile reception in the presence of multipath echoes. Table 1 compares the four transmission mode options for mobile reception in terms of the temporal guard interval duration, nominal maximum transmitter separation, and transmission frequency range (ETSI 2000).

As shown in Table 1, the use of higher frequencies allows smaller guard interval duration and shorter distance between transmitters. Mode I is most suitable for a terrestrial SFN in VHF bands because it allows the greatest distance between transmitters. Mode II can be used for medium-scale SFN in L band and is preferable for

local radio applications that require one terrestrial transmitter. Mode III is appropriate for cable, satellite, and complementary terrestrial transmission at all frequencies and for mobile reception at all frequencies up to 3 GHz. This mode has the greatest protection from phase noise. Mode IV is also used in L band and allows greater transmitter spacing in SFNs. However, it is not good for mobile reception because it is less resistant to degradation at higher vehicle speeds (ETSI 2000).

Transmission Frames. To facilitate receiver synchronization, the transmitted signal is built with a frame structure having a fixed sequence of symbols. Each transmission frame encompasses at least three information channels: synchronization channel, fast information channel, and main service channel (see Figure 2). The total frame duration, T_b , varies—including 96 ms, 48 ms, or 24 ms—depending on the selected transmission mode as shown in Table 2 and Figure 3.

The synchronization channel begins with a null symbol with no carrier that is transmitted as an initial synchronization of the frame, followed by a phase reference symbol for differential PSK demodulation.

The FIC includes the MCI and some essential SI associated with the MSC.

The major space of the frame provides the main service channel for the audio programming. The MSC can be a multichannel casting along with other data services. Each audio service within the MSC is allotted with a fixed time slot in the frame. At the beginning of each radio channel, there is a guard interval duration inserted to prevent the reception from multipath fading and interferences. The length of guard interval duration varies, depending on the transmission mode used for the DAB (see Table 2). As an example, the frequency domain of mode III transmission is shown in Figure 3 (ETSI 2000).

The diagrams in Figure 4 show the transmission frames for different transmission modes (ETSI 2001b).

PSK Modulation with OFDM. Phase shift keying is a modulation scheme, and OFDM governs the internal relationship between carriers. The basic process is to divide the digital audio signal into a large number of bit streams that individually have low bit rates (see Figure 5). These digital bit streams are then modulated individually in a PSK scheme (e.g., BPSK or QPSK) onto the carriers that are orthogonal frequency divided. The large number, N , of orthogonal carriers, referring to Table 2 and Figure 4,

Table 1: Parameter Values of Transmission Frame for Each Mode (Eureka 147)

System parameter	Transmission Mode			
	I	II	III	IV
Guard interval duration (μ s)	~246	~62	~31	~123
Nominal maximum transmitter separation for SFN (km)	96	24	12	48
Nominal frequency range (for mobile reception)	≤ 375 MHz	≤ 1.5 GHz	≤ 3 GHz	≤ 1.5 GHz

can be conveniently generated by a fast Fourier transform process.

The spectrum of the RF output signal is approximately rectangular and Gaussian noiselike, and it occupies a bandwidth of approximately 1.54 MHz (refer to Figure 5). Figure 6 shows an example of the transmitter output spectrum after amplification and filtering. In practice, the peak-to-mean ratio is limited to approximately 8 dB by digital processing. This can be further reduced by additional signal conditioning when coupled with nonlinear amplification in the transmitter (ETSI 2000).

Unique Features of Eureka 147

Prevention from Multipath Interferences. Three main techniques are used in Eureka 147 to alleviate degenerations caused by multipath fading and interferences. In the first, in the presence of multipath propagation, some of the carriers are enhanced by constructive signals, while others suffer destructive interference (frequency selective fading). Therefore, the system provides frequency interleaving by a rearrangement of the digital bit stream among the carriers so that successive source samples are not affected by a selective fade. When the receiver is stationary, the diversity in the frequency domain is the prime means of ensuring successful reception; the time diversity provided by time interleaving provides further assistance to a mobile receiver (ETSI 2000). The second technique uses convolutional coding by adding closely controlled redundancy as the UEP to the signal to be transmitted, providing strong error protection. In the third technique,

a guard interval duration is inserted before each audio data stream, which is longer than the delay to prevent the multipath interferences (ETSI 2000).

Spectrum Efficiency. Efficient spectrum utilization is achieved by (1) frequency interleaving, which supports the use of multiple subcarriers for sound coding; (2) time interleaving, which supports the ensemble of low bit rates for sound encoding; and (3) a special feature of frequency reuse, which permits transmitters carrying the same MSC within a broadcasting network to be operated on the same radiated frequency; it is known as the single frequency network. In this case, a gap filler transmitter receives and retransmits the signal on the same frequency without the processes of demodulation and remodulation.

Power Efficiency. Because digital audio transmission using PSK modulation (such as QPSK) and coded OFDM is more immune to amplitude noises and multipath interferences, it is much more power-efficient than analog audio transmission. In the Eureka 147 system, the SFNs tend to have relatively low-powered transmitters (e.g., typically below 10 kW) (ETSI 2001a).

Hybrid Terrestrial Digital Radio Broadcasting: In-Band On-Channel

In-band on-channel was developed by the iBiquity Digital Corporation and approved as the digital radio broadcasting technology by the FCC (FCC 2002b). HD Radio

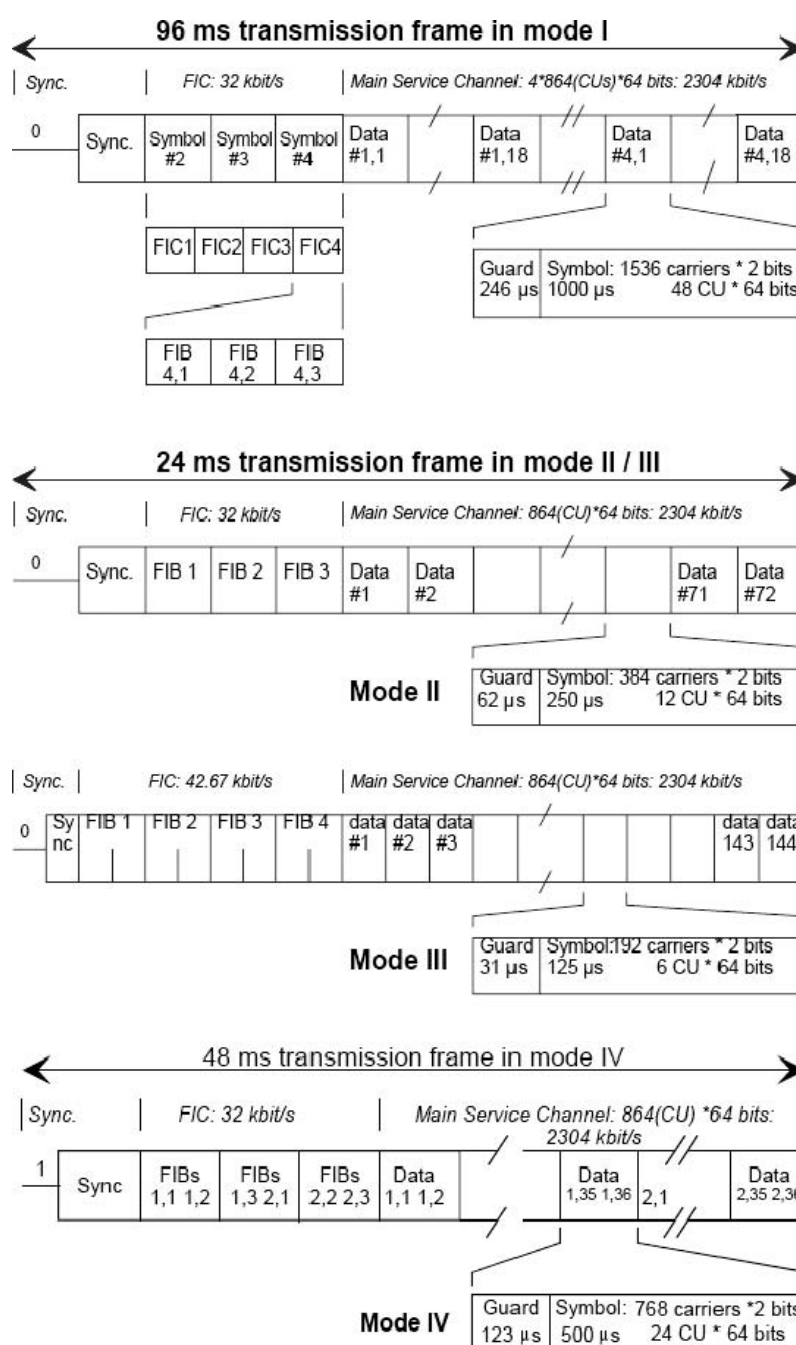

Figure 4: Structure of transmission frame in Eureka 147 (ETSI 2001b, 27)

Figure 5: The Eureka 147 signal in the frequency domain (mode III) (Evens 1998, 3)

provides enhanced sound fidelity (near-CD quality), improved reception, and new data services, such as station call letters, song titles, artist identification, stock and news information, and local traffic and weather bulletins.

IBOC is designed to permit a smooth evolution from current analog radio broadcasting to fully digital radio broadcasting. It allows broadcasters to use their current radio spectrum to transmit AM or FM analog signals simultaneously with new digital radio services to mobile, portable, and fixed receivers from terrestrial transmitters on existing AM or FM radio broadcasting channels. The IBOC technology is developed to eliminate the static, hiss, pops, and fades associated with current analog radio

Figure 6: Eureka 147 transmitter output spectrum (ETSI 2000, 15)

systems and to prevent interference to the host analog station and co-channel interference for stations operating on the same frequency channel as well as interference with adjacent channels. It also allows HD Radio receivers to be both backward- and forward-compatible, receiving traditional analog radio broadcasting from stations that have yet to convert and digital broadcasting from stations

that have converted. On the other hand, analog radio receivers continue to receive the analog portions carried by IBOC transmission signals. Moreover, the hybrid IBOC system ensures a “seamless switching from digital to analog reception when the received signal quality is not sufficient for digital audio reception or when digital packets in the DAB signal are corrupted” (National Radio Systems Committee 2005, 8). It is also used for fast channel changes, allowing the receiver to demodulate and play out the analog programming first and then “blend” to its digital version of the same program.

IBOC System Overview

Figure 7 shows the technical flowchart of the IBOC digital radio broadcast system, including three major subsystems specified by NRSC-5-A standard (National Radio Systems Committee 2005): (1) audio and data coding, (2) transport and multiplexing, and (3) RF and transmission.

The basic coding techniques used in the IBOC system for audio coding, error correction, multiplexing, and digital modulation are similar to those used in the Eureka 147 system. The audio coding scheme used in the HD Radio implementation is called “HDC,” is proprietary to iBiquity Digital Corporation, and is not specified in the NRSC-5-A standard. However, because IBOC uses the existing analog channel and bandwidth to transmit digital radio signals, the bandwidth limitation and the enclosed analog signals make the transmission process in the IBOC system much more complicated than that in the

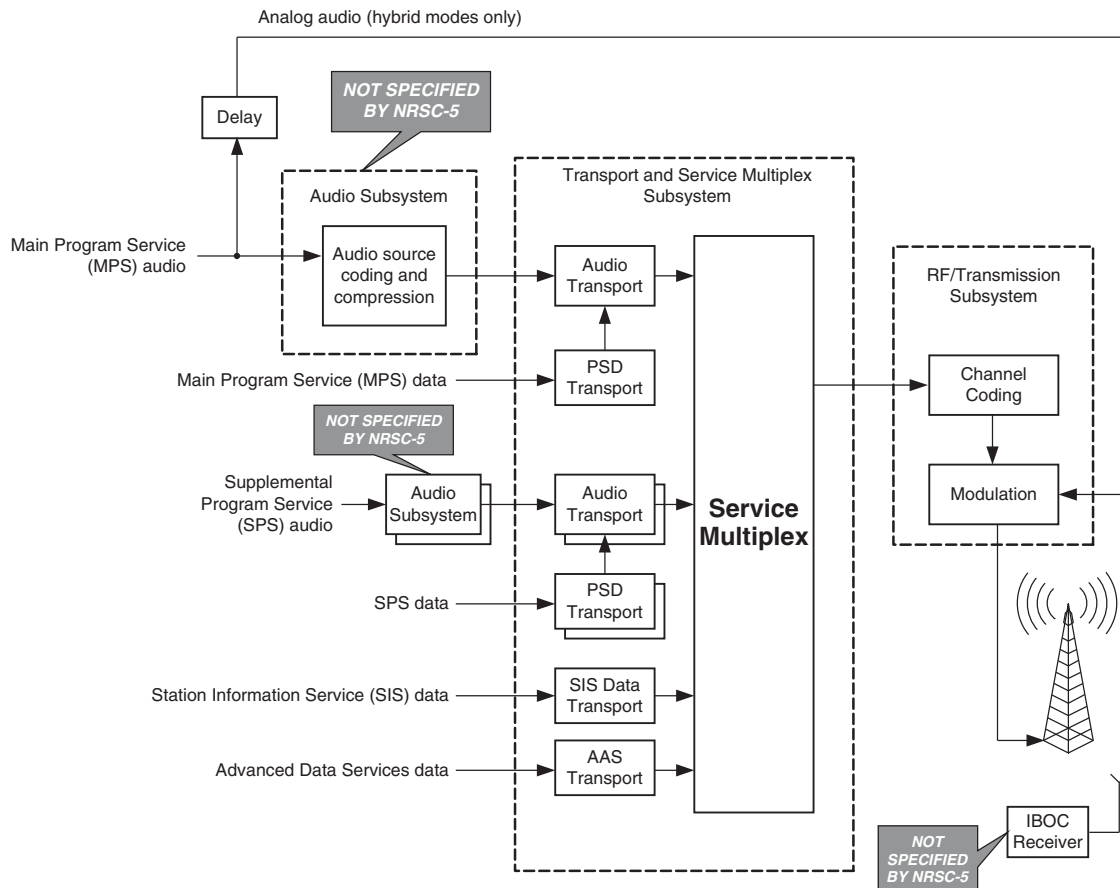

Figure 7: Overview of IBOC digital radio system (NRSC, 2005)

Eureka 147 DAB system. In the following, the discussion is focused on the RF and transmission subsystem.

Audio and Data Input Subsystems

Audio Services. For *main program service* (MPS) audio coding, there is no specific audio coding scheme standardized for the IBOC system. However, the iBiquity HDC technique is the only system to date used in any implementation of the NRSC-5-A standard.

MPS data (MPSD) are program service data associated with the MPS audio and will be integrated into the MPS packet for transmission. *Supplemental program service audio* (SPSA) is the additional program for option.

Supplemental program service (SPS) data are program service data associated with the SPSA and will be integrated into the SPSA packet for transmission.

Each audio service (either the main program service or each individual supplemental program service) has its own source coding, compression, and transport subsystem.

Data Services. *Station information service* (SIS) data includes necessary radio station control and identification information such as station call letter and sign identification.

Advanced data services (ADS) include (1) visual effects associated with MPS, SPS, or SIS services; (2) multimedia presentations with audio, text, and image for stock, news, weather, and other entertainment programming; (3) local storage of content for time shifting; (4) targeted advertising; and (5) traffic updates.

Advanced application services is the transport mechanism used to support transmission of ADS and was developed by iBiquity Digital Corporation.

Transport and Service Multiplex Subsystem

The signal processes in the transport and service multiplex subsystems are described as follows.

1. They receive signals and organize audio and data signals into packets, including the packet integrating the main audio program data with the main program service data, the packet of the station information service data, and other packets for advanced data service.
2. They multiplex the main audio program packets into a single data stream together with supplemental

program service data and station information data, as well as error detection and addressing (Johnson 2000).

3. In hybrid modes, the RF carrier is directly modulated by the analog audio signal for conventional analog receivers. The analog audio does not pass through the audio compression coding, transport, and multiplexing subsystems, so it needs to be delayed so that the analog audio signal is arriving at the receiver about the same time as the digital signal. This feature ensures that a user can listen to the same program by switching the receiver between analog mode and digital mode. When the signal received in one mode is not good, the receiver can switch to the other mode.

RF Transmission Subsystem

The RF transmission subsystem is called layer 1 in the IBOC technical documents. The output from this subsystem is the complete IBOC radio frequency waveform for transmission. The waveform is spectrally mapped and frequency partitioned across the set of OFDM subcarriers (National Radio Systems Committee 2005).

According to the FCC, to prevent reception from interchannel interferences, radio stations in the same local area are not licensed to adjacent channels. The frequencies of those stations are usually two or three channels apart. Therefore, the AM analog radio stations are allotted in 10-kHz (± 5 kHz) spacing but can operate within a 20-kHz (± 10 kHz) bandwidth. The FM radio stations are licensed in 200 kHz (± 100 kHz) spacing but can operate within a 400-kHz (± 200 kHz) bandwidth. In IBOC, the hybrid AM broadcasting is operated within ± 15 kHz bandwidth, and the all-digital AM can operate within ± 10 kHz. Both hybrid and all-digital FM IBOC systems utilize ± 200 kHz sidebands.

The RF transmission subsystem includes scrambling, channel coding, interleaving, OFDM subcarrier mapping, OFDM signal generation, hybrid transmission, and upconversion for over-the-air transmission (see Figure 8).

Scrambling. The scrambling process randomizes the bits in each encoded digital audio signal or service data to reduce periodicities of these bits in the time domain. To recover the bit sequence of the digital audio signal on

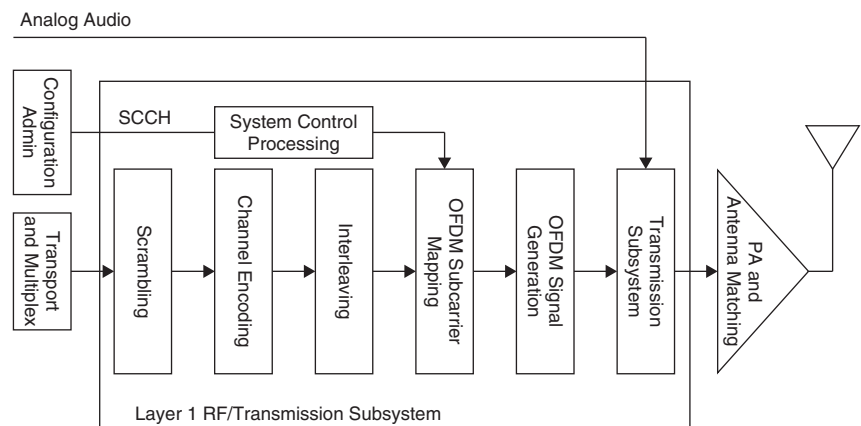

Figure 8: RF transmission subsystem of IBOC (NRSC, 2005)

receivers, the synchronization and coding information data are delivered together with the scrambled digital audio.

Channel Encoding. The channel encoding process generates forward error correction. It is characterized by punctured convolutional encoding (National Radio Systems Committee 2005). A convolutional interleaver has memory; that is, its operation depends not only on current symbols but also on previous symbols (Pohlmann 2000). The convolutional coding ratio between the number of codes for an audio channel and the total codes after the convolutional coding, varies, depending on the characteristics of the audio source and the quality requirement.

Interleaving. The interleaving process is used for error correction. It provides both time and frequency diversity. Frequency interleaving means using multiple subcarriers. Time interleaving creates a diversity delay (time) path that results in main and backup streams. Bit mapping assigns the encoded bits to specific locations in the interleaver output. The interleaver outputs are matrices, including *primary lower* (PL), *primary upper* (PU), *secondary* (S), and *tertiary* (T) sidebands and primary IBOC data service (PIDS) channel (National Radio Systems Committee 2005).

The processes of modulation differ between AM and FM in IBOC.

AM IBOC. The OFDM subcarrier mapping in AM IBOC assigns interleaver partitions to frequency partitions. The input to the OFDM subcarrier mapping is the interleaver matrices (including PL, PU, S, T, and PIDS), and R vector, or the system control data sequence that did not go through the interleaver. According to the standard of NRSC-5-A, one row of each active interleaver matrix and one bit of the system control vector R are processed every T_s seconds ($T_s = 5.805$ ms, i.e., the duration of the OFDM symbol). And all rows in all of the active interleaver matrices are processed sequentially, starting with the first row of the first matrix, to produce a frequency domain representation of the signal (iBiquity Digital 2005a). The interleaver matrices carrying the audio bit streams are

transformed into scaled 64-QAM constellation values and mapped to specific subcarriers located in primary and secondary sidebands. And the system control data are transformed into BPSK constellation values and mapped to the reference subcarriers.

Characteristics of the Subcarriers. The OFDM subcarriers are located in the sidebands and defined as *primary* (± 10.36 kHz to ± 14.72 kHz), *secondary* (± 5.09 kHz to ± 9.45 kHz), and *tertiary* (± 0.36 kHz to ± 4.72 kHz) sidebands that are underneath the baseband of the analog AM carrier (see Figure 9). There are also subcarriers assigned to reference data for indicating status and control purpose.

There are eighty-one subcarriers on each side of the unmodulated analog AM carrier, and the frequency span of each subcarrier is 181.7 Hz (iBiquity Digital 2005a; Johnson 2000).

The total power of all OFDM subcarriers for digital audio is significantly lower than the power of the unmodulated analog AM carrier. The primary sideband is -30 dBc/subcarrier and the secondary sideband is -43 dBc/subcarrier or -37 dBc/subcarrier (see Figure 9) (NRSC 2005).

OFDM Signal Generation. OFDM signal generation receives complex frequency-domain vectors of OFDM symbols from the OFDM subcarrier mapping and generates a sequence of complex, baseband, time-domain pulses that represent the digital portion of the AM IBOC signal.

Transmission of Hybrid AM IBOC. The transmission for the hybrid AM IBOC includes analog AM modulator, digital OFDM symbol concatenation, a combination of analog and digital baseband waveforms, and frequency upconversion to the radio frequency—that is, the existing AM channel (shown in Figure 10).

In the analog signal path, the baseband analog signal needs to be delayed to match the timing with its Zcorresponding digital signal and to go through a low-pass filter, either 5 kHz or 8 kHz, to meet the bandwidth

Figure 9: NRSC-5 AM hybrid waveform spectral emission limits for 5-kHz analog bandwidth (NRSC, 2005)

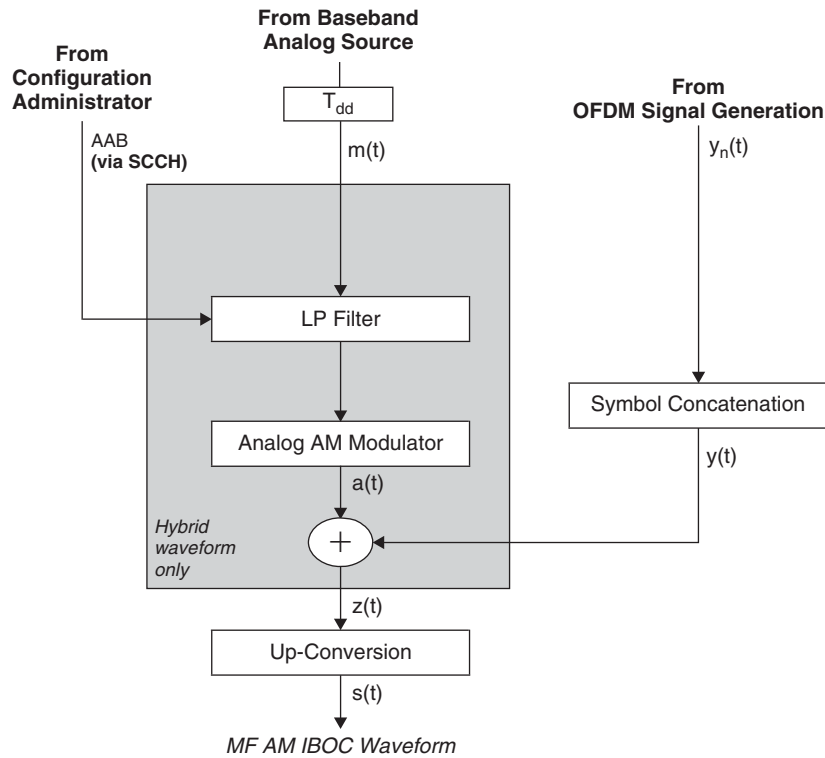

Figure 10: Hybrid AM IBOC transmission (NRSC, 2005)

requirement, when it is then modulated (refer to the respective figures).

In the digital signal path, the individual time-domain OFDM symbols are summed to form a continuum of pulses—that is, the symbol concatenation. The baseband waveforms of the analog and digital signals are combined to produce the complex baseband AM IBOC hybrid waveform. The hybrid is finally upconverted to the RF carrier frequency allocated for its existing AM radio channel.

The AM IBOC hybrid system does not support the stereo analog AM service authorized by the FCC (1998a). Thus, the analog audio signal must be monophonic. During the modulation and transmission, the overall digital

signal must maintain a 90-degree phase relationship to the unmodulated analog AM carrier in order to minimize the interference to the analog signal. Therefore, every other subcarrier in the OFDM subcarriers, which is in a 0-degree relationship with the unmodulated analog carrier, is not used to deliver information. The trade-off for interference protection is that the information content on the subcarriers in the AM IBOC hybrid mode is only half of its capacity (Johnson 2000).

For hybrid AM IBOC transmission, an 8-kHz analog bandwidth (referring to Figure 11) also can be utilized with the same allocation of the sidebands as in the 5-kHz hybrid AM IBOC mode (referring to Figure 9).

Figure 11: NRSC-5 AM hybrid waveform spectral emission limits for 8-kHz analog bandwidth (NRSC, 2005)

All-Digital AM IBOC. In the all-digital AM IBOC, the analog signal is not transmitted. Therefore, the primary sidebands are located at the baseband area around the unmodulated AM carrier ($\pm .36$ kHz to ± 4.72 kHz), and the secondary sidebands are ranged from 5.09 kHz to 9.45 kHz, with tertiary from -5.09 kHz to -9.45 kHz (see Figure 12) (NRSC 2005; Johnson 2000). The total bandwidth is reduced. Without the limitation of analog audio QAM, all of the subcarriers can be used for the information content. The power of both sidebands is increased (see Figure 12).

FM IBOC. The principle of OFDM subcarrier mapping in the FM IBOC is similar to that in the AM IBOC. However, in the FM IBOC, the interleaver matrices carrying the audio and data are transformed into scaled QPSK

constellation points and mapped to OFDM subcarriers (iBiquity Digital 2005b).

Characteristics of Subcarriers. Although FM radio stations are licensed in 200-kHz spacing, FM analog radio broadcasting usually operates with a bandwidth of ± 200 kHz. In the bandwidth of 400 kHz, there are 1092 subcarriers; the span of each subcarrier is 363.373 Hz (iBiquity Digital 2005b); 546 subcarriers spread on each side of the unmodulated FM carrier frequency. The OFDM scheme divides those subcarriers into sixty frequency partitions (see Figure 13). There are eighteen data subcarriers and one reference subcarrier in each partition (see Figure 14). The position of the reference subcarrier in a partition varies, either at the beginning or the end as shown in Figure 14. In addition to the reference subcarriers in

Figure 12: NRSC-5 AM all-digital waveform spectral emission limits (NRSC, 2005)

Figure 13: Sideband reference subcarrier spectral mapping (iBiquity Digital Corporation 2005a, 54)

Figure 14: Frequency partitions (iBiquity Digital Corporation 2005b, 12)

the partitions, there are five extra reference subcarriers inserted into the spectrum at subcarrier positions -546 , -279 , 0 , 279 , and 546 .

OFDM Signal Generation. OFDM signal generation receives complex frequency-domain OFDM symbols from the output of OFDM subcarrier mapping and generates a sequence of complex, baseband, time-domain pulses that represent the digital portion of the FM IBOC signals.

Transmission of the Hybrid FM IBOC. The transmission for the hybrid FM IBOC includes analog FM modulator, digital OFDM symbol concatenation and frequency upconversion to the VHF frequency of the existing FM channel, combination of analog FM RF signal, and digitally modulated RF signals for the hybrid FM IBOC broadcasting (see Figure 15).

The analog audio signal is delayed and sent to the analog FM modulator. The individual time-domain OFDM symbols from the OFDM signal generation are summed to form a continuum of pulses—that is, the processes of symbol concatenation—and then upconverted to the RF carrier frequency allocated to the existing FM channel.

In the hybrid FM IBOC, the analog FM audio signal occupies the baseband between ± 129.36 kHz in either monophonic or stereo. The primary digital audio sidebands are ranged from ± 129.36 kHz to ± 198.40 kHz (ten frequency partitions on each side) with the power reduction at -45.8 dBc per subcarrier (see Figures 16 and 17).

It may add one, two, or four extended sidebands to the primary digital sidebands with the power reduction at -45.6 dBc per subcarrier. However, the baseband of the analog FM signal is reduced to ± 101.74 kHz (see Figure 18).

All-Digital FM IBOC. In the all-digital FM IBOC spectrum waveform shown in Figures 19 and 20, the analog FM audio signal is removed. The primary sidebands are

fully used to operate the digital audio programming in fourteen partitions on each side (± 129.36 kHz to ± 198.40 kHz as the main bandwidth; ± 101.74 kHz to ± 129.36 kHz as extended bandwidth), and the secondary sidebands with lower power (5, 10, 15, or 20 dB below the power of the primary subcarriers) replace the baseband in a total of twenty-eight partitions (0 Hz to ± 69.40 as the main bandwidth, ± 69.40 to ± 97.02 as extended bandwidth) (see Figures 19 and 20).

Moreover, in the secondary sidebands, twelve subcarriers serve as the secondary protected region, “the area of spectrum least likely to be affected by analog or digital interference” (iBiquity Digital 2005b, 17). As mentioned above, five additional reference subcarriers are inserted at ± 198.40 kHz, ± 101.74 kHz, and the center (0 Hz from the unmodulated FM carrier).

The transmission system must address several issues of time alignment. For transmission facilities that are equipped to operate IBOC digital radio broadcasting, every data packet transmitted must be properly aligned with GPS (global positioning system) time. Also, the various data packets must be properly aligned with each other. In some service modes, certain packets are purposely delayed by a fixed amount of time to accommodate diversity, combining at the receiver for either interference protection or smoothly switching between the analog signal and the digital signal of the same programming (National Radio Systems Committee 2005).

Digital Radio Mondiale

Because Eureka 147 was developed primarily for the replacement of analog FM services, a small group of broadcasters and manufacturers formed the *Digital Radio Mondiale* (DRM) consortium in March 1998 to develop a digital radio broadcasting system for the radio stations using spectra below 30 MHz such as AM radio, medium frequency (526.5 kHz to 1,606.5 kHz in ITU regions 1 and 3), and high frequency for shortwave radio services (2.3 MHz to 27 MHz) and low frequency (148.5 kHz to 283.5 kHz in ITU region 1) (ETSI 2005). The DRM consortium is a nonprofit organization, including broadcasters, network providers, receiver and transmitter manufacturers, research institutes, and regulatory bodies [Digital Radio Mondiale (DRM) 2006]. As of June 2005, its membership had reached ninety-three organizations from thirty countries (DRM 2005b).

The DRM technology has been supported by the International Telecommunication Union (ITU), the International Electrotechnical Commission (IEC), and the European Telecommunication Standard Institute. In September 2001, ETSI published the DRM system specification (ETSI 2001c) and subsequently updated the specification. The current document was published in October 2005 (ETSI 2005). In March 2005, the DRM consortium voted to extend the system to 120 MHz to ensure digital radio availability worldwide. The design and testing of the extended DRM system are expected to be completed by 2008–10 (DRM 2005a).

The DRM system is designed similarly to the IBOC DAB system. However, it was originally considered to operate the DRM in an all-digital transmission format on a separate

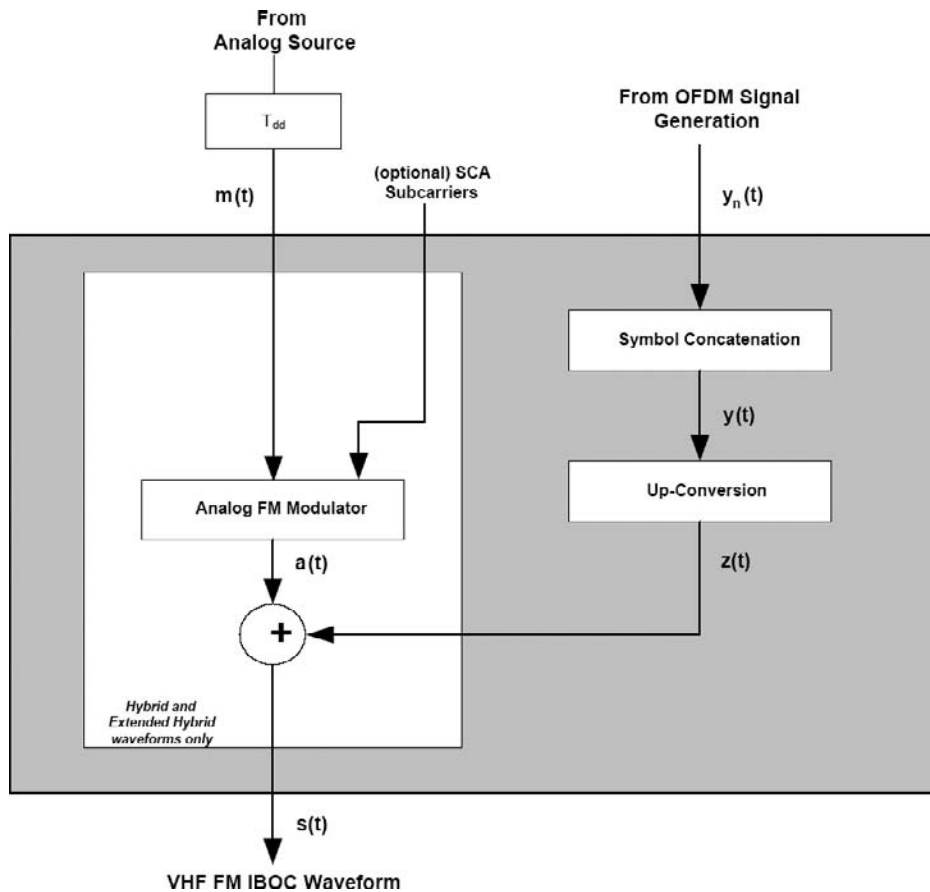

Figure 15: Hybrid FM IBOC transmission (NRSC, 2005)

Figure 16: Spectrum of the hybrid FM IBOC transmission signal (iBiquity Digital Corporation 2005b, 15)

channel from its corresponding analog AM service. Moreover, the bandwidth that can be used to carry DRM signals for the AM stations in many countries is narrower than that of the AM IBOC radio broadcasting in the United States. The difference is subject to the frequency planning for AM radio stations. For example, in Europe the AM stations are spaced at 9 kHz rather than 10 kHz as in the United States. In addition, an AM station in European and

other countries can be allocated at an adjacent frequency next to another AM station in the same geographic area; in the United States, the planners only allow stations in an adjacent area to be a minimum of two channels (20 kHz) away (Hallett 2003, "History"). Therefore, to avoid the adjacent channel interference, the DRM signal is required to fit in the existing AM broadcast bandwidth, as narrowly as 4.5 kHz or 5 kHz. The DRM signal occupies 4.5 kHz or

Figure 17: NRSC-5 hybrid FM IBOC waveform noise and emission limits (NRSC, 2005, 25)

Figure 18: Spectrum of the extended hybrid FM IBOC transmission signal (iBiquity Digital Corporation 2005b, 15)

5 kHz, whereas the other half bandwidth is used to transmit the one sideband of its analog AM signal (ETSI 2001c).

The DRM technology has been developed rapidly. According to H. Donald Messer (2006), DRM technical committee chairman, the DRM can be used with a variety of bandwidth allocations. In all-digital DRM, there are applications for 9/10 kHz RF channel (LF, MF, and HF), 18/20 kHz RF channel (MF and HF), and 50–100 kHz RF channel (VHF bands < 108 MHz). The simulcast DRM

(digital plus AM or FM channel) applications include 18/20 kHz (1/2 for DRM), 27/30 kHz (2/3 for DRM), 250–300 kHz (50–100 kHz for DRM), and 15 kHz (10 kHz for DRM and 5 kHz for the one sideband of AM analog signal). DRM technology also can be applied to a single frequency network, automatic frequency switching, a multiple frequency network, an AM signaling system, and displays of program data and other low bit-rate data such as traffic information (Messer 2006).

Figure 19: Spectrum of the all-digital FM IBOC transmission signal (iBiquity Digital Corporation 2005b, 17)

Figure 20: NRSC-5 all-digital FM IBOC waveform noise and emission limits (NRSC, 2005, 25)

A DRM signal consists of three kinds of data: the *main service channel* (data for all program services), *fast access channels* (service selection information, details of audio encoding information, etc.), and the *service description channels* (details of alternative frequencies, frequency schedules, audio metadata information, etc.). The technical processes of DRM include (1) audio coding, (2) multiplexing, (3) channel coding, and (4) transmission (OFDM cell mapping, OFDM signal generator, and quadrature amplitude modulation) (Hallett 2003, "Development").

Audio Encoding

In the audio coding process, the near-FM quality is achieved by using MPEG-4 *advanced audio coding* (AAC) with *spectral band replication* (SBR), which is called *MPEG-4*

aacPlus. For speech, the audio coding uses *code-excited linear prediction* (CELP) and harmonic vector excitation coding (HVXC) together with SBR to reduce the bit rates.

Kunz (2006) describes the technical concept of SBR in Figure 21. From a technical point of view, SBR is a new method for highly efficient coding of high frequencies in audio compression algorithms. When used in conjunction with SBR, the underlying coder is only responsible for transmitting the lower part of the spectrum. The higher frequencies are generated by the SBR decoder, which is mainly a postprocess following the conventional waveform decoder. Instead of transmitting the spectrum, SBR reconstructs the higher frequencies in the decoder based on an analysis of the lower frequencies transmitted in the underlying coder. To ensure an accurate reconstruction,

Figure 21: Technical concept of spectral band replication (SBR) (Kunz 2006, 2)

some guidance information is transmitted in the encoded bit stream at a very low data rate.

The reconstruction is efficient for harmonic as well as for noiselike components and allows for proper shaping in the time domain as well as in the frequency domain. As a result, SBR allows full bandwidth audio coding at especially low data rates, thus offering a significantly increased compression efficiency compared to the core coder (Kunz 2006).

Multiplexing

The process in the multiplexing is similar to that in the AM HD Radio system. The multiplexer combines the protection levels of all data and audio services. The data coded with MPEG AAC and CELP in the main service channel use unequal error protection in which higher protection is assigned to more sensitive information. Yet the data coded with HVXC only use equal error protection (ETSI 2005). Because the information carried in the *fast access channel* (FAC) and the *service description channel* (SDC) are used to decode the MSC programming signals, they should be arriving in the receiver before the MSC signals. The FAC and SDC signals pass through neither the multiplexing nor interleaving processes. They are integrated with the MSC signals at the transmission section (ETSI 2005).

Error Protection: Energy Dispersal, Channel Encoder, and Interleaving

The energy dispersal process predetermines selective complementing bits in order to reduce the possibility of a systematic pattern in the transmitted signal. The systematic pattern is vulnerable to the interference caused by the environment. The channel encoder adds redundant

information for error protection and defines the mapping of the digital information onto QAM cells (a cell means one cycle in a waveform). The interleaving spreads consecutive QAM cells onto a sequence of cells separated in time and frequency in order to provide robust transmission of digital radio signals. The pilot generator provides information to demodulate the signal in the receiver (ETSI 2005).

Transmission

In the transmission block, the data from MSC, FAC, and SDC are merging with the information from the pilot generator. The process including OFDM mapping, OFDM signal generation, and modulation.

OFDM Cell Mapping. The OFDM cell mapper collects the different classes of cells and places them on the time-frequency grid that assigns the QAM cells onto specific subcarriers. The mapping constellations are 4-QAM, 16-QAM, or 64-QAM. The output is a frequency representation with time index—that is, the time when the frequency exists.

The time-related OFDM symbol parameters are expressed in multiples of the elementary time period, T , which is equal to $83\frac{1}{3}\mu\text{s}$. These parameters are:

- T_g , the duration of the guard interval;
- T_s , the duration of an OFDM symbol; and
- T_u , the duration of the useful (orthogonal) part of an OFDM symbol (i.e. excluding the guard interval).

The OFDM symbols are grouped to form transmission frames of duration T_f (ETSI 2005) (see Table 3).

OFDM Signal Generator. The OFDM signal generator transforms each ensemble of cells with same time index to a time domain representation of the signal. The OFDM symbol is obtained by inserting a guard interval before the time domain representation of the useful ensemble. All OFDM symbols contain data (MSC) cells and reference information cells, including pilot cells and system control information cells. The pilot cells can be used for frame, frequency and time synchronization, channel estimation, and robustness mode identification. The system

Table 3: OFDM Symbol Parameters in Each Transmission Mode in DRM

Parameters list	Robustness mode			
	A	B	C	D
T (μs)	$83\frac{1}{3}$	$83\frac{1}{3}$	$83\frac{1}{3}$	$83\frac{1}{3}$
T_u (ms)	$24 (288 \times T)$	$21\frac{1}{3} (256 \times T)$	$141\frac{1}{3} (176 \times T)$	$9\frac{1}{3} (112 \times T)$
T_g (ms)	$2\frac{2}{3} (32 \times T)$	$5\frac{1}{3} (64 \times T)$	$5\frac{1}{3} (64 \times T)$	$7\frac{1}{3} (88 \times T)$
T_g / T_g	1/9	1/4	4/11	11/14
$T_s = T_u + T_g$ (ms)	$26\frac{1}{3}$	$26\frac{2}{3}$	20	$16\frac{2}{3}$
T_f (ms)	400	400	400	400

Table 4: OFDM Frame Parameters in Each Transmission Mode in DRM

Robustness mode	Duration (T_u) (ms)	Carrier spacing ($1/T_u$) (Hz)	Duration of guard interval (T_g) (ms)	Duration of symbol ($T_s = T_u + T_g$) (ms)	T_g/T_u	Number of symbols per frame (N_s)
A	24	$41^{2/3}$	2.66	26.66	1/9	15
B	21.33	$46^{7/8}$	5.33	26.66	1/4	15
C	14.66	682/11	5.33	20	4/11	20
D	9.33	1071/7	7.33	16.66	11/14	24

control information includes a FAC and a SDC. Because the OFDM signal consists of many separately modulated carriers, each OFDM symbol can be considered as an ensemble of individual cells, each cell corresponding to either data or reference information modulated on one carrier within this OFDM symbol (ETSI 2005).

Transmission Frame and Superframe. The transmitted signals are organized into transmission frames. Three transmission frames are combined to a transmission superframe. Each transmission frame is in a duration of 400 ms (ETSI 2005), and consists of fifteen to twenty-four OFDM symbols, depending on the robustness modes of transmission (see Tables 4 and 5).

Modulation and Transmission. The modulator converts the digital representation of the OFDM signals into the analog RF signal. This operation includes digital-to-analog conversion to the RF carrier frequency for transmission, as well as bandwidth filtering to comply with the RF protection ratio requirement (ETSI 2005).

SATELLITE DIGITAL AUDIO RADIO SERVICES

There are alternative approaches to the practical implementation of digital radio broadcasting such as Web-casting, cable, and satellite transmission. Among those,

satellite digital audio radio services (SDARS) have been widely accepted in the United States, especially by the automobile and aircraft industries. Two American companies, XM and Sirius, provide the service in North America, for which subscribers pay a monthly fee.

Regarding SDARS, the FCC allocated a portion of the S band from 2320 MHz to 2345 MHz for national satellite radio broadcasting downlink frequency with a bandwidth of 12.5 MHz for each service. Only two licenses were available. An auction was held with four applicants: CD Radio, American Mobile Radio Corporation (AMRC), Digital Satellite Broadcasting Corporation, and Primosphere Limited Partnership. The two winners were CD Radio (\$83.3 million) and AMRC (\$89.9 million) (FCC 1997). The term of the renewable SDARS license is eight years. AMRC debuted its service as XM (2332.5 MHz to 2345 MHz) in 2001, and CD Radio launched its service as Sirius (2320 MHz to 2332.5 MHz) in 2002. The SDARS providers offer 120 to 160 digital channels of choice, including music, sports, talk, news, comedy, children's programming, and advanced traffic and weather information. The radio programs reach the receivers directly by satellite or terrestrial repeaters.

As of the end of 2005, XM had 5.9 million subscribers, an increase of 84 percent over 2004 (XM Satellite Radio 2006). Sirius had more than 3.3 million subscribers, an increase of 190 percent over 2004 (Sirius Satellite Radio 2006, "Reports"). Most major brands and affiliates of automakers have made alliances with the SDARS companies to use their radio services. Electronic manufactures are actively participating in the process of developing SDARS radio receivers. The XM and Sirius radio sets are also available in retail stores. The price ranges from \$50 to \$250. Early in 1997, the FCC ordered XM and Sirius to jointly develop a unified standard for satellite radios so that radio sets can receive both satellite radio channels; the two SDARS providers also planned to make their receivers compatible with existing AM and FM stations (Sirius Satellite Radio 2005). However, this work has progressed slowly.

Another service, WorldSpace Satellite Radio, launched AfriStar and AsiaStar in 1990 to provide sixty-two channels of international satellite radio programming, including news, music, talk, sports, education, spiritual, and special brand content in seventeen languages to

130 countries, including India and China, all of Africa and the Middle East, and most of Western Europe. The company claims that it does not conduct business with people, business, or companies or people doing business with several countries: Burma, Iran, Libya, North Korea, Sudan, Syria, Angola, Serbia, and Montenegro (WorldSpace Satellite Radio, 2007). The content of thirty-two channels are provided by international, national, and regional third parties; thirty channels are produced by WorldSpace-branded stations. WorldSpace owns production studios in Washington, D.C., Bangalore, India and Nairobi, Kenya, where original music and lifestyle channels are created. It also has a programming partnership with the XM Satellite Radio network.

The Development of SDARS in the United States

Satellite digital radio technologies have been developed along with direct satellite television services since the late 1980s. They use similar digital audio coding techniques such as those used to compress audio signals in terrestrial digital video, and they apply frequency or phase modulation to transmit encoded audio signals for the reception of fixed, portable, and cable television receivers. However, as an independent industry, the SDARS only began in the 1990s (FCC 2006a). In 1990, Satellite CD Radio (the predecessor of CD Radio and Sirius) filed a petition with the FCC to allocate spectrum for SDARS and to grant permission for providing CD-quality audio programs to American consumers (FCC 1997a). Initiated by Satellite CD Radio's 1990 petition, the FCC called for investigation into the effects of satellite digital radio services on existing AM and FM stations. The timeline of the SDARS implementation is as follows.

1. November 1992: The FCC established a proceeding to allocate SDARS spectrum domestically and announced a cutoff date of December 15, 1992, for SDARS license applications. Four companies applied for the licenses, including AMRC, Digital Satellite Broadcasting Corporation, Primosphere Limited Partnership, and Satellite CD Radio (FCC 1997a).
2. January 1995: The commission allocated the 2310 MHz to 2360 MHz band for SDARS on a primary basis.
3. June 1995: the FCC requested detailed information on the potential economic impact of SDARS on terrestrial broadcasters. The public notice proposed three possible licensing options and rules to allow expeditious licensing after an option was chosen. The U.S. Congress directed the commission to (a) allocate spectra at 2305 MHz to 2320 MHz and 2345 MHz to 2360 MHz for SDARS to be consistent with international allocations and (b) award licenses in those portions by auction.
4. March 1997: The FCC approved SDARS and announced the date of its auction as April 1, 1997. Despite a petition by the National Association of Broadcasters, the commission did not think the effect of SDARS would be significant on existing free radio service in terms of advertising revenue (FCC 1997a).

5. April 2, 1997: The FCC announced that Satellite CD Radio and AMRC had won the SDARS auction (FCC 1997b).
6. October 1997: The FCC granted two licenses of the S-band frequency. Satellite CD Radio was given the 2320 MHz to 2332.5 MHz spectrum (FCC 1997c), and AMRC was given the 2332.5 MHz to 2345 spectrum (FCC 1997d). The FCC proposed that these satellite licensees begin construction of their space station within one year of the auction, launch and begin their first satellite within four years, and begin to operate their entire system within six years. The FCC determined that satellite DARS license terms should be for eight years. Each license term commences when each service is put into operation and is subject to renewal or termination after the initial eight-year period (FCC 1997a).

XM Satellite Radio

XM Satellite Radio began as AMRC in 1992 and was granted a SDAR license for 12.5 MHz of the S band (2332.5 MHz to 2345.0 MHz) in October 1997 (FCC 1997d). XM is a wholly owned subsidiary of XM Satellite Radio Holdings, Inc. XM Radio is transmitted by satellite, now taking its place alongside AM and FM on the radio dial, as well as by the newly debuted HD Radio in the United States. XM has its corporate headquarters and eighty end-to-end fiber-optic programming and broadcast studios in Washington, D.C., and broadcast facilities in New York; Nashville; Boca Raton, Florida; Southfield, Michigan; and Yokohama, Japan. XM has been publicly traded on the NASDAQ exchange (XMSR) since October 5, 1999.

XM launched two satellites in March and May 2001—Rock and Roll, respectively—in cooperation with Hughes Space and Communications International (now Boeing Space Systems). Both are HS702 geostationary satellites with payloads provided by Alcatel. In September 2001, XM formally launched services in two major markets: Dallas–Fort Worth and San Diego. XM charges a basic monthly subscription fee of \$12.95. Under the XM Family plan, subscribers get a discounted rate of \$6.99 per month for additional radios. Premium channels are available at an additional monthly cost. Currently, XM uses three Boeing geostationary satellites and approximately 800 terrestrial repeaters located throughout the continental United States. The repeaters receive the XM signal directly from the satellites and then retransmit it to XM radios where the reception directly from the satellite is not acceptable. The repeater network ensures signal coverage, particularly in urban areas where tall buildings and other obstructions may otherwise interfere with signal reception.

XM's programming includes more than 170 digital channels of option from coast to coast, including commercial-free music channels; channels of premier sports coverage, talk, news, comedy, and children's and entertainment programming; and advanced traffic and weather information channels. XM's programming partners include Sesame Workshop, NASCAR, Associated Press, ABC News, CNBC, BBC World Service and BBC Concerts, Radio One, The Sporting News, CNN,

Bloomberg, Fox News, C-SPAN Radio, Disney, and ESPN. XM provides entertainment and data services for the automobile market through partnerships with General Motors, Honda, Toyota, Hyundai, Nissan, and Volkswagen and Audi. As of 2005, XM Radio was being installed in more than 120 different vehicle models.

At the end of December 2001, XM had 28,000 subscribers; 347,000 subscribers at the end of 2002; and 1.36 million subscribers at the end of 2003. XM claimed that it ended 2004 with 3.2 million subscribers and 5.9 million by the end of 2005, reflecting an 84 percent increase in total subscribers over 2004 (XM Satellite Radio 2006, "Reports"). In April 2007, XM announced its first quarter results, indicating that its subscribers reached 7.9 million (XM Satellite Radio 2007, "Investor Information").

XM collaborates with electronics industries such as Delphi, Pioneer, Audiovox, and Yamaha to manufacture radio receivers. The XM Radio receivers are also available at retailers nationwide including Wal-Mart, Best Buy, Circuit City, Sears, and independent dealers. XM Radio receivers are designed for different users: handheld, car plug-in radios, and home tuners. Robust features are embedded in the radio sets, such as more than one hundred channels of programming, LCD display, remote controller, thirty-minute relay, stock ticker, sports score ticker, built-in antenna or FM wireless modulator that translates XM signals to nearby radio sets, and so on. The home tuner can be connected to a television.

Sirius Satellite Radio

Sirius Satellite Radio was originally incorporated as Satellite CD Radio in Delaware in May 1990. Its name was changed to CD Radio in December 1992 and changed again to Sirius Satellite Radio in November 1999. Its headquarters are in New York City's Rockefeller Center. In 1990, Satellite CD Radio filed a petition with the FCC to allocate spectrum for satellite digital audio radio service, and it filed a license application in 1992. In April 1997, Satellite CD Radio successfully won the bid of FCC's auction and was licensed in October 1997 a 12.5-MHz bandwidth of the S band, 2320 MHz to 2332.5 MHz, to provide SDARS radio programming (FCC 1997c). Its uplink transmission spectrum ranges from 7060 MHz to 7072.5 MHz (Sirius Satellite Radio 2003).

Space Systems/Loral launched three operating satellites in the Loral FS-1300 model series in July, September, and December 2000 for Sirius radio services. A fourth satellite, as a spare one, was delivered to ground storage in April 2002. The satellites are designed to have life spans of approximately fifteen years in orbit. Sirius uses the three satellites and almost one hundred terrestrial repeaters to serve subscribers throughout the United States. According to Sirius,

Each operating satellite travels in a "figure eight" pattern extending above and below the equator, and spends approximately 16 hours per day north of the equator. At any time, two of our three satellites operate north of the equator while the third satellite does not broadcast as it traverses the portion of the orbit south of the equator. This

orbital configuration yields high signal elevation angles, reducing service interruptions that can result from signal blockage. In some areas with high concentrations of tall buildings, such as urban centers, and in tunnels, signals from our satellites may be blocked and reception of our satellite signal can be adversely affected. In many of these areas, we have deployed terrestrial repeaters to supplement our satellite coverage. To date, we have deployed 98 terrestrial repeaters in 61 urban areas. We may deploy additional terrestrial repeaters if we discover that our existing terrestrial repeaters fail to cover a significant number of subscribers or potential subscribers (Sirius Satellite Radio 2003, 6).

In February 2002, Sirius began its service in selected markets, and in July 2002 extended its service nationwide. By charging a monthly subscription fee of \$12.95, Sirius provides more than 125 channels of CD-quality audio programs, including sixty-eight channels of commercial-free music and almost sixty channels of news, sports, weather, talk, comedy, public radio, and children's programming (Sirius Satellite Radio 2005). Both Sirius FM-modulated radios and three-band radios (AM/FM/SDARS) have been designed so that the receivers can be plugged into or installed in cars, trucks, recreational vehicles, homes, offices, stores, and even outdoors. Boaters around the country, and as far as 200 miles offshore, can also hear Sirius programming. As of the end of 2002, Sirius had 29,947 subscribers; by the end of 2003, 261,061 subscribers; and by the end of 2004, 1,143,258 subscribers. The company reported that it "ended 2005 with 3,316,560 subscribers, reflecting a 190 percent increase in total subscribers for the year 2004" (Sirius Satellite Radio 2006, "Reports"). In May 2007, Sirius announced its first quarter results, indicating approximately 6.6 million subscribers (Sirius Satellite Radio 2007, "Investor Relations").

Sirius's primary source of revenue is its monthly subscription fee, activation fees, and revenue from limited advertising on its nonmusic channels (Sirius Satellite Radio 2003, 2005). Hertz currently offers Sirius radio at major locations around the country and has signed an agreement with Sirius for charging car renters' activation fees.

Sirius currently has partnership with automobile companies including Audi, BMW, Chrysler, Dodge, Ford, Infiniti, Jaguar, Jeep, Land Rover, Lexus, Lincoln-Mercury, Mazda, Mercedes-Benz, MINI, Nissan, Scion, Toyota, Porsche, Volkswagen, and Volvo to manufacture and sell the vehicles equipped with Sirius radios. The radios are produced by Alpine, Audiovox, Blaupunkt, Clarion, Eclipse, Jensen, JVC, Kenwood, Panasonic, and U.S. Electronics, and they can be purchased at major retailers including Advance Auto Parts, Best Buy, Car Toys, Circuit City, Crutchfield, Good Guys, Wal-Mart, Sears, Tweeter, and Ultimate Electronics along with RadioShack and DISH Network outlets (Sirius Satellite 2006, "Corporate"). In addition, Sirius is also available at heavy truck dealers and truck stops nationwide.

Sirius's state-of-the-art studios are located in New York City. It also broadcasts from Los Angeles, Memphis,

Nashville, New Orleans, Houston, and Daytona. Sirius offers sports radio programming, including broadcasting play-by-play action, for more than 350 professional and college teams. Its corporate overview states,

Sirius programming features news, talk and play-by-play action from the NFL, NBA, NHL, Barclays English Premier League soccer, the Wimbledon Championships and more than 125 colleges, plus live coverage of several of the year's top thoroughbred horse races. SIRIUS is the only radio outlet to provide listeners with every NFL game and airs over 1000 NBA games per season, plus up to 40 NHL games per week. SIRIUS also features programming from ESPN Radio and ESPNNews (Sirius Satellite Radio 2006, "Corporate").

AUDIO WEBCASTING

Audio Webcasting is one of the applications developed by streaming media technologies. Streaming media is a technology that converts conventional audio and video signals to compressed digital packets and delivers the packets sequentially in real time through computer networks to players installed on users' computers. The compressed digital packets are reassembled and decompressed into audio and video signals that can be played on users' computers (Mack and Rayburn 2006; Austerberry 2002). Streaming media can be employed to deliver live audio and video programming and provide playlists for simulated live broadcasts of prerecorded audio and video materials or for media on-demand requests. The details of streaming technology are described in Chapter 17. Mp3 and so-called podcasting are other digital audio formats made available on the Internet for downloading to personal players such as mp3 players (audio only) and iPods (audio and video).

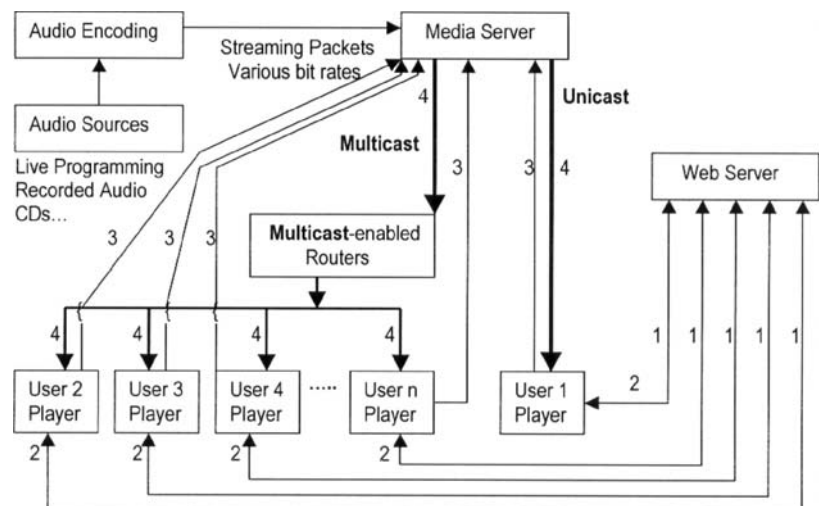

Brief History of Audio Webcasting

Audio Webcasting was started by RealNetworks in 1995 through its RealPlayer and RealAudio software. Apple QuickTime, originally used for progressive downloading, became available for Webcasting. Microsoft joined the Webcasting business in 1999. RealNetworks has acquired companies specializing in online software development, music, business management, and distribution and publishing such as Zylom Media Group BV, the Helsinki-based Mr.Goodliving, Seattle-based GameHouse, Listen.com, Netzip, Xing Technology, and Vivo Software. Currently, RealNetworks, Apple QuickTime, and Microsoft Windows Media are three leading proprietary architectures of streaming media compression. Shoutcast is a streaming audio-only system.

To promote Webcasting technology, RealNetworks, QuickTime, and Windows Media provide free downloads of their players that are accepted by Internet browsers for plug-in display of Webcasting materials. Windows Media also offers free encoding software under an agreement with users. Radio networks such as Westwood One, BBC, and ABC Radio, and many independent radio stations provide free audio Webcasting as a supplementary outlet to reach listeners. Satellite radio services XM and Sirius have online radio as well. In addition to supporting Webcasts, those players are commercialized by connecting to advertising, online audiovisual stores, and music industries. Although such free programming as news, sports, and music clips are offered, listeners need to pay subscription fees for high-quality programming or to download music items.

Audio Webcasting System

There are four basic components necessary for operating an audio Webcasting system: streaming audio encoder, streaming audio server, distribution, and streaming audio player. A conceptual diagram of audio Webcasting system is shown in Figure 22.

1. User sends a request for an audio Webcasting to a Web server.
2. Web server returns a metafile indicating the URL of the audio Webcast.
3. The user opens the player and sends a request to the relevant media server.
4. The media server sends the audio programming to the player.

Figure 22: Conceptual diagram of audio Webcasting system

Streaming Audio Codec: Encoding and Player

Similarly, the streaming audio codec compression is based on psychoacoustics technology. The encoding compression rate varies depending on the audio source, such as voice or speech and various music formats. Because the delivery is over the Internet, the encoding also takes into account Internet bandwidth and connection speed—for example, dialup modems (56 kbit/s), dual ISDN (128 kbit/s), cable modems and DSL (300 kbit/s–2 Mbit/s), T1 lines (1.5 Mbit/s), and 10baseT LAN (3 Mbit/s). For high-quality audio, such as music, variable bit rate coding is used; for limited connection speeds, consistent bit rate coding is used. There are one-pass and two-pass coding processes. During two-pass coding, the first pass is for the codec to gather information about the audio source so that the second pass is able to result in the optimized encoding.

Both RealAudio 10 for bit rates less than 128 Kbps and QuickTime audio apply the MPEG 4 ACC algorithm to their stream encoding. Windows Media 10 Professional offers a wide range of streaming applications, from low bit-rate coding at 24 Kbps for audio broadcasting (voice with music), to high bit-rate coding at 320 Kbps to 1.5 Mbps for 7.1 sound systems. The streaming media clip can be encoded for multiple bit rates. It will automatically switch to a lower bit rate for transportation over a lower bandwidth network. Shoutcast uses mp3 encoding.

The players reassemble and decompress the received streaming packets. For missing packets, a player will contact the source to acquire the missing packet in order to recover the audio signal. For this reason, playback starts a few minutes after live programming begins. It will be stopped if there are too many missing packets. All of the basic players are free for downloading, but players with extra features can be purchased. The player can display the Webcasting content in an independent window, embedded in a file, or plugged into a browser. Players are upgraded constantly, and the information about new version and features is sent to the users automatically via e-mail lists. The latest versions of codecs are all backward-compatible with their previous decoders.

Streaming Audio Server: Delivery and Distribution

As shown in Figure 22, the delivery of streaming audio needs media servers. RealNetworks employs Helix Universal Server to stream the RealMedia clips, and it also supports streaming content for QuickTime and Windows Media players. Apple QuickTime uses QuickTime Streaming Server 5.5 that supports QuickTime and international standards such as H.264, MPEG 4, and 3GPP. Apple employs Darwin Streaming Server for Real and Windows Media players, but Darwin Server does not get technical support from the company. Instead, user groups have been organized to discuss and support technical problems. Windows Media streaming is delivered through MMS servers. To ensure live Webcasting, there should be redundant encoders and servers. Each encoder feeds an intake server and then feeds public servers. There is a load balancer or metafile to control the connection between intake servers and public servers (Mack and Rayburn 2006).

Two Internet protocols support the transportation of audio messages: real-time transport protocol, a one-way streaming model; and real-time streaming protocol, an

interactive streaming model that allows user control over content such as rewind and fast forward for on-demand users (Austerberry 2002).

Unlike on-the-air broadcasting, the content delivery between a media server and listeners for Webcasting is one-on-one transportation, so-called unicast. Therefore, on unicast the bandwidth needed for content delivery via the Internet is incremental by the number of listeners. According to QuickTime, a server with 4 GB of available disk space supports 10,000 simultaneous streams of 20 kbps ACC audio for live Webcasting and 8000 streams of 20-Kbps ACC audio for on-demand streams. To save the bandwidth, multicast is a content delivery method that transports a single stream to multiple listeners by means of routers and switchers. Listeners do not have direct contact to the server. Instead, they receive Webcasting through their Internet service providers (ISPs), which must install multicast-enabled routers to distribute the content to subscribers and end users. However, unicast is still the major content delivery method because multicast routers have not yet been offered by ISPs.

Advantages and Disadvantages of Webcasting

The Internet has become a new form of mass media. It integrates interpersonal, organizational, mass, and public communication through one medium. Therefore, audio Webcasting possesses many characteristics of the Internet. In this chapter, audio Webcasting is featured as one mass communication that transmits audio programming from one station to many listeners. The advantages and disadvantages of Webcasting follow.

Advantages

1. Interactive process between stations and listeners: It facilitates such services as audio on-demand and downloading music for purchase, and it provides supplementary information about programs, artists, songwriters, and so on.
2. Lower cost of entry: Webcasting does not need transmitters and towers. Media servers and Web servers cost much less than the construction of traditional radio broadcasting infrastructure, and there are few or no regulatory hurdles.
3. Not limited by geography: The Internet is a global medium.
4. Not limited by time: The programming of a popular station can be enjoyed by listeners located in different time zones.
5. Cost-effective for small numbers of listeners: The cost of Webcasting is incremental per listener. Small numbers of receivers would cost less for the delivery fees through the Internet.
6. Quality optimized for different content (such as speech and music) and Internet connection speeds (such as dialup, DSL, and broadband).

Disadvantages

1. Small size of listeners: (a) The penetration of the Internet is smaller than that of traditional radio broadcasting; (b) the Internet's limited bandwidth cannot support large numbers of listeners through unicast; and (c) the incremental cost per listener.

2. Quality: (a) Limited by the bandwidth available on the Internet, the compression ratio is high; and (b) the audio quality of complementary Webcasting from NPR stations and traditional radio stations is fair but worse for listening to free programming from commercial audio Webcasting.
3. Cost: It is not free. The cost is much higher than purchasing a radio set. Webcasting listeners need to have updated computers and subscriptions to their Internet services and the streaming audio and radio materials (paying either for downloading single items or yearly radio passes).
4. Complexity: Because of nonstandardized streaming architectures, listeners need to install three or more players.
5. Technical knowledge and skills are needed for downloading and installing players on personal computers.

Overall, Webcasting is still in its developmental stage in which companies are practicing and public users are trying different new technologies. The FCC and international telecommunication organizations have not yet taken rule-making or licensing actions.

THE IMPLEMENTATION OF DIGITAL RADIO BROADCASTING

Domestic Digital Radio Broadcasting System

United States of America: IBOC HD Radio

Because no spectrum was available in VHF band III or L band for digital audio broadcasting in the United States and U.S. broadcasters were highly supportive of an in-band digital radio broadcast strategy, in October 2002 the FCC approved IBOC as the technology to broadcast digital radio programming (FCC 2002b). In fact, iBiquity has also been actively pursuing adoption of its IBOC technology by the international community. In October 2002, the ITU adopted Recommendation ITU-R BS.1514-1, which endorses iBiquity's AM IBOC technology as a standard for digital broadcasting in the broadcasting bands below 30 MHz (International Telecommunication Union 2002, "System for digital sound"). In January 2007, the ITU approved the recommendation ITU-R BS.1114-6 "Systems for terrestrial digital sound broadcasting to vehicular, portable and fixed receivers in the frequency range 30–3,000 MHz" (ITU 2007). iBiquity's FM IBOC system is listed as its Digital System C (refer to ITU-R BS.1114-6 "Annex 4: Digital System C" at <http://www.itu.int/rec/R-REC-BS.1114-6-200701-I/en>).

The IBOC technology that uses each station's current frequency and bandwidth to broadcast a hybrid of analog and digital programming has been accepted by the radio industry. HD Radio is the trademark of IBOC technology developed by iBiquity Digital. According to the FCC, as of October 1, 2003, more than 280 radio stations had licenses for iBiquity's technology and had begun HD radio broadcasting or were in the process of conversion (FCC 2004).

iBiquity Digital is the leading company of IBOC technology. It has partnership with companies of receivers,

semiconductors, radio broadcasters, automakers, and data service providers, and is supported by financial industries. Among the partners, consumer electronics manufacturers include Alpine, Clarion, Delphi, Denon, Fujitsu Ten, Harman Kardon, iLAB America, JVC, Hyundai AutoNet, Kenwood, Marantz, Mitsubishi, Onkyo, Oritron (Orient Power), Panasonic, Sanyo, Visteon, and Yamaha. Radio broadcasters include ABC, CBS, Clear Channel, Cox Radio, Beasley Broadcast Group, Bonneville International, Citadel Communications, Cumulus Media, Emmis Communications, Entercom Communications, Hispanic Broadcasting, Radio One, Regent Communications, Saga Communications, and Susquehanna Communications. Manufacturing owners include Ford Motor Company, Harris Corporation, Texas Instruments, and Visteon Corporation. Leading financial institutions such as J.P. Morgan Partners, Pequot Capital, and New Venture Partners are also owners of iBiquity Digital.

The National Association of Broadcasters, the National Radio Systems Committee, and the Consumer Electronics Association have been fully participating in evaluation, standard setting, promotion, and training activities to help the transition process from analog radio to digital radio. In October 2004, the NAB conducted an HD Radio workshop in San Diego, California. The certification workshop was "designed to familiarize broadcast engineers and managers with iBiquity Digital Corporation's HD Radio digital audio broadcast system for the AM and FM bands." Experts from iBiquity Digital, equipment manufacturers, consultants, and broadcasters gave presentations on a variety of topics, including "Signal Performance and Antenna Systems For HD Radio," "Transmitters, Tests and Measurements for HD Radio," and "Studios, Audio and Data for HD Radio" (National Association of Broadcasters 2004, "Certification"). Since then, this workshop has been continuously offered online via Webcasting (National Association of Broadcasters 2004, "Workshop Webcast").

There have been a few "firsts" in the history of HD Radio.

In Los Angeles, KROQ 106.7 became the first FM radio broadcaster to convert to HD Radio digital broadcasting on the West Coast, using a Harris Z series exciter to amplify both analog and digital signals. According to the iBiquity report, KROQ's digital broadcasting is generated by a lower power (43-watt) transmitter and delivered through a relatively lower height antenna, but it covers as much of the Los Angeles market as that covered by the station's 4.3 KW analog signal. It not only provides near-CD sound without static, hiss, pops, or fades but also supports on-demand interactive audio that gives listeners more control over what program they want to choose and when they want to listen to it (iBiquity Digital 2006, "KROZ-FM").

In New York City, WOR 710 became the first AM station in the United States to widely test the HD Radio system. WOR first went on the air to test and demonstrate the HD Radio technology for iBiquity Digital on October 11, 2002. iBiquity was able to assess the quality and reliability of the HD Radio system's signal and equipment. WOR became fully licensed in December 2002. The station is impressed by the near-FM quality of the AM digital

audio and the elimination of noises and other interferences (iBiquity Digital 2006, "WOR-AM").

On January 7, 2004, the Ultimate Electronics store in Cedar Rapids, Iowa, sold the first HD Radio tuner, a model Kenwood KTC-HR100, to Nathan Franzen. Franzen became the first consumer nationwide to purchase an HD Radio receiver and listen to HD Radio programming. He appreciated the HD Radio sound quality while tuning to the music program from KZIA-FM 102.9 (Z102.9), a radio station in Cedar Rapids. This sale marked the introduction of HD Radio to the consumer market. This event was part of the activities sponsored by the 2004 International Consumer Electronics show in Las Vegas. According to an iBiquity press release, "Cedar Rapids, Iowa, was selected partly because of its heritage as the hometown of Arthur Collins and the Collins Radio Company. In 1925, Collins, as a fifteen-year-old, received radio transmissions for the first time from Greenland. He eventually founded Collins Radio, which provided voice communication technology for every American traveling in space" (iBiquity Digital 2006, "Iowa").

Although the FCC did not announce a cutoff date, the progress in adopting and converting to HD Radio has been quite impressive (see Table 6). As of July 2007, there were 1,344 HD Radio stations on the air. Among those, 627 stations provide multichannel programs to the listeners.

United Kingdom and Other Countries:

Eureka 147 and DRM

Eureka 147. In 1994, Eureka 147 was adopted as a world standard (Digital Radio Development Bureau 2006), and in September 1995 the BBC debuted its national digital radio broadcasting in the United Kingdom (BBC 2006c). In accordance with the technological development, trade bodies such as the World DAB (an international nongovernmental organization) and Digital Radio Development Bureau (sponsored by the BBC and UK commercial radio multiplex operators) were

established to promote and coordinate the implementation of digital radio services based on the Eureka 147 system. Those nonprofit trade organizations developed membership from more than one hundred companies and organizations in thirty countries. The membership consists of public and private broadcasters, digital radio receiver and other electronic equipment manufacturers, transmission providers, regulators, and governmental bodies. Therefore, technological achievement has been converted to a worldwide commercial marketing success. According to the World DAB, "Over 475 million people around the world can now receive more than 1,000 different DAB services. Commercial DAB receivers have now been on the market since summer 1998. There are now more than 200 different DAB and over 150 DMB receivers commercially available. A receiver archive is available on this site, which exhibits DAB/DMB car radios, hi-fi's, portable receivers, PC cards, USBs, mobile phones, computers and other DAB/DMB equipment that have been developed." (World DAB 2007).

Currently, European countries such as Denmark, Norway, Belgium, the Netherlands, Switzerland, Germany, Spain, Portugal, and Italy have digital radio services. Sweden has been continuously on a national trial of digital radio broadcasting. France began digital radio services in five major cities in October 2005. Finland's national public service broadcasting, YLE Communications, introduced DAB in 1997 but announced in February 2005 that it would shut down DAB to consider other alternatives to implement digital radio broadcasting. Canada, Singapore, Korea, and Australia have launched operational or pilot services. Hong Kong (L band from 1998 to 2001; VHF band III from August 2004 to February 2006), Taiwan, China, and India have begun experimental service, and Mexico and Paraguay have expressed their advanced interest in digital radio broadcasting. Table 7 shows recent status of implementation among European, Asian, and African countries.

A receiver archive is available on World DAB's Web site, which exhibits DAB car radios, stereo systems, portable

receivers, PC cards, and other DAB equipment. According to a sales report by the World DAB Forum (World DAB 2006, "International"), in December 2005 a cumulative total of 2.716 million DAB sets were used in UK homes. Approximately 5.4 million people listened to digital radio on DAB sets (GfK Marketing Services 2005). Approximately 11.1 percent of UK residents lived in DAB households, and there were more listeners to digital radio via DAB sets than via the Internet and DTV combined (RAJAR 2006).

Digital Radio Mondiale. The DRM system has been tested and adopted by counties around the world. DRM broadcasts are now available in Europe, North America, and North Africa. Testing is underway in Latin America and Asia. The DRM services are also delivered online via the DRM Consortium Web site (www.drm.org) and in Germany (www.deutsches-drm-forum.de), France (www.drmfrance.com), and Russia (www.radiostation.ru/drm/index.php), as well as by U.S. DRM group (www.usdrm.com). In September 2005, the

BBC used DRM technology to launch its World Service programming in English to the Benelux countries and neighboring parts of France and Germany (BBC 2005).

During the International Broadcasting Convention (IBC) held in Amsterdam in September 2002, different DRM receivers were demonstrated. According to Jackson (2003, 1),

All the receivers were demonstrated receiving, at different times of the day, live SW transmissions from Sines in Portugal (Deutsche Welle: 1,922 km.), Sackville in Canada (Radio Canada International: 4,892 km), Bonaire in the Netherlands Antilles (Radio Netherlands: 7,796 km.), Juelich in Germany (T-Systems Media-Broadcast: 188 km.) and Rampisham in the UK (VT Merlin Communications carrying BBC WS programmes: 546 km.) and a continuous local 26 MHz SW service of audio with multimedia from Hilversum (RNW: 22 km).

During the ITU's World Radiocommunication Conference in June 2003, leading international, national, and local broadcasters simultaneously sent the world's first live, daily Digital Radio Mondiale broadcasts to Geneva. Broadcasters in Europe (International Broadcasters, BBC World Service, Christian Vision, Deutsche Welle, Radio France Internationale, Radio Netherlands, Radio Vaticana, Swedish Radio International, Voice of Russia, and Wales Radio International), the Middle East (Kuwait Radio and Ministry of Information of Kuwait), and North America (Radio Canada International and Voice of America) participated in the DRM debut broadcasting (DRM 2003).

In September 2005, the world's first, affordable DRM-capable consumer receivers, as well as car radios, were unveiled at the consumer electronics show IFA in Berlin. These products were also showcased in Amsterdam at the IBC that month. Texas Instruments and RadioScape introduced three multistandard, tabletop consumer radios with DRM, DAB, long-wave, medium-wave, and short-wave capabilities. Those radio sets used RadioScape's RS500 module and TI's DRM350 multistandard digital radio baseband. The receivers also possessed a variety of features such as storage, pause, built-in stereo speakers, recording, and playback (DRM 2005b).

International Digital Radio Broadcasting: DRM

The DRM system was originally developed for the band below 30 MHz, including low frequency, medium frequency radio services for AM spectrum stations, and high frequency shortwave stations. The shortwave radio is usually used for international radio broadcasting. The DRM Consortium Web site lists DRM live international broadcast schedules (DRM 2006). Approximately 110 stations worldwide broadcast DRM service daily. Among them, the majority are shortwave radio stations targeting international listeners.

Webcasting

Theoretically, audio Webcasting should be an ideal digital radio format to meet the needs of both domestic and international information, sports, and entertainment. It also provides interactive functions to let listeners control what they want to listen to and when to listen to it with no limitation of time or geography. However, the delivery and distribution of Webcasting is problematic. The quality is not good enough, and the signals are often delayed or interrupted during peak Internet hours. It needs more research and development. Therefore, audio Webcasting currently seems more technological promise than realistic radio industry. It serves for online music purchasing and as a supplementary archiving and promotional tool for traditional audio broadcasting.

CONCLUSION

The three kinds of terrestrial digital radio systems—Eureka 147, in-band on-channel, and Digital Radio Mondiale—have been tested and adopted for domestic and

international radio broadcasting. Originally developed to be a supplementary system of Eureka 147, DRM has been used by countries worldwide to replace analog AM and FM radio services allotted in the LF, MF, HF, and VHF spectra. Although Eureka 147 provides excellent-quality radio and data services, DRM seems more attractive to those countries that do not have the resources for extra spectra in VHF band III or L band. The DRM Consortium plays a leading role in developing DRM technology and membership and in coordinating technical and marketing activities internationally. DRM has shown great potential in digital radio broadcasting.

IBOC is the standard of digital audio broadcasting in the United States as approved by the FCC. HD Radio has become an industry standard promoted by the National Association of Broadcasters. Still, the DRM system, as an international standard, is also promoted in the United States by the USA DRM Group. The group is examining "the possibility of using 26 MHz frequencies in the United States in DRM mode for local broadcasting (and maybe even sky wave broadcasting) with low power (10 watts to 1 kilowatt) to cover small areas such as universities and towns" (USA DRM Group 2005).

As a matter of fact, HD Radio provides multicasting capabilities to terrestrial radio stations that maintain analog programs along with digital programs and lets listeners receive programs for free. The 2006 NAB radio show in Dallas and the 2007 NAB convention in Las Vegas paid special attention to promoting and converting to HD Radio. In May 2007, the FCC released rules for HD Radio, such as operating hours and AM nighttime operation (FCC 2007b). The adoption of HD radio grows daily. Up to July 2007, there were 1,344 HD radio stations on air, of which 627 were multicasting (see Table 6). It is important to notice that the current 1,344 HD radio stations constitute approximately 10 percent of the total number of radio stations (13,837, which is the total number of the traditional AM and FM stations, excluding FM translators and boosters, and low-power FM stations) in the United States. Therefore, the conversion from analog to digital radio broadcasting seems an inevitable trend.

The two satellite digital radio services provided by XM and Sirius are still in their growing stages in the United States. The total number of SDARS subscribers reached 14.5 million in the first quarter of 2007 (Sirius Satellite Radio 2007; XM Satellite Radio 2007). The advantage of the SDARS is situated in the potential of program content, which enjoys more freedom of expression than traditional radio broadcasting, and its capability of providing international radio services such as WorldSpace. However, the FCC is closely monitoring the SDARS performance and does not allow interference of the SDARS with conventional free radio.

The competition among satellite radio, HD Radio, and Webcasting in the United States is critical to XM and Sirius satellite radio providers. The satellite radio companies, XM and Sirius, need more collaboration than competition in order to stay strong in the radio market. In February 2007, Sirius and XM reached an agreement to merge and retain the XM name; the consolidated applications were submitted to the FCC for approval in March 2007. According to the merging plan, a new board of directors

selected by both Sirius and XM will control the surviving entity and "its equity will be represented equally by former shareholders of XM and Sirius prior to the merger" (FCC 2007c, "Public Notice"). This action initiated a great deal of discussion in the radio industry regarding monopoly and antitrust matters. In June 2007, the FCC issued a notice of proposed rule making to seek comments on this merger application "because the proposed transfer conflicts with language prohibiting such a combination in the Commission's 1997 Order establishing the Satellite Digital Audio Radio Service (FCC 1997a, "SDARS Report & Order"; FCC 2007d). The rule-making focus is on "whether the language in question constitutes a binding Commission rule and, if so, whether the Commission should waive, modify, or repeal the prohibition in the event that the Commission determines that the proposed merger, on balance, would serve the public interest" (FCC 2007d).

Although the satellite radio merge has not been decided, terrestrial HD Radio, SDARS, and audio Webcasting will co-exist. More collaboration among these three outlets will be seen as enhancing program production and distribution in order to better serve the public interest, a mission set up early in the Communication Act of 1934.

GLOSSARY

Audio Webcasting: Audio programs such as news, music, sports, and talk shows are delivered through the Internet and can be accessed through the Web pages of content providers.

Digital Audio Broadcasting (DAB): Trademark of the Eureka 147 project's digital radio broadcasting system.

Digital Radio Broadcasting (DRB): The generic term used to describe digital radio/digital audio broadcasting systems.

Digital Radio Mondiale (DRM): Digital radio broadcasting licensed for the band under 30 MHz. Currently, the DRM technologies are adopted mostly for international radio broadcasting.

Eureka 147: DAB system developed under the Eureka 147 Project and standardized by the European Telecommunications Standards Institute in 1995.

HD Radio: Trademarked IBOC technology implementation that provides enhanced sound fidelity (near-CD quality), improved reception, and new data services.

In-Band On-Channel (IBOC): Developed by the iBiquity Digital Corporation and approved as the digital radio broadcasting technology by the FCC in October 2002.

INTRODUCTION

In the developed countries, the number of wireless access connections between the user terminals of a telecommunication network (phones, laptops, palmtops, etc.) and the fixed, high-capacity transport network has already exceeded the number of wired connections. Untethered communications and computing has become sort of a lifestyle, and the trend will undoubtedly continue in the near future with the development of Wi-Fi hot spots, wireless voice-over-IP (VoIP) terminals, and so on. The picture we have just depicted is what we may call the *wireless revolution* (Rappaport 1991). Beginning in Europe in the early 1990s, it is still ramping up with its adoption by Asian countries (Sasaki, Yabusaki, and Inada 1998). The driving elements of this revolution are the reduction of size and cost, together with the performance increase, of electronic components for *digital signal processing* (DSP), which allows a highly efficient implementation of source and channel coding, modulation, signal synchronization and equalization, and multiple access functionalities. In particular, modern mobile cellular systems have benefited from the adoption of *spread-spectrum* (SS) signaling techniques that will be treated in detail in the following sections.

Second- and Third-Generation Cellular Systems

The real start of the revolution was the advent of *second-generation* (2G) communications, which was inaugurated in 1991 by the well-known *global system for mobile* (GSM)

communications (Padgett, Günther, and Hattori 1995), a digital pan-European *time division multiple access* (TDMA) cellular communication system. Actually, the growth of cellular communications had already started with earlier *first-generation* (1G) analog systems, but the real breakthrough was marked by the initially slow, then exponential, diffusion of GSM terminals, fostered by continent-wide compatibility through international roaming. In the United States, the advent of 2G digital cellular telephony was somewhat slowed down by the coexistence of incompatible systems and the consequent lack of a nationwide accepted unique standard (Padgett, Günther, and Hattori 1995). The two competing 2G American standards were the so-called digital *advanced mobile phone system* (AMPS) IS-54/136, whose technology was developed with the specific aim of being backward-compatible (as far as the assigned radio channels are concerned) with the preexisting 1G analog AMPS system, and the highly innovative *code division multiple access* (CDMA) system *interim standard* 95 (IS-95) (Kohn, Meidan, and Milstein 1995; Gilhousen et al. 1991). Although slower to gain momentum, 2G systems in the Americas had the merit of being the first to commercially introduce the SS technology and CDMA that in a few years would have been adopted worldwide for *third-generation* (3G) systems. A similar story about 2G digital cellular telephony could be told about Japan and its personal digital cellular system, which is actually quite similar from a technical standpoint to the American IS-54/136. China did not align itself with any of the digital 2G standards, while India adopted GSM but with a relatively

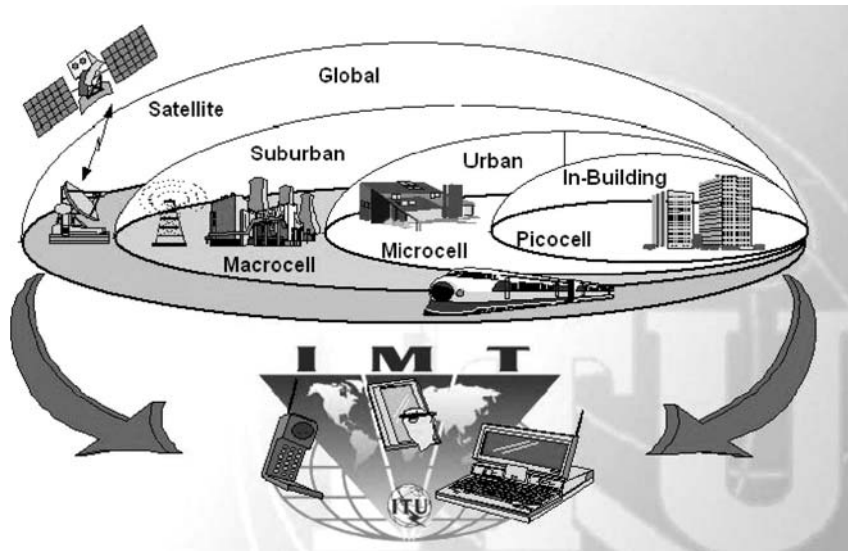

Figure 1: Architecture of a system compliant with International Mobile Telecommunications-2000 (from www.itu.org)

low level of penetration into the market. The number of GSM subscribers in India reached 65 million (i.e., approximately 6.5 percent of the population) by February 2006 (Cellular Operators Association of India 2007).

At the dawn of the third millennium, the International Telecommunications Union based in Geneva, Switzerland, took the initiative of promoting the development of a universal 3G mobile and personal wireless communication system with high capacity and a high degree of interoperability among the different network components (see Figure 1). Under the initiative International Mobile Telecommunications for the Year 2000 (Chia 192), a call for proposals was issued in 1997 to eventually set up the specifications and technical recommendations for a universal system. At the end of the selection procedure, and in response to the different needs of the national industries and telecom operators, three major but incompatible standards survived: *Universal Mobile Telecommunication System* (UMTS) for Europe and Japan (Dahlman et al. 1998; Adachi, Sawahashi, and Suda 1998), *CDMA2000* for the Americas (Knisely et al. 1998) and *time division synchronous code division multiple access* (TD-SCDMA) for China (Li et al. 2005). All are based on a different mixture of TDMA and CDMA technologies, but the real common innovative factor is the universal adoption of SS signals for a maximum of flexibility and multimedia support. A more detailed description of 2G and 3G CDMA-based wireless systems will be presented later.

In the following, we briefly outline the different SS techniques that are currently adopted to establish a multimedia (i.e., voice, video, and data) full duplex link between a *mobile terminal* (MT) and the *base station* (BS) of a cellular radio communication access network.

FUNDAMENTALS OF DIGITAL SPREAD-SPECTRUM SIGNALING

Narrowband

By the term *narrowband*, we indicate a data-modulated signal whose bandwidth around its carrier frequency is

comparable to the information bit rate. Most popular narrowband modulated signals are *phase shift keying* (PSK), *quadrature amplitude modulation* (QAM), and a few nonlinear modulations such as *Gaussian minimum shift keying* (GMSK) which belongs to the broader class of continuous phase modulation (Proakis 1995). More details about these formats can be found in other chapters of this handbook. For the convenience of the reader, before describing SS signals we will review the basics of linearly modulated PSK and QAM signals.

The expression of a bandpass modulated signal $s_{BP}(t)$ is

$$s_{BP}(t) = s_I(t) \cdot \cos(2\pi f_0 t) - s_Q(t) \cdot \sin(2\pi f_0 t) \quad (1)$$

where f_0 is the carrier frequency and $s_I(t)$ and $s_Q(t)$ are two baseband signals that represent the *in-phase* (I) and *quadrature* (Q) components, respectively, of the *phase-quadrature* (I/Q) modulated signal. A more compact representation of the modulated signal in Equation 1 is its complex envelope (or baseband equivalent), defined as $s(t) \triangleq s_I(t) + js_Q(t)$, where $j \triangleq \sqrt{-1}$. The relationship between the bandpass modulated signal and its own complex envelope is straightforward: $s_{BP}(t) = \Re\{s(t) \cdot \exp(j2\pi f_0 t)\}$, where $\Re\{\cdot\}$ stands for the “real part” of the complex-valued argument. In the case of a linear modulation, the complex envelope of $s_{BP}(t)$ is made of uniformly spaced data pulses as follows:

$$s(t) \triangleq A \cdot \sum_{i=-\infty}^{\infty} d[i] \cdot g_T(t - iT_s) \quad (2)$$

where $d[i] \triangleq d_1[i] + jd_2[i]$ is the i th transmitted symbol taken from a constellation of W points lying in the complex plane. The usual assumption is that the i th data symbol $d[i]$ is a random variable with uniform probability distribution over the W -point constellation alphabet and that $d[i]$ is statistically independent of $d[k]$, $i \neq k$. In addition, T_s is the signaling interval (i.e., the inverse of the symbol rate R_s), and $g_T(t)$ is a T_s -energy pulse.

If we denote with P_s the average power of the modulated signal in Equation 1, the average energy per data symbol is $E_s = P_s \cdot T_s$, and the amplitude coefficient in Equation 2 is equal to $A \triangleq \sqrt{2P_s/E[d[i]^2]}$, where $E\{\cdot\}$ stands for statistical expectation. Each symbol $d[i]$ in the constellation is addressed (labeled) by a word of $\log_2(W)$ binary symbols (bits) from a binary information source running at rate $R_b = R_s \log_2(W)$.

The *power spectral density* (PSD) of the signal in Equation 2 is proportional to $|G_T(f)|^2$, where $G_T(f)$ is the Fourier transform of the pulse shape $g_T(t)$. As a result, the (one-sided) spectral occupancy B of a narrowband modulated signal is strictly related to the bandwidth of the pulse shape $g_T(t)$. For instance, in the case of a transmission with *non-return-to-zero* (NRZ) rectangular pulses, the baseband occupancy, evaluated at the first spectral null, is $B = R_s$, whereas in the case of Nyquist's *square root raised cosine* (SRRC) band-limited pulse, the baseband occupancy is $B = (1 + \alpha)R_s/2$, where $0 \leq \alpha \leq 1$ is the pulse roll-off factor. Notice that the bandwidth occupancy B_{RF} of the modulated signal is twice that of the baseband signal—that is, $B_{RF} = 2B$.

Spread Spectrum

With the term *spread spectrum*, we address any modulated signal that has a bandwidth around the carrier frequency that is much larger than its information bit rate. In SS signaling, the bandwidth occupancy of the transmitted signal is intentionally increased well beyond the value required for conventional narrowband transmission, leaving unchanged the transmitted power. This is done to enhance signal robustness against interference, be it intentional (i.e., hostile jamming) or unintentional (e.g., human-made noise or narrow- and wideband transmitters operating on the same carrier frequency), and against the distortion caused by a frequency-selective radio channel. Spectral spreading also reduces the level of radiated power density (i.e., watts per hertz) and thus allows the simultaneous utilization of the same (wide) bandwidth by multiple users (this is called *multiple access*). Spectrum spreading can be essentially accomplished in two ways—namely, by frequency hopping and direct sequence.

Frequency-Hopping Spread Spectrum

Frequency-hopping spread spectrum (FHSS) was conceived in 1941 to provide secure military communications during World War II (Scholtz 1982), and it is based on a simple idea: Just (rapidly) change the transmit carrier frequency every T_{hop} seconds. The radio signal spectrum then “hops” from frequency to frequency following a periodic, pseudorandom (i.e., apparently random) sequence of carrier values to escape hostile jamming or eavesdropping by unauthorized listeners. The long-term spectrum of such signal “spans” a large *radio frequency* (RF) bandwidth and implements a spread-spectrum modulation (Simon et al. 1994; Dixon 1994). The (periodic) frequency hop pattern is also made known to the authorized receiver which is then capable of tracking the transmitted carrier and demodulate the transmitted data. The majority of commercial applications rely on *direct sequence spread spectrum* (DSSS),

while military communications often adopt FHSS because of the larger spreading factors (see “Spectral Spreading Performance Figures” below).

The current most popular technology that uses some form of FHSS is Bluetooth (Haartsen et al. 2000), which is an open standard for short-range, low-power, low-cost, and low-speed wireless data communications. Bluetooth radio interfaces are currently available in PCs and peripherals (allowing cable-free connections), in cell phones and headsets (allowing hands-free telephony), and in many other home appliances and consumer electronic equipments. Bluetooth operates in the unlicensed 2.4-GHz *industrial, scientific, and medical* (ISM) band, which is also used by 802.11 b/g devices, HomeRF devices, portable phones, and microwave ovens. To minimize the amount of interference caused against these devices operating in the same band, Bluetooth radio access is based on an FHSS technology that uses seventy-nine channels, each with a nominal bandwidth of 1 MHz at a “hop” rate of 1600 changes of frequency per second. Tight restrictions about the maximum allowed peak power output in the ISM band limit the range of Bluetooth devices to approximately a few tens of meters.

In the following, we will restrict our attention to the most popular cellular communication standards that account for the vast majority of commercial applications. Therefore, proprietary or local solutions having limited diffusion; military communications, for which scarce up-to-date information is available, will not be dealt with any further. However, the general knowledge of spread-spectrum signals should be enough also to understand the basic operation of such systems.

Direct Sequence Spread Spectrum

Spectral spreading is accomplished by direct multiplication in the time domain of the information-bearing symbols, running at rate $R_s = 1/T_s$, with a sequence of pseudorandom binary symbols (the so-called chips) $c[k]$ running at the much higher rate $R_c \triangleq 1/T_c \gg R_s$, with T_c the chip interval (Dixon 1994; Pickholtz, Schilling, and Milstein 1982; Simon et al. 1994). The result of this product (which is carried out before transmit pulse shaping takes place) is a stream of “chipped” high-rate symbols running at the chip rate R_c . The signal to be transmitted turns out to have a bandwidth occupancy that is much wider than that of conventional modulation schemes—in particular, comparable to the chip rate. The binary sequence $\{c[k]\}$, addressed as spreading sequence or spreading code, is periodic with period L chips, and has *pseudonoise* (PN) characteristics—that is, zero mean and an autocorrelation sequence as close as possible to an impulse function (Dinan and Jabbari 1998).

DSSS Signal Model

Assuming that one symbol interval T_s spans an integer number M of chip intervals T_c of the spreading sequence (i.e., $M \triangleq T_s/T_c = R_c/R_s$ is an integer), a DSSS signal can be represented as

$$s^{(ss)}(t) \triangleq A \cdot \sum_{k=-\infty}^{\infty} d[k/M] \cdot c[k]_L \cdot g_T(t - kT_s) \quad (3)$$

where we defined the operators $k//M \triangleq \text{int}(k/M)$, and $|k|_L \triangleq k \bmod L$. The spreading sequence $c[k]$, either real- or complex-valued, runs at rate $R_c = 1/T_c$, and therefore a new T_c -energy chip shaping pulse $g_T(t)$ is generated every T_c seconds. The chip index k “ticks” at the rate R_c , and the spreading code index $|k|_L$ cycles over the interval $0, 1, \dots, L-1$ every L chip intervals scanning the whole code length. The data index $k//M$ runs at the symbol rate $R_s = R_c/M$ —that is, it is updated every M ticks of the index k . The normalization constant is again $A \triangleq \sqrt{2P_s/E[d[i]]^2}$, and the average energy per chip is now $E_c = P_s \cdot T_c$.

Real Spreading

In *real spreading* DSSS (RS DSSS), the spreading sequence $c[k]$ is real-valued, and the chips usually belong to the alphabet $\{-1, +1\}$. In the particular case of complex-valued data $d[i]$, such a DSSS format is named *quadrature real spreading* (Q-RS).

Complex Spreading

In complex spreading DSSS (CS DSSS), the spreading sequence $c[k]$ is complex-valued—that is, $c[k] \triangleq c_r[k] + j c_o[k]$, where both the real and the imaginary part of the sequence are as in RS above. Two spreading codes are thus needed for the transmission of a CS DSSS signal. This popular spreading technique is employed by several commercial systems (see “A Review of 2G and 3G Standards for CDMA” for more details): IS-95 uses CS with real-valued data symbols $d[i]$, whereas UMTS or CDMA2000 also feature CS with complex data.

DSSS Bandwidth Occupancy

The bandwidth occupancy of the DSSS signal is dictated by the chip rate R_c (as is apparent from Equation 3) and by the shape of the basic pulse $g_T(t)$. For instance, in the case of a DSSS transmission with NRZ rectangular chip shaping, the baseband occupancy of the SS signal in Equation 3, when evaluated at the first spectral null, is $B^{(ss)} = R_c$ and thus $B^{(ss)} \gg B$. However, apart from particular applications, mainly military communications and the global positioning system radiolocation system, the spectrum of the DSSS signal is strictly band-limited because of regulatory issues. This leads to the definition of a band-limited spread spectrum signal (which may sound as a sort of paradox). As in the case of conventional narrowband modulations, spectrum limitation can be achieved by resorting to Nyquist SRRC shaping of the chip pulses so that the bandwidth occupancy becomes $B^{(ss)} = (1 + \alpha)R_c/2$ for the baseband signal and $B_{RF}^{(ss)} = (1 + \alpha)R_c$ for the modulated signal.

Spectral Spreading Performance Figures

The bandwidth spreading of a DSSS system is quantified by two parameters, namely, the spreading factor and the processing gain.

The spreading factor is defined as $M \triangleq T_s/T_c = R_c/R_s$ and represents the ratio between the bandwidth occupancy of the SS signal $B^{(ss)}$ and the bandwidth B of the corresponding narrowband modulated signal with the same

symbol rate. Typical values of the spreading factor commonly adopted in commercial wireless communication systems range from 4 to 512. If channel coding is used, and the chip and bit rates are kept constant, the spreading factor is reduced by a factor r , where $r < 1$ is the coding rate. This is easily understood because channel coding has the effect of increasing the symbol rate by a factor $1/r$, thus expanding the signal bandwidth by the same factor before spectrum spreading takes place. Keeping the chip rate constant means keeping the same RF bandwidth, and so the net result is a decrease of the spreading factor.

The processing gain is defined as $G_p \triangleq T_b/T_c = R_c/R_b$ and, in the absence of channel coding, is related to the spreading factor as $G_p = M/\log_2(W)$. As is apparent, the two are coincident only in the case of binary modulation with no channel coding. The processing gain is the standard figure of merit of the antijamming capability of the DSSS signal (Simon et al. 1994).

Short Code

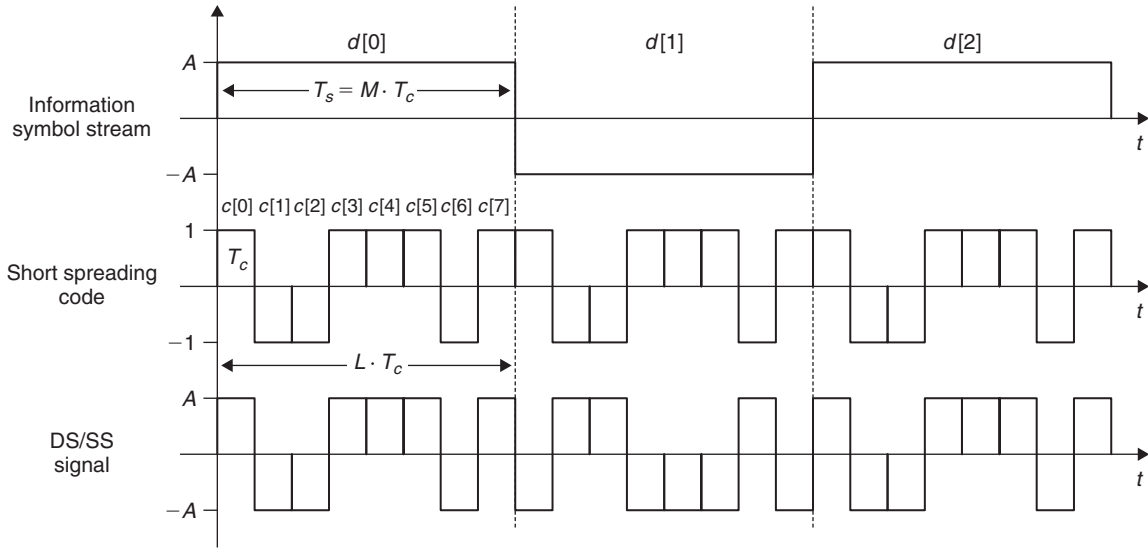

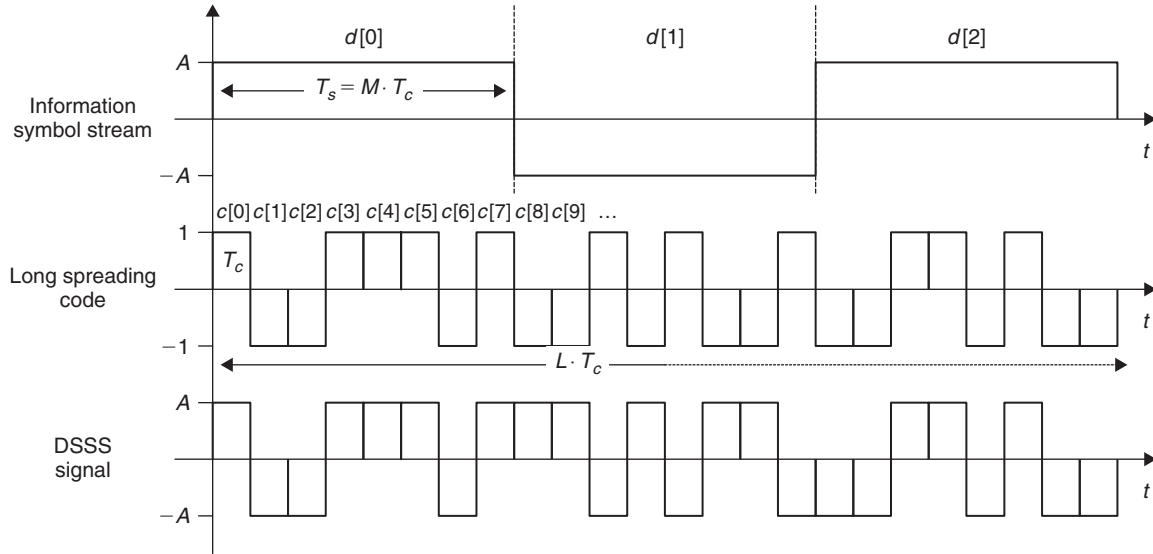

A spreading sequence is called *short code* when one data symbol interval exactly spans a (small) integer number n of the spreading sequence repetition periods—that is, $T_s = nLT_c$. In this case, the spreading factor is $M = nL$. The simplest and most adopted short code spreading arrangement is the case with $n = 1$, whereby the code repetition period is equal to one symbol interval, and $M = L$. An example of signal spreading by a short code, with $M = L = 8$ and NRZ chip shaping is shown in Figure 2. Short code spreading is specified as an option for the *uplink* (UL)—that is, from MT to BS—of UMTS (see “A Review of 2G and 3G Standards for CDMA Mobile Communications” below) to enable multi-user detection.

Long Code

A spreading sequence is called *long code* when its repetition period is much longer than the data symbol duration—that is, $LT_c = T_s$. In this case, the spreading factor is $M \ll L$. An example of signal spreading by a long code, with $M = 8$ and $L = 24$, is shown in Figure 3. Long code spreading is specified for the *downlink* (DL)—that is, from BS to MT—of UMTS and for both the DL and UL of IS-95 and CDMA2000 (see “A Review of 2G and 3G Standards” for more details).

Pseudorandom Sequence Generators

A real-valued binary spreading sequence $c[k]$ with pseudo-noise properties is also called *pseudorandom binary sequence* and can be generated by an m -stage *linear feedback shift register* (LFSR) whose taps are properly set according to polynomial theory (Peterson and Weldon 1972). In particular, it is possible to design sequence generators based on one or more LFSR structures (Dixon 1994; Pickholtz, Schilling, and Milstein 1982; Simon et al. 1994; Dinan and Jabbari 1998) so as to obtain spreading codes with random-like appearance and special features as far as the repetition period and the correlation properties are concerned (Sarwate and Pursley 1980). The reader is referred to Dixon (1994) for further details on the main sets of

Figure 2: DSSS signal with short code, $M = L = 8$ Figure 3: DSSS signal with long code, $M = 8, L = 24$

pseudorandom codes used in the practice (maximal length codes, Gold codes, and Kasami codes).

Basic Architecture of a DSSS Modem

Figure 4 shows the general outline of the modulator section of a digital DSSS modem, where, as customary, thick lines denote complex-valued signals (such a graphical notation will be used also in the subsequent diagrams). The information-bearing binary data undergo channel encoding and are mapped onto a complex constellation, thus yielding the data symbol stream $d[i]$ running at symbol rate R_s .

The symbol stream $d[i]$ is then oversampled (repeated) by a factor M , and spectrum spreading is eventually accomplished by direct multiplication with the spreading code $c[k]$ running at chip rate $R_c = MR_s$. Next, chip pulse shaping is performed in the digital domain by a finite

impulse response filter featuring SRRC response $g_T[m]$ and operating at sample rate $R_{sa} \triangleq 1/T_{sa}$ (for instance, $R_{sa} = 4R_c$). The resulting baseband DSSS signal at the filter output is a digital version of the signal in Equation 3 with a sampling frequency R_{sa} . Such a DSSS signal is up-converted to a digital *intermediate frequency* (IF) f_D , then digital-to-analog conversion takes place, followed by conventional analog processing (final upconversion to RF, power amplification, and band limiting) before the signal is sent on the air.

The basic outline of the twin demodulator section is sketched in Figure 5. The analog received signal undergoes RF amplification and filtering, followed by downconversion to IF. In many state-of-the-art implementations, analog-to-digital conversion takes directly place at IF with bandpass sampling techniques as shown. The conversion rate R_{ADC} is invariably faster than the chip rate R_c to perform subsequent baseband filtering with no aliasing issues

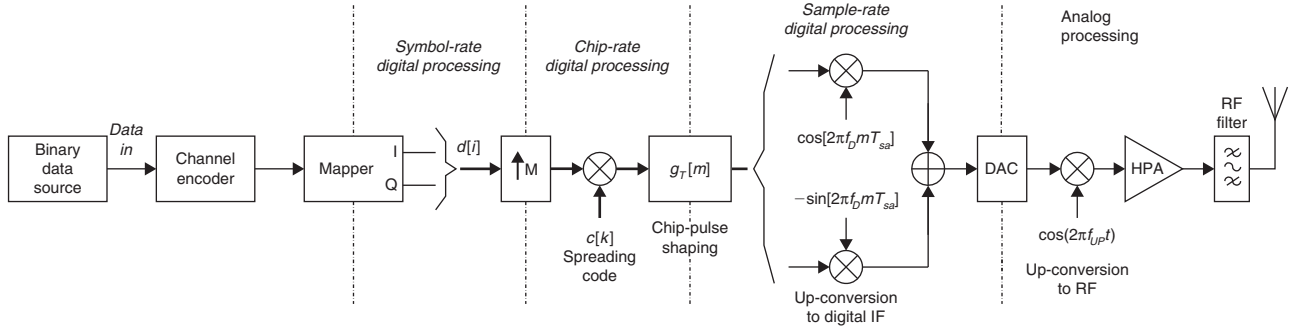

Figure 4: Block diagram of the transmit section of a digital DSSS modem

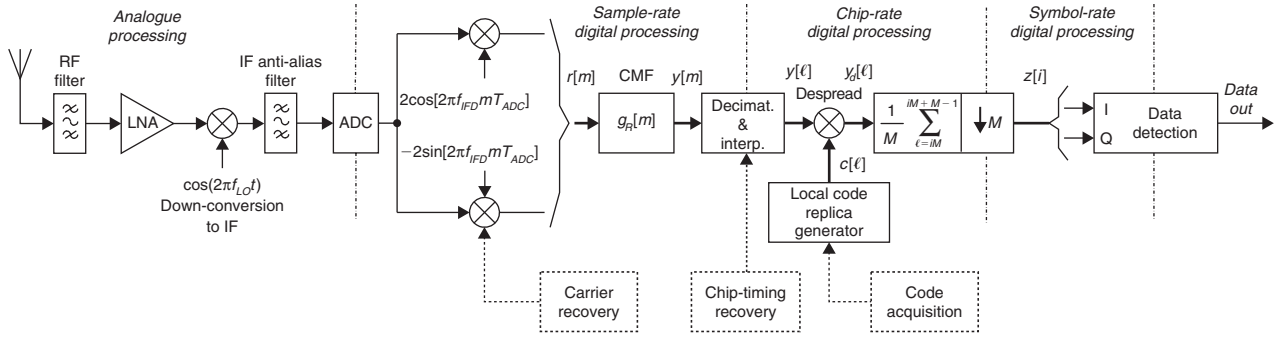

Figure 5: Block diagram of the receive section of a digital DSSS modem

(e.g., $R_{ADC} = 4R_c$). The digital signal is then converted to baseband by an I/Q demodulator driven by a digital oscillator under the control of the carrier synchronization unit (see “Architecture of Spread-Spectrum Receivers”). Each component of the resulting complex signal $r[m]$ is fed to a filter $g_R[m]$ matched to the chip pulse (*chip-matched filter*, CMF). On both I/Q rails, a decimator-interpolator changes the clock rate of the digital signal $y[m]$ and takes the optimum samples $y[\ell]$ at chip rate from the digital stream available at the filter output.

Assuming SRRC chip pulse shaping in the transmitter, propagation channel affected by *additive white Gaussian noise* (AWGN), ideal CMF in the receiver, and perfect chip timing and carrier synchronization, the chip-rate signal $y[\ell]$ at the decimator-interpolator output is

$$y[\ell] = A \cdot d[\ell/M] \cdot c[\ell]_L + n[\ell] \quad (4)$$

where $n[\ell]$ is a random process (which represents the contribution of the filtered channel noise) whose I/Q components are independent, identically distributed zero-mean Gaussian random variables with variance $\sigma_n^2 = N_0/T_c$ (N_0 is the one-sided power spectral density of the receiver noise). Subsequently, the spreading code is removed from the received signal by performing the so-called despread-ing operation:

$$y_d[\ell] = y[\ell] \cdot c[\ell]_L = A \cdot d[\ell/M] \cdot c^2[\ell]_L + n[\ell]c[\ell]_L = A \cdot d[\ell/M] + n'[\ell] \quad (5)$$

where we took into account that $c^2[\ell]_L = 1$, and where $n'[\ell]$ is a noise component statistically equivalent to $n[\ell]$. It is seen that despreading requires a local replica $c[\ell]$ of the same spreading code used by the transmitter, and also requires perfect synchronicity of the remote and local codes. After despreading, we are left with a (digital) narrowband rectangular pulse signal plus AWGN. The optimum processing for data detection is thus (digital) integration over a one-symbol period to yield the following complex-valued quantity that is optimum for data detection (also called *sufficient statistics*)

$$z[i] \triangleq \frac{1}{M} \cdot \sum_{\ell=iM}^{iM+M-1} y_d[\ell] = \frac{1}{M} \cdot \sum_{\ell=iM}^{iM+M-1} y[\ell] \cdot c[\ell]_L \quad (6)$$

Recalling Equations 4 and 5, we obtain

$$z[i] = \frac{1}{M} \cdot \sum_{\ell=iM}^{iM+M-1} A \cdot d[\ell/M] + \frac{1}{M} \cdot \sum_{\ell=iM}^{iM+M-1} n'[\ell] = A \cdot d[i] + v[i] \quad (7)$$

where $v[i]$ is a noise term whose I/Q components are independent, identically distributed zero-mean Gaussian random variables with variance $\sigma_v^2 = \sigma_n^2/M = N_0/(MT_c) = N_0/T_s$. From Equation 6, we see that despreading accumulation is equivalent to the operation of cross-correlation between the received signal $y[\ell]$ and the local code replica $c[\ell]$, computed on the i th symbol period to yield the i th sufficient statistics $z[i]$. This is why we also speak of *correlation receiver* (CR).

The decision strobe of Equation 7 is eventually passed to the final detector, which may be a slicer to regenerate the transmitted digital data stream or, if channel coding is adopted, a soft-input channel decoder such as a Viterbi algorithm (Viterbi 1967; Viterbi and Omura 1979). Looking at Equation 7, we also see that the sufficient statistics is exactly the same we would obtain in the case of conventional narrowband transmission of the symbol stream $d[i]$ over an AWGN channel with matched filter detection. The conclusion is that spreading-despreading is completely transparent to the end user as far as the bit error rate (BER) performance of the link over an AWGN channel with matched filter detection is concerned.

As already mentioned, Figure 5 also shows ancillary functions—namely, carrier frequency and phase and chip timing recovery, together with spreading code time alignment—that will be dealt with later. Also, other receiver architectures different from the one in Figure 5 (for instance, the so-called zero-IF receiver) are used in the practice.

CODE DIVISION MULTIPLE ACCESS

Frequency, Time, and Code Division Multiplexing

In the DSSS signaling schemes discussed above, the data stream generated by an information source is spread over a wide frequency band using one or two spreading codes. Starting from this consideration, we can devise an access system that allows multiple users to share a common radio channel. This can be achieved by assigning each user a different spreading code and letting all of the signals concurrently access the same frequency spectrum. All of the user signals are therefore transmitted at the same time and over the same frequency band, but they can nevertheless be identified thanks to the particular properties of the spreading codes. The users are kept separated in the code domain, instead of the time or the frequency domain, as in conventional *time* or *frequency division multiple access*, respectively (TDMA and FDMA). Such a multiplexing or multiple-access technique, based on DSSS transmission, is called *code division multiple access*, and the particular spreading sequence identifying each user is also addressed to as signature.

In the DL of a cellular network, the N user signals in DSSS format are obtained from a set of N traffic-bearing channels that are physically co-located into a single site—for instance, the radio base station. The BS keeps all N tributary streams $d_n[k/M]$, $n = 1, 2, \dots, N$ synchronous and performs spectrum spreading on each channel using a set of N different signature codes $c_n[k]$, $n = 1, 2, \dots, N$, all having the same start epoch (i.e., the start instant of the repetition period). The resulting *synchronous code division multiplexing* (SCDM) signal is

$$s^{(CDM)}(t) \triangleq A \cdot \sum_{k=-\infty}^{\infty} \left(\sum_{n=1}^N d_n[k/M] \cdot c_n[k] \right) g_T(t - kT_c) \quad (8)$$

The most popular class of binary spreading codes commonly used for SCDM in DL of cellular networks is the

Walsh-Hadamard (WH) set (Ahmed and Rao 1975; Dinan and Jabbari 1998), which is made of $L = 2^\zeta$ sequences (with ζ an integer) with repetition period L each (in practical systems $L = 32, 64, 128$, or 256). The WH sequences are orthogonal—that is,

$$\frac{1}{L} \sum_{k=0}^{L-1} c_n[k] \cdot c_m[k] = \begin{cases} 0 & n \neq m \\ 1 & n = m \end{cases} \quad (9)$$

When SCDM is used with WH codes, it is also addressed to as synchronous orthogonal CDM (SOCDM). Demultiplexing of channel i out of the multiplex signal in Equation 8 is easily accomplished by the simple correlation receiver described earlier, provided of course that it uses the signature code $c_i[k]$. Thanks to the orthogonality property of the WH codes, no interference from the other channels is experienced (see also “Multiple Access Interference” below). The set of WH codes of length 2, 4, and 8 is reported in the second, third, and fourth columns of Figure 6, respectively.

In the UL of a cellular network, the DSSS signals are originated by N spatially separated MTs that access the same physical medium (the same RF bandwidth), and their superposition is collected at the receiver antenna. Synchronization of the different sparse MTs is extremely difficult to achieve, and so the access is asynchronous and therefore termed *asynchronous CDMA* (ACDMA). The resulting received signal at the BS receiver is

$$r(t) = \sum_{n=1}^N e^{j(2\pi\Delta f_n t + \theta_n)} s_n^{(SS)}(t - \tau_n) + w(t) \quad (10)$$

where τ_n , Δf_n , and θ_n are the propagation delay, carrier frequency, and phase offsets, respectively, of the generic n th signal, and $w(t)$ is an AWGN contribution. We neglect here multipath propagation, which will be dealt with later under “Rake Receiver.” Recalling the DSSS signal description presented earlier, the generic n th traffic channel in DSSS format can be expressed as

$$s_n^{(SS)}(t) \triangleq A_n \cdot \sum_{k=-\infty}^{\infty} d_n[k/M] \cdot c_n[k] g_T(t - kT_c) \quad (11)$$

where A_n , $d_n[i]$, and $c_n[k]$ are the n th channel signal amplitude, data symbols, and signature sequence, respectively. The signal received by a MT in the DL can actually be seen as a special case of Equation 10, with $\tau_n = \tau$, $\Delta f_n = \Delta f$, and $\theta_n = \theta$, for every n —that is, all signals are synchronous and experience the same carrier frequency or phase shift. Orthogonality among asynchronous signals cannot be enforced.

Multirate Code Division Multiplexing

Advanced communication systems (2G and 3G cellular) support different kind of services (e.g., voice, video, data), and so the required bit rate per user can be variable from a few kbit/s up to a few Mbit/s. The spreading scheme has to be flexible enough to allocate signals with different bit rates on the same bandwidth. This can be achieved

Layer 0	Layer 1	Layer 2	Layer 3
$\mathbf{c}_0(0)$ +1	$\mathbf{c}_1(1)$ +1-1	$\mathbf{c}_2(3)$ +1-1-1+1	$\mathbf{c}_3(7)$ +1-1-1+1-1+1+1-1
		$\mathbf{c}_2(2)$ +1-1+1-1	$\mathbf{c}_3(6)$ +1-1-1+1+1-1-1+1
		$\mathbf{c}_2(1)$ +1+1-1-1	$\mathbf{c}_3(5)$ +1-1+1-1+1-1+1
		$\mathbf{c}_2(0)$ +1+1+1+1	$\mathbf{c}_3(4)$ +1-1+1-1+1-1+1-1
	$\mathbf{c}_1(0)$ +1+1		$\mathbf{c}_3(3)$ +1+1-1-1-1-1+1+1
			$\mathbf{c}_3(2)$ +1-1-1+1+1-1-1+1
			$\mathbf{c}_3(1)$ +1+1-1-1-1-1+1
			$\mathbf{c}_3(0)$ +1+1+1+1+1+1+1

Figure 6: OVFS codes tree; each layer is the complete set of WH codes of a particular length

basically by three different techniques—multicode, symbol repetition, or variable spreading factor—or a mixture of the three. In the multicode option, if users require a higher bit rate than the one of the basic channel, then they are simply allocated more than one signature code, and the high-rate bit stream is split into a number of parallel lower-rate streams each occupying a single (basic rate) channel. This is done in UMTS and CDMA2000 (see “A Review of 2G and 3G Standards for CDMA”). With symbol repetition, the basic rate is by definition the highest in the network. If a lower rate is needed, then it is obtained by generating a “fake” high-rate stream obtained by repetition a number of times of the same low-rate datum. This is the technique used in IS-95 (see “A Review” later in the chapter). Using a variable spreading factor, the chip rate R_c (and therefore SS bandwidth $B^{(ss)}$) is kept constant, but the spreading factor M is varied according to the bit rate of the signal to be transmitted. This has also to be done without altering the property of mutual code orthogonality outlined above. The solution to this issue, applied in UMTS, CDMA2000, and TD-SCDMA (see “A Review” below) is the special class of codes named *orthogonal variable spreading factor* (OVFS) (Adachi, Sawahashi, and Okawa 1997; Dinan and Jabbari 1998). The OVFS code set is a reorganization of the WH codes into layers, as shown in Figure 6, wherein the codes on each layer have twice the length of the codes in the previous layer. Each code is labeled using an array notation $\mathbf{c}_n(k)$, wherein the subscript n denotes the layer, and the index k denotes the code within each layer.

Also, the codes are organized in a tree, wherein any two “children” codes on the layer to the right of a “parent” code are generated by repetition and repetition with sign change, respectively, of the parent. The peculiarity of the tree is that any two codes are not only orthogonal within each layer (each layer is just the complete set of the WH codes of the corresponding length) but also orthogonal across layers, provided that the shorter is not an “ancestor” of the longer one. The shorter code is used for

a higher-rate transmission with a smaller spreading factor, and the longer code is used for a lower-rate transmission with a higher spreading factor (recall that the chip rate is always the same). OVFS are used as channelization code in the DL of both CDMA2000 and UMTS to keep the user channels separated. Unfortunately, the radio signal undergoes distortion during propagation because of the multipath phenomenon, which will be discussed in detail later under “Rake Receiver.” Multipath causes the loss of signal orthogonality in spite of the use of OVFS codes. This effect can be mitigated by orthogonality-restoring techniques (channel estimation and equalization) whose efficacy is measured by an orthogonality loss factor that quantifies the receiver performance degradation with respect to the case of perfect code orthogonality (no multipath propagation).

Multiple Access Interference

In the DL of a cellular network each BS sends out an N -channel SOCDM signal so that any MT located within a cell experiences no interference from the other channels in the multiplex thanks to the orthogonality of the channelization WH codes. To see this, assume that the generic mobile receiver intends to detect the useful traffic channel h . The output of the relevant correlation receiver is (see Equation 6)

$$z_h[i] = A_h \cdot d_h[i] + \mu[i] + v[i] \quad (12)$$

where $v[i]$ is channel noise, and

$$\begin{aligned} \mu[i] &\triangleq \sum_{\substack{n=1 \\ n \neq h}}^N \left\{ \frac{1}{M} \cdot \sum_{\ell=iM}^{iM+M-1} A_n \cdot d_n[\ell/M] \cdot c_n[\ell/L] \cdot c_h[\ell/L] \right\} \\ &= \sum_{\substack{n=1 \\ n \neq h}}^N \left\{ \frac{A_n \cdot d_n[i]}{M} \cdot \sum_{\ell=0}^{M-1} c_n[\ell] \cdot c_h[\ell] \right\} \end{aligned} \quad (13)$$

represents a cross-talk term caused by the presence of the other user signals and is addressed as *multiple-access interference* (MAI). Recalling Equation 9, if WH codes are used, then the MAI term $\mu[i]$ vanishes and Equation 12 collapses to Equation 7.

Without entering into further detail, we can easily argue that MAI is, on the contrary, intrinsic to detection of an UL channel. In this case, in fact, the N aggregate DSSS signals of Equation 10 are received by the BS in ACDMA mode. The output of the correlation receiver for channel h can still be put in a form similar to Equations 12 and 13, with a different, slightly more involved expression of the MAI term $\mu[i]$. But now the asynchronous access that is peculiar of the UL prevents the use of orthogonal codes to cancel MAI and $\mu[i] \neq 0$. The usual choice of the channelization codes is thus a set of (long) PN sequences that, thanks to their “randomness,” makes $\mu[i]$ similar to additional Gaussian noise, uncorrelated with respect to the useful traffic signal. This approach is pursued in the UL of all of the 2G and 3G commercial systems currently in use.

An MAI-dominated ACDMA system heavily suffers from the so-called near-far effect, where strong-powered users (usually, those located in the vicinity of the receiver in the radio base station) interfere with the weaker ones (usually, those located far from the receiver, i.e., at the edge of a cell). This is why all CDMA cellular systems adopt power control systems that, by continually adjusting the power sent by the user terminals, let the signals from different users arrive at the receiver with well-balanced power (Gilhausen et al. 1991).

Capacity of a CDMA System

In the DL of a cellular network, SOCDM is commonly adopted. Therefore, any BS can radiate a CDM signal containing up to L traffic channels (i.e., the size of the orthogonal code set) without introducing any *quality-of-service* (QoS) degradation because of the presence of multiple users. With WH codes, the spreading factor M is equal to the code length L (short codes), and this represents the key to understanding the interplay between spectrum spreading and multiplexing. Using DSSS transmission, the signal bandwidth is expanded by a factor M , and this is a potential bandwidth waste. But using SOCDM, as many as M signals can be allocated in the same bandwidth with no mutual interference, thus regaining the original bandwidth efficiency. This is exactly what happens with FDMA (whereby the total bandwidth is increased by the number of channels M that are put onto adjacent carriers) and with TDMA (where the channel signaling rate is increased by a factor M to accommodate the M tributary signals). The spreading factor represents thus the ultimate capacity of the DL in a CDMA network, and in this respect CDMA is no better or no worse than FDMA and TDMA.

In the UL, on the contrary, synchronization of the MTs is no longer feasible and ACDMA with long spreading codes (e.g., PN sequences) is adopted. The receiver may experience a significant amount of MAI (as is apparent from Equations 12 and 13) that may cause a significant degradation of the QoS in the terms of BER. The nice feature of ACDMA, also referred to as *graceful degradation property*, is that the QoS degradation can be traded off with a capacity

increase (Gilhausen et al. 1990, 1991). To see this, observe that MAI can be seen as an additional, independent noise term summing up the usual receiver noise contributions. If N traffic channels are active (i.e., the useful one plus $N - 1$ interferers) and all of the interfering channels are received with the same power level P_s , then the MAI can be modeled as a white Gaussian noise process, whose equivalent PSD is found to be

$$I_0 \triangleq \frac{(N-1) \cdot P_s}{B^{(SS)}} = \frac{(N-1) \cdot P_s}{1/T_c} = (N-1) \cdot E_c \quad (14)$$

All 2G and 3G CDMA systems implement specific power control strategies to ensure that the condition of power balancing is attained within a small error margin. As a consequence, the BS correlation receiver experiences an equivalent total noise PSD given by $N_0 + I_0$. Assuming *quadrature PSK* (QPSK) modulation, the BER of the link is

$$\begin{aligned} P(e) &= Q\left(\sqrt{\frac{2E_b}{N_0 + I_0}}\right) = Q\left(\sqrt{\frac{2E_b}{N_0 + (N-1) \cdot E_c}}\right) \\ &= Q\left(\sqrt{\frac{2E_b}{N_0} \cdot \frac{1}{1 + (N-1)/G_p \cdot E_b/N_0}}\right) \end{aligned} \quad (15)$$

where $Q(x) \triangleq \sqrt{1/2\pi} \int_x^\infty \exp(-y^2/2) dy$ represents the Gauss integral function, and $G_p = E_c/E_b$ is the so-called processing gain. It is apparent that the number N of concurrently active users depends on the specification about the QoS of the link, expressed in terms of a target BER: The lower the required QoS (i.e., the larger is the target BER), the higher the capacity in terms of number of active users. From this standpoint, it is easily seen that the UL capacity of CDMA can be further boosted up by the appropriate use of channel coding (Viterbi 1979).

A more advanced solution to the issue of the MAI is *multi-user data detection* (MUD) wherein demodulation of all of the UL data streams is performed in a single, centralized signal processing unit (Verdù 1998). With such a centralized detection approach, the presence of a certain amount of MAI coming from interfering channels can be accounted for when demodulating the useful, intended channel. This standpoint applies reciprocally to all of the channels, leading to the above-mentioned notion of “multi-user” demodulation. By concurrently observing all of the correlators’ outputs, the MAI can be taken into account when detecting each channel, and it can be mitigated or “cancelled” by suitable signal processing. This leap forward in the performance of the CDMA receiver, not surprisingly, comes at the expense of a substantial increase in the complexity (signal processing power) of the demodulator.

Cellular Networks and the Universal Frequency Reuse

As outlined above, multiple access can be granted to DSSS signals by assigning different spreading codes to all

of the different active users served by a single BS. In this case, the capacity is limited by the number of orthogonal codes in the DL. With reasonable spreading factors (up to 256), the number of concurrently active channels is too low to serve a large user population such as in a large metropolitan area or a vast suburban area. This also applies to conventional FDMA or TDMA radio networks, where the number of channels is equal to the number of carriers in the allocated bandwidth or the number of time slots in a frame, respectively. In the context of narrow-band signals (FDMA and TDMA networks), the solution to this issue lies in the well-known notion of cellular network with frequency reuse. In a nutshell, the area to be served by the wireless system is divided into smaller cells, and the channels within the RF allocated bandwidth are distributed over the different cells. In so doing, the same channels can be allocated more than once to different cells (they can be reused), provided that the relevant cells are sufficiently far apart so that the mutual interference caused by the use of the same channels on the same frequency is sufficiently low. The distribution of cells on the coverage area (territory) is characterized by the so-called frequency reuse factor Q . Of course, frequency reuse has an impact on the overall network efficiency in terms of users per cell (or users/km²) because the number of channels allocated to each cell is a fraction $1/Q$ of the overall channels allocated to the communications service provider. For instance, in the GSM network Q is equal to 7 or 9. In such a cellular environment, it happens that a mobile user traverses the boundary between two adjacent cells, leaving its own coverage cell to enter another coverage area. To keep possible communications active without service interruption, a network management procedure called *handoff* (or *handover*) is started just before the mobile leaves the “setting” cell to assign new frequency resources to the mobile in the “rising” cell and to disengage the older ones and thus ensure a seamless connection (Rappaport 1991).

In CDMA-based networks, efficiency is maximized by universal frequency reuse whereby the same carrier frequency is used in each cell, and the same OVFSF orthogonal codes set (i.e., the same DL channels) are used within each cell on the same carrier. Of course, something has to be done to prevent neighbors at the edge of two adjacent cells from using the same WH code to heavily interfere with each other. The solution is to use a different scrambling code on different cells to cover the channelization (traffic) OVFSF codes (Fong, Bhargava, and Wang 1996; Dinan and Jabbari 1998). This arrangement represents a

sort of universal code reuse technique, where *code* refers to the (orthogonal) channelization codes in each cell. Denoting with $c_m[k]$, $m = 1, 2, \dots, M$, the set of M WH codes to be used by the generic cell u and with $p_u[k]$ the overlaying sequence, the resulting composite spreading signature code is $c'_{u,m}[k] \triangleq p_u[k] \cdot c_m[k]$. The orthogonality between any pair of composite sequences in the same cell is preserved. In a cellular network with universal frequency reuse, the hand-off procedure merely consists of a reassignment of the spreading code at every cell change with no carrier frequency change.

ARCHITECTURE OF SPREAD-SPECTRUM RECEIVERS

Correlation Receiver

This is the conventional receiver for DSSS transmissions and was described in detail earlier. The correlation receiver is optimum in each of the following conditions:

- single-user transmission over the AWGN channel;
- multi-user transmission over the AWGN channel in SOCDM mode (no MAI is experienced by the receiver); and
- multi-user transmission over the AWGN channel in ACDMA mode with long PN codes with a large number of equi-powered active users (allowing the modeling of MAI as an additional white Gaussian noise contribution).

Synchronization Functions

The word *synchronization* refers to those signal-processing functions that in digital communication receivers are carried out to achieve correct time alignment of the incoming waveform with certain locally generated references.

Figure 7 shows the general outline of (the baseband equivalent of) a conventional coherent correlation receiver for DSSS user h in a CDMA system, where we have highlighted the relevant synchronization functions. For the sake of simplicity, the synchronization functions are described for the AWGN case only. After carrier frequency and phase offset correction, the received waveform $r(t)$ is fed to the CMF and then sampled at chip rate. Spectral despreading is performed by multiplying the samples $y_h[\ell]$ by a locally generated replica of the user's code $c_h[\ell]$ and, finally, the resulting sequence is accumulated over

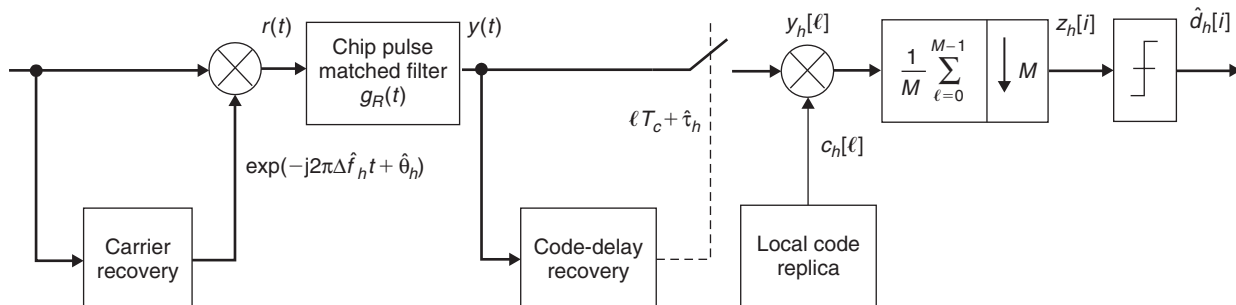

Figure 7: Coherent DSSS CDMA receiver

a symbol period $T_s = MT_c$ (see also the earlier “Fundamentals” section). Correct receiver operation requires accurate recovery of the signal time offset τ_h to ensure that the local code replica is properly aligned with the signature sequence in the received signal. This goal is usually achieved in two steps: (1) coarse alignment is obtained first, and (2) it is used as a starting point for fine code tracking.

From the discussion above it appears that the synchronization problem in CDMA systems is similar to that encountered with narrowband signals, as far as carrier frequency and phase are concerned (Mengali and D’Andrea 1997; De Gaudenzi, Giannetti, and Luise 1998). On the contrary, SS signals are peculiar in the function of delay estimation. As mentioned earlier, data detection relies on the availability at the receiver of a time-aligned version of the spreading code. The delay τ_h must be therefore estimated to ensure such an alignment. The main difference with respect to narrowband modulations is estimation accuracy. In narrowband systems, timing errors must be small compared to the symbol time, whereas in spread-spectrum systems they must be small compared with the chip time, which is M times smaller. This is why, as mentioned above, code delay estimation is broken into two phases: First, a coarse estimate of the delay is obtained (initial acquisition), then the coarse estimate is used to start a continuous process of refinement (fine tracking) (De Gaudenzi, Giannetti, and Luise 1998).

Rake Receiver

The radio signal in a wireless mobile communication system, especially when operating in an urban or indoor environment experiences the phenomenon of *multipath propagation* (Turin 1980). In such scenarios, both the transmit and receive antennae have usually moderate to weak directivity so that the signal can propagate from the transmitter to the receiver through a number of different *propagation paths*. The different paths (or *rays*, as they are called in electromagnetism) result from reflection and scattering on walls, buildings, trees, furniture, and other surfaces or obstacles. A simple model for the received signal at the receiving end is thus

$$r(t) \triangleq \sum_{k=1}^K a_k \cdot s^{(ss)}(t - \tau_k) + w(t) \quad (21)$$

where $s^{(ss)}(t)$ is the (baseband equivalent of) the transmitted DSSS signal, $w(t)$ is the usual channel noise, K is the number of propagation paths, $a_k \triangleq |a_k| \cdot \exp(j\angle a_k)$ is a complex random variable representing the amplitude and phase shift experienced by the signal traveling on the generic k th path, and finally τ_k is the relevant propagation delay. In Equation 21, we neglected for simplicity the time variation resulting from terminal mobility of the channel parameters (amplitudes, phase shifts, and delays). In an urban environment, the amplitude coefficient $|a_k|$ is usually modeled as a Rayleigh random variable, whereas the phase shift $\angle a_k$ is assumed to be uniformly distributed over $[0, 2\pi)$. From Equation 21, the frequency response of the multipath channel turns out to be

$$H(f) = \sum_{k=1}^K a_k \cdot e^{-j2\pi f \tau_k} \quad (22)$$

Typical values of the delays τ_k are 1–10 μ s for rural environments, 0.1–1 μ s for urban scenarios, and 1–100 ns for indoor propagation. In general, the channel amplitude and phase response from Equation 22 reveal considerable variability over the signal bandwidth, thus causing non-negligible distortion on the received signal: We have a *frequency-selective channel*.

On the multipath channel, the CR is no longer optimal because the additional rays may cause intersymbol interference. A popular way to deal with DSSS signal detection consists of resorting to the *rake receiver*; its architecture is depicted in Figure 8. The rake is a kind of time diversity receiver made of a bank of N_R ($N_R = 3$ in Figure 8) identical conventional DSSS detectors, operating in parallel, and called *fingers* (just like the fingers of a gardener’s rake). In the code acquisition phase, DSSS demodulator 1 tries to locate the strongest path within the multipath signal of Equation 21 by finding the strongest correlation peak of the local code replica with the received signal and “tunes” onto it. After this, the other detectors will try to find the second and third strongest paths and lock onto them. To achieve this, they carry out a continuous search around the previously found locations, in particular looking for secondary correlation peaks generated by weaker signal “echoes.” The search range is limited to a few chip intervals, depending on the maximum channel delay the receiver has to cope with. Eventually, as shown in Figure 8, each finger of the rake locks onto a different time-delayed replica of the incoming signal (see the time delays τ_i , $i = 1, 2, 3$), correlates it with a properly shifted version of the local code replica (see the code delays δ_i , $i = 1, 2, 3$), and yields a decision strobe $z_n[i]$ at symbol rate. This operation mode presumes that the different signal replicas (echoes) can be resolved—that is, they can be singled out by a correlation procedure. This is true only when the difference between the various signal delays is at least approximately one chip time. In this case, in fact, the different signal echoes on the different propagation paths turn out to be uncorrelated (because of the properties of the spreading code) and can be resolved via correlation processing. By resorting to advanced signal-processing techniques, paths separated by less than one chip time can also be resolved.

Assume now for simplicity that finger 1 locks onto path 1, finger 2 onto path 2, and so forth. The different partial decision variables $z_n[i]$ are phase-corrected by $\exp(-j\angle a_n)$ to perform coherent detection. Then, a *combination logic unit* (CLU) controls a combination unit that is in charge of selecting or combining the fingers outputs to provide a final decision strobe $z[i]$ for data detection. The selection and combining criterion may be one of the following:

- *selection combining* in which the CLU just selects the maximum amplitude strobe:

$$z[i] \Big|_{sc} \triangleq z_n[i] \Leftrightarrow \bar{n} : |z_n[i]| = \max_n \{|z_n[i]|\} \quad (23)$$

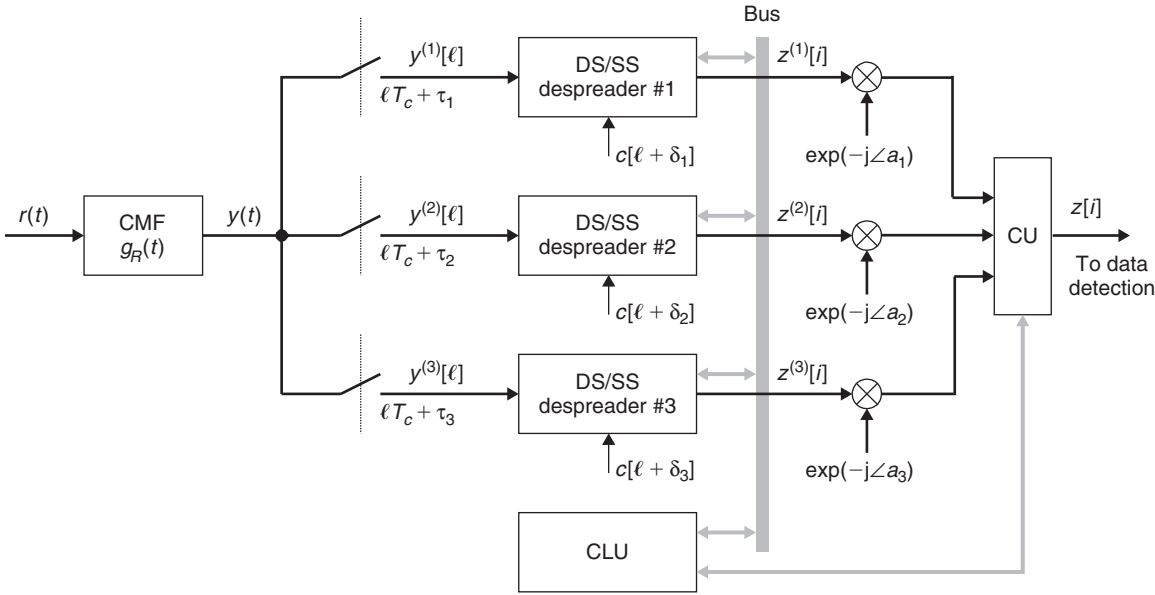

Figure 8: Outline of a rake receiver

- *equal gain combining* in which the CLU sums up all strobes at the fingers outputs (upon carrier phase counter-rotation):

$$z[i] \Big|_{EGC} \triangleq \sum_{n=1}^{N_R} z_n[i] \cdot e^{-j\angle a_n} \quad (24)$$

- *maximal ratio combining* (MRC) in which the CLU performs a weighted sum of all the strobes at the fingers' outputs:

$$z[i] \Big|_{MRC} \triangleq \sum_{n=1}^{N_R} |a_n| \cdot z_n[i] \cdot e^{-j\angle a_n} = \sum_{n=1}^{N_R} a_n^* \cdot z_n[i] \quad (25)$$

It can be shown that MRC maximizes the signal-to-noise ratio at the rake output because Equation 25 implements a channel-matched filter. The rake represents the optimum receiver for DSSS single-user reception over multipath channel, provided that all the following conditions are met:

1. the number of the rake fingers is exactly equal to that of the propagation paths;
2. the rake can resolve all the paths—that is, each finger locks onto a different path;
3. interchip interference is negligible—that is, perfect fine time recovery is carried out; and
4. the spreading code is delta-correlated—that is, it has null off-zero autocorrelation.

According to 1 and 2 above, the number of fingers in the rake should be equal to the number of resolvable paths in the channel. In practice, a reasonable trade-off between complexity and multipath robustness is represented in many cases by the choice $N_R = 3$ (De Gaudenzi and Giannetti, 1994, 1998).

A REVIEW OF 2G AND 3G STANDARDS FOR CDMA MOBILE COMMUNICATIONS

Interim Standard 95

The “mother of all” commercial CDMA systems is the American standard IS-95 (Kohno, Meidan, and Milstein 1995) that was issued in 1993 and later evolved into a well-established family of different systems—namely, cdmaOne—whose main representatives are summarized in Table 1. The chip rate is the same in both the UL and the DL and is equal to 1.2288 Mchip/s for a nominal bandwidth occupancy of 1.25 MHz (with roll-off factor 0.2). In the DL, SCDM with length-64 WH codes is used for as many as sixty-four multiplexed channels. The maximum net bit rate on each channel is 9600 bit/s. In addition, some channels are reserved for control. In particular, the channel corresponding to the WH function that is constant throughout the code period bears no data modulation (the so-called pilot channel) and is used as a reference for synchronization and channel estimation (see the preceding section). The traffic channels are all protected against transmission errors by a convolutional forward error-correcting code whose coding rate is $r = 1/2$ so that the actual maximum signaling rate is 19,200 symbol/s. Considering the spreading factor 64 of the WH codes, we end up with the chip rate $19.2 \times 64 = 1228.8$ kchip/s as above. The modulation and spreading format is “real data, complex code” because two different codes are used on the I and Q rails on the same “copy” of the digital datum. The I and Q codes are “long” (although in the standard they are termed *short codes*), and they also serve as scrambling code to perform BS identification. If a lower data rate than 9600 bit/s has to be used, the channel encoder just reclocks the slower output data so as to make them enter the DSSS modulator at the same invariable rate of 19.2 ksymbol/s. This is called *symbol repetition* and allows supported bit rates that are integer submultiples of

Table 1: The cdmaOne Family

System name	System kind	UL frequency band (MHz)	DL frequency band (MHz)
TIE/EIA IS-95	Cellular	824–849	869–894
ANSI J-STD-008	Personal communication system (PCS)	1850–1910	1930–1990
Globalstar	Satellite	1610–1626.5	2483.5–2500

Table 2: UMTS' UTRA-FDD and UTRA-TDD Main System Parameters

Parameter	UTRA-FDD	UTRA-TDD
Frequency Band	UL: 1920–1980 DL: 2110–2170	1900–1920 and 2010–2025
Maximum data rate	2.048 Mbit/s	
Framing	10 msec	
Chip rate	3.840 Mchip/s	3.840 Mchip/s or 1.280 Mchip/s
Pulse shaping	SRRC roll-off factor 0.22	
Carrier spacing	5 MHz	
Spreading factor	4 to 256	Either 1 (no spreading, pure TDMA) or 16
DL multiplexing	SOCDM Optional short codes	SOCDM Short codes
UL multiple access	ACDMA Long codes	
UL pilot channel	Dedicated physical control channel running in parallel with the data channel	“Midamble”: short series of pilot symbol at the center of the data burst
DL pilot channel	Common pilot channel plus dedicated pilot symbol in the traffic channels	

the maximum basic rate (in this case, 4800, 2400, and 1200 bit/s).

The arrangement for the UL of IS-95 is a little bit more complicated. We have here ACDMA with extremely long codes, whose periodicity is $2^{42} - 1$ chips. The chip rate is the same as in the DL (1.2288 Mchip/s), as is the basic maximum data rate (9600 bit/s). But the coding rate is now 1/3, and so the symbol rate at the modulator input is $3 \times 9.6 = 28.8$ ksymbol/s. At the other end of the modulator we also have a conventional “real data, complex code” section with scrambling codes. In between, we have multilevel 64-ary modulation with a set of sixty-four orthogonal WH functions (Proakis 1995). Here the WH functions are not used as orthogonal codes to perform multiplexing as they are in the DL. Rather, they are used as symbols in a signal constellation to implement the robust process of orthogonal functions modulation that is suited to efficient noncoherent demodulation. As a consequence, the signaling rate of the orthogonal-modulated stream raises to $28.8/\log_2(64) = 307.2$ ksymbol/s. After $\times 4$ symbol repetition, spreading with the extremely long channelization code and I/Q modulation and scrambling take place. In the UL, the two I/Q components of the modulated signal are staggered in time (i.e., delayed one with respect to the other) by half a chip period. This reduces the envelope fluctuations of the modulated signal, thus preventing

distortion by the subsequent stages of nonlinear amplification in the MT radio frequency transmitter.

UMTS and UTRA

In 1998, several telecommunications standards bodies established a collaboration agreement called the 3rd-Generation Partnership Project (3GPP) (3GPP undated), whose scope was to bring forth globally applicable technical specifications and technical reports for a third-generation mobile system. In 2001, the 3GPP produced the 3G Euro-Japanese standard UMTS (release 4) that, despite many substantial differences, incorporated many of the good ideas that were introduced in IS-95 (Ojanpera and Prasad 1998). Table 2 summarizes the main parameters of the two versions of UMTS—namely, *UMTS terrestrial radio access–frequency division duplexing* (UTRA-FDD) and *UMTS terrestrial radio access–time division duplexing* (UTRA-TDD). In UTRA-FDD, the chip rate is 3.840 Mchip/s with a roll-off factor 0.22 for a nominal bandwidth occupancy of 5 MHz, both the UL and the DL. This explains the qualification of “wideband” CDMA of UTRA-FDD. The two links are symmetrical with supported bit rates ranging from 16 (the basic, slowest rate) to 2,048 kbit/s, with variable spreading factor (OVSF codes; see the earlier “Multirate Code Division Multiplexing” section).

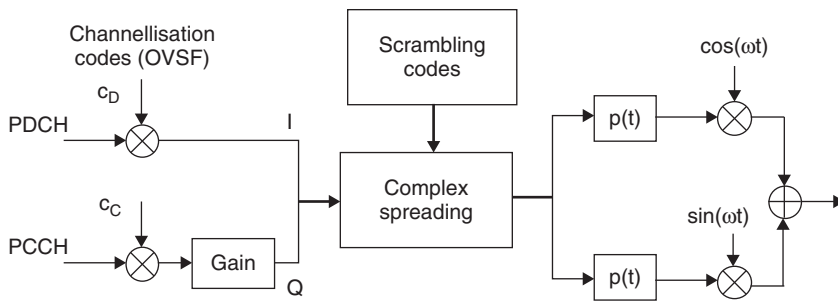

Figure 9: UTRA-FDD UL spreading and modulation

As is seen in Figure 9, each user has a UL *physical dedicated control channel* (PCCH) in addition to the customary traffic channel (*physical dedicated data channel*, PDCH). The two channels, which may have different bit rates, are locally multiplexed and spread with channelization OVSF codes, and the two of them are further scrambled via complex spreading—that is, computing the product between the complex-valued, I/Q spread PDCH/PCCH signal and the complex-valued I/Q scrambling code.

The arrangement for modulation and spreading in the DL (traffic and control channels) is similar but a little bit more complicated (see Figure 10). The presence of the serial-to-parallel converters on the data fluxes indicates that modulation is QPSK (complex binary data), but spreading with the channelization codes (synchronous OVSFs) is real (single code per channel). After I and Q multiplexing, a base-station-unique real scrambling code is applied.

UTRA-TDD is different from UTRA-FDD for the duplexing mode: Instead of placing the UL and the DL on two different carrier frequencies as in FDD, the UL and DL share the same carrier and simply alternate in time (see Table 2). This gives total symmetry of signal format between UL and DL, but on the contrary allows asymmetry of capacity by simply “moving” the boundary between the UL slots and the DL slots in every 10-msec frame as sketched in Figure 11. The signal format is actually somewhat simpler than its FDD counterpart (fixed spreading factor, option for a factor-of-three slower chip rate, etc.), and so UTRA-TDD is left for less demanding applications than FDD.

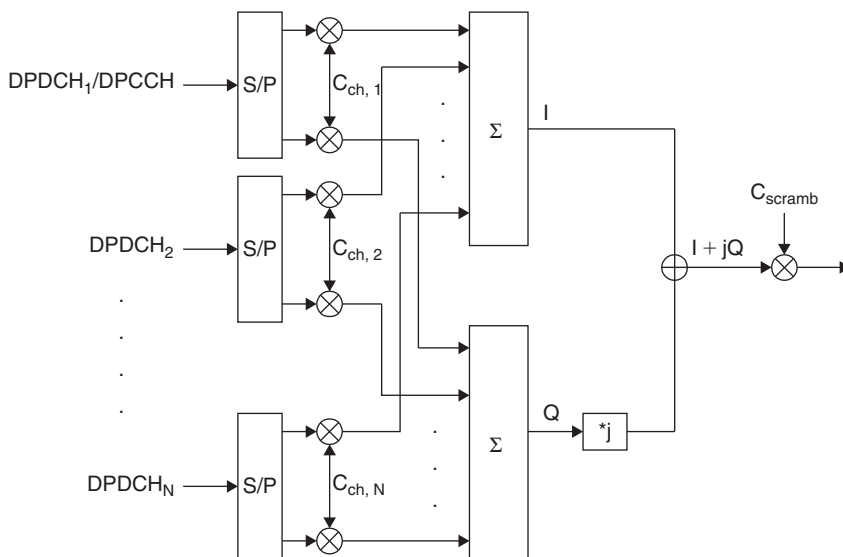

Figure 10: UTRA-FDD DL modulation, spreading, multiplexing, and scrambling

CDMA2000

As far as the general architecture is concerned (at least from a physical layer perspective), the differences between CDMA2000 and UTRA-FDD are not much relevant. The main differentiation lies in a sort of “multicarrier” mode of CDMA2000 that allows best backward compatibility with IS-95 (Knisely et al. 1998). The chip rates of CDMA2000 are integer multiples of the IS-95 chip rate (for instance, $1.2288 \times 3 = 3.6864$ Mchip/s) so that one wideband CDMA2000 carrier exactly fits into the bandwidth of an integer number of cdmaOne channels. Many features such as OVSF codes, dedicated control channels in the UL, common pilot channel in the DL, coherent demodulation in both the UL and the DL, packet access, and fast power control are shared with UTRA-FDD, and the relevant end-user performance and services are similar. For real worldwide roaming, the design of dual-mode CDMA2000/UMTS terminals is being pursued by most equipment manufacturers.

China’s TD-SCDMA

In 1999, the China Wireless Telecommunication Standards group was founded by the People’s Republic of China Ministry of Information and Industry and joined the 3GPP. In October 2002, the Chinese ministry assigned a total of 155-MHz asymmetrical bandwidth for the TD-SCDMA standard (Li et al. 2005; TD-SCDMA Forum 2003)

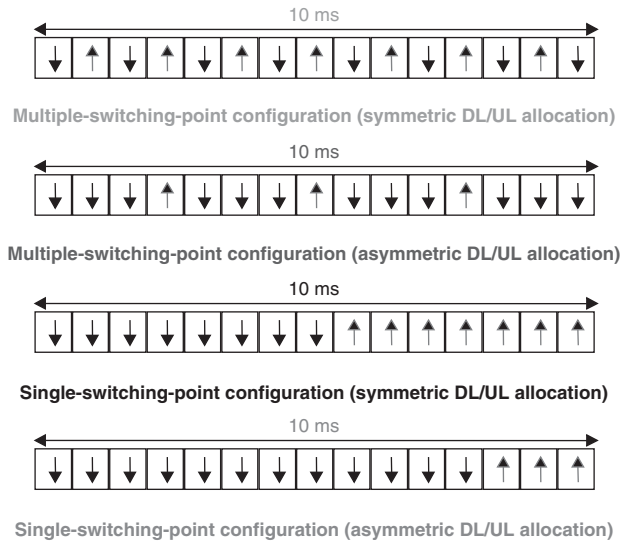

Figure 11: Asymmetric UL and DL capacity in UTRA-TDD

(1880–1920 MHz, 2010–2025 MHz) plus a supplementary spectrum (2300–2400 MHz). In January 2006, the ministry formally approved TD-SCDMA as the country's standard of 3G mobile telecommunications. Some may say that TD-SCDMA is a variant of UTRA-TDD. Admittedly, the two share several features, starting from the basic arrangement of time division duplexing on a single carrier with dynamic UL and DL allocation. TD-SCDMA also uses TDMA in addition to CDMA to reduce the number of concurrently active codes in a cell. As already stated, the "S" in the acronym of this standard stands for *synchronous*, meaning that the different CDMA channels are always synchronous in both the UL and the DL. The two also share the same framing and spreading and modulation format, just like UTRA-TDD. Designed for 1.6-MHz channels, TD-SCDMA is compatible with 5-MHz unpaired 3G bands in any region of the world. The universal chip rate is 1.28 Mchip/s (much like cdmaOne), and the frame length is 10 ms (see also Figure 12). Each frame

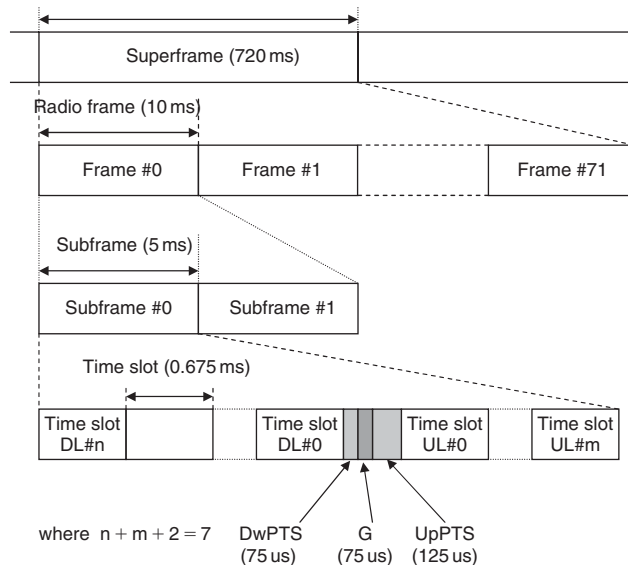

Figure 12: TD-SCDMA framing; PTS = pilot slot; G = guard slot

has seven slots with dynamic but single UL-DL switching point. The information rate of the channel varies with the symbol rate and the spreading factor. The spreading factor ranges from 16 to 1 for both the UL and the DL. Thus, the respective modulation symbol rates vary from 80.0 ksymbols/s to 1.28 Msymbols/s. Modulation is QPSK (8-PSK for higher-rate services with reduced mobility) and channel coding has rates 1/2 and 1/3. Thus, the supported bit rates are 9.6 (packet only), 12.2 (circuit only), 64, 144, 384, and 2,048 kbits/s. Considering all of the features above, we could say that TD-SCDMA is a mix of both the 2G and 3G CDMA systems.

CONCLUSION

Currently, more and more packet-based applications are being developed and put into service (video streaming, voice over IP, etc.), so wireless networks have to face the need for better support of differentiated quality of service, higher spectral efficiency, and higher data rates with full mobility. This need drives a continuously ongoing evolution of 3G systems' technologies (Dahlman and Jou 2006).

Although the end user may not be aware of it, at the same time 3G systems are being commercially developed (and ameliorated), research-and-development laboratories worldwide are also working to devise prototypes and proposals for standards of 4G wireless networks. At the moment, a great many so-called 4G architectures exist, according to the different visions of producers and research labs (Berezdivin, Breinig, and Raytheon 2002; Hui and Yeung 2003). The main ambition of 4G is to combine traditional cellular communications, WLANs, *broadband wireless access* (BWA) systems, and possibly broadcasting into a ubiquitous, universal, broadband, flexible wireless access network that can accommodate business as well residential users, multimedia communications, as well as Internet access. In a word, 4G will go where 3G cannot go.

In this ambitious picture, a variety of signal-processing techniques will be integrated, and SS probably will no longer be the fundamental one as in the previous generation. Many proposals for 4G systems or even 3.5G systems (that is, an intermediate generation between current 3G and long-term future 4G, just like Samsung's Wi-Bro (Cherry 2005), are based on MIMO (multiple-input multiple-output) signal transmission technologies as the factor to boost system capacity (Telatar 1999). With 3G, we can say that SS has attained its full maturity and will be either integrated or replaced by different and at times more advanced techniques. One of them is certainly multicarrier CDMA, which tries to capitalize on the advantages of both SS and MC modulations. Some envisage also the comeback of pure FDMA for multiple access in its modern variant, orthogonal FDMA (OFDMA) (IEEE 802.16 Working Group, undated). In a sense, OFDMA, that has been standardized for BWA applications by the IEEE 802.16 committee (IEEE 802.16 Working Group, undated), is a by-product of the OFDM multicarrier technology mentioned above. Also, the lesson of intentionally broadening the signal spectrum well beyond the Nyquist bandwidth has been completely taken up by those who support *ultra-wide band* (UWB) signaling for short-range communications

("Ultra wide band radio" 2002). In UWB systems, the information conveyed by a single bit is coded into a sequence of ultrashort pulses (less than 1 ns each) whose spectrum is thus spread over a ultrawide bandwidth. Admittedly, this is not conventional DSSS or FHSS but is indeed a form of "wide-spectrum" signaling. The debate among different laboratories and standardization bodies about the pros and cons of such technologies is really hot, so insisting on one instead of on another would be, in the writers' opinion, currently unfair or unmotivated.

GLOSSARY

Chip: One binary symbol of the spreading sequence.

Code: Sequence of pseudorandom binary symbols used in DSSS schemes to spread the bandwidth occupancy of the information-bearing signal. Also termed *spreading sequence*.

Code division multiple access (CDMA): Multiplexing or multiple-access technique based on DSSS transmission wherein all of the user signals are transmitted at the same time and over the same frequency band and are kept separated in the code domain.

Complex spreading (CS): DSSS spreading scheme employing a complex-valued code.

Correlation receiver: Receiver for DSSS transmissions wherein the transmitted data are detected by correlating the incoming received signal with a locally generated replica of the spreading code sequence used by the transmitter.

Despreading: Removal of the spreading code from the received DSSS signal; performed by a correlation receiver.

Direct sequence spread spectrum (DSSS): SS transmission technique wherein the information-bearing symbols are multiplied in the time domain with a sequence of pseudorandom binary symbols running at much higher rate.

Frequency-hopping spread spectrum (FHSS): SS transmission technique wherein the spectrum of the modulated signal "hops" from frequency to frequency following a periodic pseudorandom sequence of carrier values.

Long code: Spreading sequence whose repetition period is much longer than the data symbol duration.

Processing gain: The ratio between the chip rate of the SS signal and the transported bit rate.

Rake receiver: Time diversity receiver made of a bank of identical conventional DSSS detectors, operating in parallel, and suitable for data detection over time-dispersive channels.

Real spreading (RS): DSSS spreading scheme employing a real-valued code.

Short code: Spreading sequence such that a small integer number of the spreading sequence repetition period exactly spans one data symbol interval.

Spreading factor: The ratio between the bandwidth of the SS signal and the bandwidth of the corresponding narrowband modulated signal having the same symbol rate.

Spreading sequence: Sequence of pseudorandom binary symbols used in DSSS schemes to spread the

bandwidth occupancy of the information-bearing signal. Also termed *code*.

Spread spectrum (SS): Transmission technique wherein the modulated signal has a bandwidth occupancy around the carrier frequency that is much larger than the information bit rate.

INTRODUCTION

The goal of an *optical fiber communication* (OFC) system is to transmit the maximum number of bits per second over the maximum possible distance with the fewest errors. A typical digital fiber-optic link is depicted in Figure 1.

Data encoded as electrical pulses are recoded as optical pulses. Electrical data signals are converted to optical signals via a transducer. The numeral 1 is transmitted as a pulse of light, whereas a 0 has no light output. This modulation is referred to as *on-off keying*.

The use of light as communication methods can be dated back to antiquity if we define optical communications in a broader way. Humans have used mirrors, fire beacons, and smoke signals to convey single pieces of information.

The main idea of using glass fiber to carry an optical communications signal was conceived in the last half of the nineteenth century. However, this idea had to wait for almost a century. In 1966, Charles Kao and George Hockham at Standard Telecommunications Laboratories in England published their famous landmark theoretical

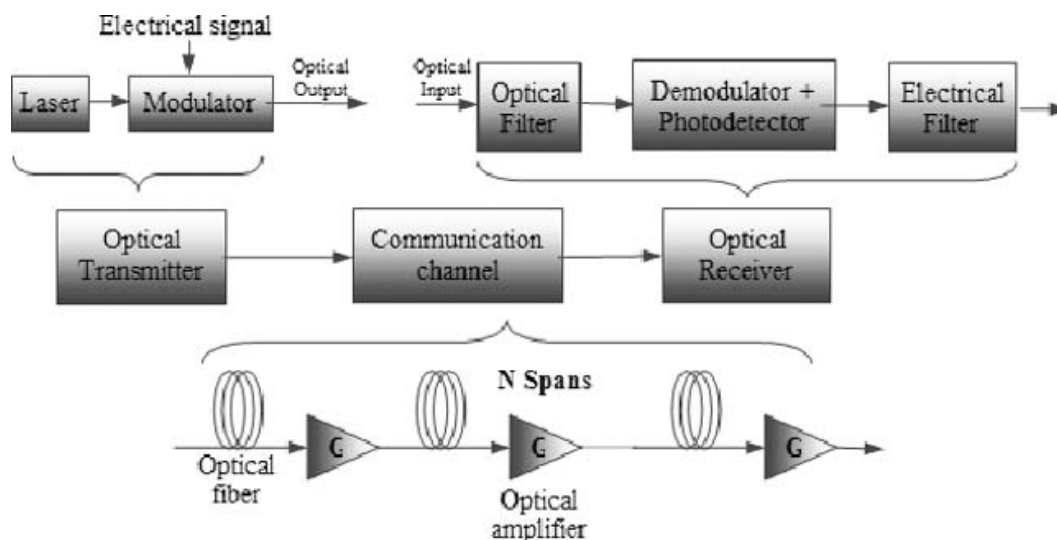

Figure 1: General optical fiber system transmission system layout

paper that described how better forms of glass and low-cost electronics made the idea useful in practical situations (Kao and Hockham 1966). The modern fiber-optic communications started in the 1970s when a gallium arsenide semiconductor laser was invented and the optical fiber loss could be reduced to 20 dB/km in the wavelength region near 1 μm (Dutton 1998).

Over the last four decades, optical communications in public networks evolved from a curiosity to become the dominant technology. Among the thousands of developments and inventions that have contributed to this progress, five major inventions stand out as milestones (Dutton 1998):

1. the invention of the laser in the early 1960s;
2. the development of low-loss optical fiber in the 1970s;
3. the invention of the FBG in the late 1970s;
4. the invention of the optical fiber amplifier in the late 1980s; and
5. the development of the *wavelength-division multiplexing* (WDM) technique in the 1990s.

OPTICAL FIBER TRANSMISSION SYSTEMS

Overview

In general, an optical communications system consists of an optical source, a transmitter, a medium, and a receiver. The digital optical transmission system in which the data bit rate per channel is assumed to be in the range of multi-Gb/s (as many as 40 Gb/s per channel are currently feasible). In the transmitter, a time division multiplexer combines several parallel data channels into a single data stream with a high bit rate. Then a driver stage generates the current required for driving the laser diode directly or the voltage required to drive an external modulator indirectly. *Non-return to zero* and *return to zero* are the most commonly applied modulation formats because of their simple implementation at extremely high speeds.

Similar to frequency-division multiplexing in radio systems, WDM can be used to increase the transmission capacity beyond that limited by the speed of electronics. The idea of WDM is to simultaneously transmit data at multiple carrier wavelengths over a fiber. Interaction among these different channels is minimized by placing these wavelengths sufficiently apart from each other. WDM can expand the capacity of the link into the Terabit/s region, well beyond the capabilities of electrical transceivers (Dutton 1998; Keiser 2000; Agrawal 2002; Zhu et al. 2001; Frignac et al. 2002; Winters and Gitlin 1990).

Traditionally, the optical link span was limited by fiber attenuation, and repeaters had to be placed wherever the optical power dropped below a certain level. To regenerate an optical signal with a conventional repeater, an optical-to-electrical conversion, electrical amplification, retiming, reshaping, and then electrical-to-optical conversion are necessary. This is expensive for a high-speed, multi-wavelength system. Instead, optical amplifiers such as erbium-doped fiber amplifiers (EDFAs) are used. Transparent to bit rates and modulation formats, optical

amplifiers provide the advantage of easy system upgrading by changing the equipment at the ends of the link. Another advantage is that the optical amplifiers can amplify signals at many wavelengths simultaneously. However, the link now becomes limited by other fiber impairments such as *chromatic dispersion* (CD), *polarization mode dispersion* (PMD), and nonlinear effects in the fiber. For long-haul applications, *dispersion-compensating modules* such as *dispersion-compensation fiber* are placed periodically along the link to compensate for CD.

At the end, an optical demultiplexer routes each wavelength to its designated electrical receiver. In the latter, a photodetector (which can be either a PIN diode or an avalanche photodiode) converts the optical pulses into small current pulses. This low-level signal is amplified by a low-noise preamplifier, followed by a main amplifier, which is either an automatic gain control amplifier or a limiting amplifier. A clock extraction and data regeneration circuit recovers the timing information from the random data and samples the data stream at the appropriate instant. Finally, a serial-to-parallel converter demultiplexes the retimed serial data to a lower rate, where the data are processed by other circuitry.

System Concepts

Fiber-optic communications systems have been deployed worldwide and have certainly revolutionized current telecommunication infrastructures and will continue to do so in the future. Currently, virtually all telephone conversations, cellular phone calls, and Internet packets must pass through some pieces of optical fibers from source to destination. Although initial deployments of optical fiber are intended mainly for long-haul or submarine transmissions, light-wave systems are currently used in virtually all metro and access networks and are considered as a backbone in local area networks.

As shown in Figure 2, a fiber-optic system can generally be seen as a system with three main components: a transmitter (dashed box), a transmission medium (the rest), and a receiver (dashed box). A regenerator might be used if the distance between the transmitter and the receiver is long enough that the signal would be drastically deformed and attenuated before reaching the receiver. As a model, the fiber-optic system is similar to the copper wire system it is replacing. The difference is that fiber optics uses light pulses to transmit information down a fiber instead of using electronic pulses to transmit information down copper lines. In the following sections, we study the three main components in the fiber-optic chain to give a better understanding of how the system works in conjunction with wire-based systems.

A serial bit stream in electrical form is presented to a modulator, which encodes the data appropriately for fiber transmission. A light source—either a *light-emitting diode* (LED) or a laser—is modulated by the modulator and the light is focused into the fiber. The light travels down the fiber (and suffers loss, reducing its intensity). At the receiver end, the light is incident onto a detector and converted to electrical form. The signal is then amplified and fed to another detector, which isolates the individual state changes and their timing. It then decodes the sequence

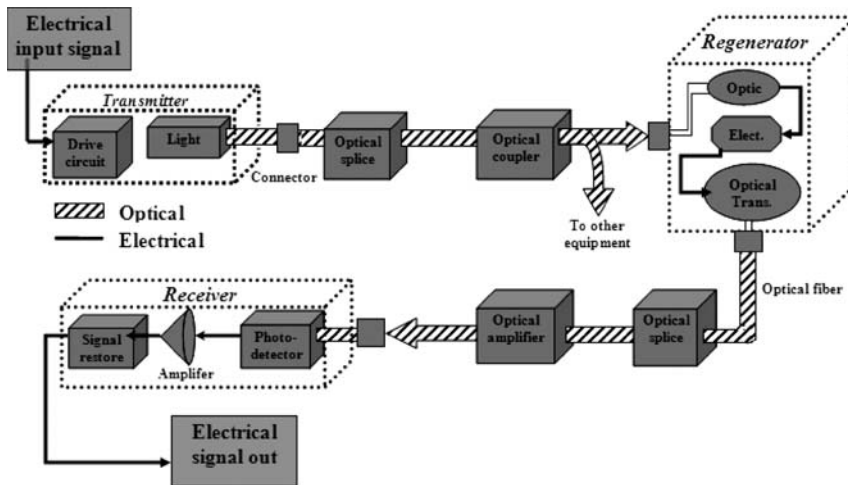

Figure 2: A general view of an optical fiber link

of state changes and reconstructs the original bit stream (Dutton 1998).

Optical Transmitters

A fiber-optic transmitter modulates the intensity of an optical carrier generated by a light source. This can be done in either of two ways: by directly modulating the input power to the light source or by using a separate optical component that changes the intensity of the light leaving the light source. Each approach has its own advantages and disadvantages.

Direct modulation is simple and inexpensive. It is suitable for LEDs and semiconductor lasers because their light output increases with the drive current passing through the semiconductor device once a certain threshold bias current has been exceeded (in the case of the laser). The input signal modulates the drive current, so the output optical signal is proportional to the input electrical signal. However, LEDs take time to respond to changes in the drive current. Semiconductor lasers are much faster, but their optical properties change slightly with the drive current, causing a slight “chirp” in the wavelength as the signal switches on and off. External modulation is needed for high-speed systems (>2.5 Gb/s) to minimize such undesirable nonlinear effects. A variety of external modulators are available either as separate devices or as integral parts of the laser transmitter packages.

Light-Emitting Diode

A LED in essence is a P-N junction solid-state semiconductor diode that emits light when a current is applied through the device. The essential portion of the LED is the semiconductor chip, which is divided into two parts or regions that are separated by a boundary called a *junction*. The P region is dominated by positive electric charges (holes), and the N region is dominated by negative electric charges (electrons). The junction serves as a barrier to the flow of the electrons between the P and N regions. This is somewhat similar to the role of the band gap because it determines how much voltage needs to be applied to the semiconductor chip before the current can flow and the electrons pass the junction into the P region. Band gaps

determine how much energy is needed for the electron to jump from the valence band to the conduction band. As an electron in the conduction band recombines with a hole in the valence band, the electron makes a transition to a lower-lying energy state and releases energy in an amount equal to the band-gap energy. This energy is released in photons. Because the recombinations do not always generate emitted photons, the nonradiative recombinations heat the material. In an LED, the emitted photons may give infrared or visible light.

Lasers

Semiconductor lasers are similar to LEDs in structure. A laser diode is a P-N junction semiconductor that converts the electrical energy applied across the junction into optical radiation. In both laser diodes and LEDs, the wavelength of the output radiation depends on the energy gap across the P-N junction. However, the output from a laser diode is highly coherent and can be collimated, whereas the output from an LED has many phases and is radiated in different directions.

Mach-Zehnder Interferometer Modulators

The *Mach-Zehnder interferometer* (MZI) (named after physicists Ernst Mach and Ludwig Zehnder) is used to split an optical signal into two components and directs them down two separate paths before recombining them. A phase delay between the two optical signals causes them to interfere when recombined, giving an output modulated intensity. Such a device can modulate the optical power from 100 percent (constructive interference) to 0 percent (destructive interference).

MZIs as illustrated in Figure 3 are used in a wide variety of applications within optics and optical communications. The basic principle is that there is a balanced configuration of a splitter and a combiner connected by a pair of matched waveguides. When a phase difference is created between the signals in the two matched waveguides, interference in the recombination process causes differences in the amplitude of the output signal. Thus, an intensity modulator based on an MZI converts changes in phase to changes in signal amplitude. The principle is simple:

Figure 3: Modulator using Match-Zehnder interferometer (L = length, g = width, and V = voltage)

The signal entering the device is split through a Y splitter into two directions. In a properly constructed device, one-half of the signal goes in each direction and polarization is not affected. When there is no phase delay (both arms of the interferometer are equal in length), the signal is recombined at the Y junction (coupler) immediately before the light exits the device. Because the signals in each arm are coherent, they reinforce during recombination. When there is a phase delay of 180 degrees, the output will be zero (Dutton 1998).

Optical Transmission Medium

The optical fiber is the transmission medium. An ideal transmission medium would have no effect on the signal it carries, but any medium inevitably has some effects. In a fiber, the two principal limiting effects on the signal are attenuation of the signal strength and pulse spreading (dispersion). Both depend on how far light travels through the fiber. Attenuation reduces the intensity of the optical signal. Pulse spreading limits the data rate, increases the *bit error rate* (BER) of the digital signal, or reduces the signal-to-noise ratio of an analog signal. Both attenuation and dispersion in the glasses used to make the fiber have low values in the wavelength ranges between 1250 and 1650 nanometers (Dutton 1998).

Optical Amplifiers

An optical amplifier can boost the strength of optical signals so they can travel farther through optical fibers. They amplify light directly in optical form, without converting the signal to electrical form. More details will be given later in “Optical Devices.”

Repeaters and Regenerators

Repeater and regenerator first convert the optical signal to electrical form and then amplify it and deliver the electrical signal they generate to another transmitter. That transmitter then generates a fresh optical version of the signal. Regenerators can clean up the effects of dispersion and distortion on optical signals.

Optical Splices

Normally, optical fibers are connected to each other by either connectors or splicing—that is, joining two fibers together to form a continuous optical waveguide.

The generally accepted splicing method is arc fusion splicing, which melts the fiber ends together with an electric arc. For quicker fastening jobs, a “mechanical splice” could be used, too.

Optical Splitters and Couplers

In an optical network there are many situations when it is necessary to combine signals, split them multiple ways, or both. Splitters are designed to split an optical signal into two or more components. Fiber-optic couplers are optical devices that connect three or more fiber ends, dividing one input between two or more outputs or combining two or more inputs into one output. The cable type accepted by fiber-optic couplers could be single-mode or multimode. *Single mode* describes an optical fiber that will allow only one mode to propagate. *Single-mode fiber* (SMF) has an exceptionally small core diameter of approximately 8 μm . It permits signal transmission at extremely high bandwidth and allows long transmission distances.

Optical Receivers

Receivers are the final elements in any communication systems. They convert a signal transmitted in one form into another form. For example, a radio receiver detects weak radio waves in the air and processes them electronically to generate sound. Fiber-optic receivers detect the optical signal emerging from the fiber and transfer the data in the form of an electrical signal. A photodetector generates an electrical current from the light it receives. Electronics in the receiver then amplify that signal and process it to decode the signal. After long distances and for better and improved reception, a preamplifier precedes the photodetector.

Optical Filters

An optical filter is a device that selectively transmits light having certain properties (often, a particular range of wavelengths—that is, a range of colors of light) while blocking the remainder (see “Optical Devices” below).

Photodetectors

The fundamental mechanism behind the photodetection process is optical absorption. The main objective of the photodetector is to receive the optical signal, remove the data from the optical carrier, and output it as a modulated electrical photocurrent through the photoelectric effect. The requirements for a photodetector are fast response, high sensitivity, low noise, low cost, and high reliability. Its size should be compatible with the size of the fiber core.

PROPAGATION OF LIGHT IN OPTICAL FIBERS

The fiber itself is one of the most significant components in any optical fiber system. Because its transmission characteristics play a major role in determining the performance of the entire system, several questions arise concerning optical fibers: What is the structure of the fiber? How does light propagate through the fiber? What is the nature of light traveling through the fiber?

Figure 4: Electromagnetic wave spectrum

The Nature of Light and Its Propagation Characteristics

Through the history of physics, the view of the nature of light has varied. Light is the basis of our most important sensory function. It was generally believed that light consisted of a stream of tiny particles that were emitted by luminous sources. These particles were pictured as traveling in straight lines. However, the answer to the question about what light “really is” varies depending on the situation. Light is usually described in one of three ways: rays, electromagnetic waves, and photons.

The accurate explanation of the electromagnetic nature of light was given by Augustin-Jean Fresnel in 1815. He showed that the approximately rectilinear propagation character of light could be interpreted on the assumption that light was a wave motion, and that the diffraction fringes could thus be accounted for in detail. Later, James Clerk Maxwell in 1864 theorized that light waves must be electromagnetic in nature. Furthermore, observation of polarization effects indicated that light waves are transverse (i.e., the wave motion is perpendicular to the direction in which the wave travels) (Dutton 1998; Keiser 2000; Agrawal 2002; Zhu et al. 2001). Figure 4 illustrates the electromagnetic wave spectrum of light.

Light as an Electromagnetic Wave

An electromagnetic wave consists of two fields: an electric field and a magnetic field, both of which have a direction and a strength (or amplitude). Within the electromagnetic wave, the two fields are oriented at precisely 90 degrees to one another as illustrated in Figure 5. The fields move (by definition, at the speed of light) in a direction 90 degrees to both of them. In three dimensions, we could consider the electric field to be oriented on the x -axis and the magnetic field on the y -axis. Direction of travel would then be along the z -direction.

As the electromagnetic wave travels, the field at any point in space oscillates in direction and strength. Figure 5 shows the electric and magnetic fields separately, but they occupy the same space. They should be overlaid on one another and are only drawn this way in the figure for clarity. We could consider the z -direction in Figure 5 to represent

Figure 5: Electric and magnetic fields are orthogonal to each other and to the direction of propagation

passing time, or it could represent a wave traveling in space at a single instant in time.

If the electromagnetic wave is watched from a stationary viewpoint, we see that at the start the field is oriented from bottom to top (increasing values of x). Some time later, the field direction reverses. At a still later time, the field direction reverses again back to its original direction (Dutton 1998).

Light Propagation in Multimode Fibers

Fiber types, including *multimode fibers* (MMFs), will be handled below in “Optical Fibers.” The key feature of light propagation in a fiber is that the fiber may bend around corners. Provided the bend radius is not too tight—1.4 cm is more or less the minimum for most MMFs and waveguides (Papakonstantinou et al. 2007)—the light will follow the fiber and propagate without loss because of the bends as shown in Figure 6. This observable fact is called *total internal reflection*. A ray of light entering the fiber is guided along the fiber because it reflects from the interface between the core and the cladding, which has a lower *refractive index* (RI). Light is said to be “bound” within the fiber.

Figure 6: Light propagation in a multimode fiber

Figure 7: Incident and reflected rays

Figure 8: Refraction

If we consider the propagation of a “ray” in a multi-mode step index fiber, the angle of incidence is equal to the angle of reflection. This is illustrated in Figure 7. This means that $\theta_i = \theta_r$.

The important thing to realize about propagation along a fiber is that not all light can propagate this way. The angle of incidence of the ray at the core-cladding interface must be quite small or the ray will pass into the cladding and (after awhile) will leave the fiber. The geometric interpretation of light can be handled more rigorously by electromagnetic theory. In this case, Maxwell equations combined with boundary conditions should be considered.

Geometrical Optics Laws and Parameters

Snell's Law

To understand ray propagation in a fiber, we need one more physics law. This is referred to as *Snell's law*. Refer to Figure 8:

$$n_1 \sin(\theta_1) = n_2 \sin(\theta_2)$$

where n denotes the refractive index of the material. One can notice here that:

1. The angle θ_i is the angle between the incident ray and an imaginary line normal to the plane of the core-cladding boundary;
2. when light passes from a material of a higher refractive index to a material of a lower index, the (refracted) angle θ_2 becomes larger; and
3. when light passes from a material of a lower refractive index to a material of a higher index, the (refracted) angle θ_2 becomes smaller (Dutton 1998).

Critical Angle

If we consider Figure 9, we notice that as the angle θ_1 becomes increasingly larger, so does the angle θ_2 . At some point, θ_2 will reach 90 degrees while θ_1 is still well less than that. This is called the *critical angle*. When θ_1 is increased

Figure 9: Critical angle

more, refraction ceases and the light is all reflected rather than refracted. Thus, light is perfectly reflected at an interface between two materials of different refractive index if and only if (1) the light is incident on the interface from the side of higher refractive index and (2) the angle θ is greater than a specific critical angle.

If we know the refractive indexes of both materials, then the critical angle can be derived quite easily from Snell's law. At the critical angle, we know that θ_2 equals 90 degrees and $\sin(90) = 1$, so

$$n_1 \sin(\theta_1) = n_2 \sin(90) = n_2$$

$$\text{Therefore, } \sin(\theta_1) = \frac{n_2}{n_1}.$$

Another aspect here is that when light meets an abrupt change in refractive index (such as at the end of a fiber), not all of it is refracted. Usually, approximately 4 percent of the light is reflected back along the path from which it came, depending on the end surface finish (Dutton 1998).

When we consider rays entering the fiber from the outside (into the end face of the fiber), we see that there is a further complication. The refractive index difference between the fiber core and the air will cause any arriving ray to be refracted. This means that there is a maximum angle for a ray arriving at the fiber end face at which the ray will be bound in a propagating mode (Agrawal 2002).

Numerical Aperture

One of the most often quoted characteristics of an optical fiber is its *numerical aperture* (NA), which is intended as a measure of the light-capturing ability of the fiber. However, it is used for many other purposes. For example, it may affect the amount of loss that we might expect in a bend of a particular radius.

Figure 10 shows a ray entering the fiber at an angle close to its axis. This ray will be refracted and later encounter the core-cladding interface at an angle such that

Figure 10: Calculating the numerical aperture

it will be reflected because the angle θ_2 will be greater than the critical angle θ_c . The angle is greater because we are measuring angles from a normal to the core-cladding boundary, not a glancing angle to it. It is clear that there is a “cone” of acceptance (illustrated in Figure 10). If a ray enters the fiber at an angle within the cone, then it will be captured and propagate as a bound mode. If a ray enters the fiber at an angle outside the cone, then it will leave the core and eventually leave the fiber itself.

The NA is the sine of the largest angle contained within the cone of acceptance. Looking at Figure 10, the $NA = \sin(\theta)$. The NA is also found to be given by the following:

$$NA = \sqrt{n_1^2 - n_2^2}$$

where n_1 = refractive index of the core and n_2 refractive index of the cladding.

Another useful expression is $NA = n_1 \sin(\theta_1)$. This relates the NA to the RI of the core and the maximum angle at which a bound ray may propagate (angle measured from the fiber axis rather than its normal). The typical NA for SMF is 0.1. For MMF, NA is between 0.2 and 0.3 (usually closer to 0.2). NA is related to several important fiber characteristics. It is a measure of the fiber’s ability to gather light at the input end (as discussed above). It is also a measure of the contrast in RI between the core and the cladding, so it is a good measure of the fiber’s light-guiding properties. The higher the NA, the tighter (i.e., the smaller the radius) the bends in the fiber can be before loss of light becomes a problem.

The higher the NA, the more modes we have. Rays can reflect at greater angles and therefore there are more of them. This means that the higher the NA, the greater will be the dispersion of this fiber (in the case of MMF).

In SMF, a high RI contrast usually implies a high level of dopant in the cladding. Because a significant proportion of optical power in SMF travels in the cladding, we get a significantly increased amount of attenuation because of the higher level of dopant. Thus, as a rule of thumb, the higher the NA of SMF, the higher will be the attenuation of the fiber (Dutton 1998).

Refractive Index

Refractive index is the ratio of the velocity of light in vacuum to the velocity of light in a medium. It is referred to as the *medium’s refractive index*, denoted by n and given by

$$n(RI) = C/V$$

where C is the speed of light in a vacuum and V is the velocity of light in the material.

The velocity of light in a vacuum is 3.0×10^8 m/s or approximately 186,000 miles/s. Refractive index of a transparent substance or material is defined as the relative speed at which light moves through the material with respect to its speed in a vacuum. By definition, the refractive index of a vacuum is defined as having a value of 1.0, which serves as a universally accepted reference point.

OPTICAL FIBERS

Conventional Fibers

Like other waveguides, an optical fiber guides waves in distinct patterns called *transverse modes*, which describes the distributions of light energy across the waveguide. The precise patterns depend on the wavelength of light transmitted and on the variations in refractive index across the fiber core. There are three basic types of fiber: *multimode step-index*, *multimode graded-index*, and *single-mode* or *step-index*.

The difference between the fiber modes is in the way light travels along the fiber. There is a core of 50 microns (μm) diameter for multimode fiber and a cladding of 125 μm diameter (these are the dimensions of standard glass fibers used in telecommunications). (Fiber size is normally quoted as the core diameter followed by the cladding diameter. Thus, the fiber is identified as 50/125.) The cladding surrounds the core. The cladding glass has a different (lower) refractive index than that of the core, and the boundary forms a partially reflecting interface.

Light is transmitted (with low loss) down the fiber by reflection from the boundary between the core and the cladding. This phenomenon is called *total internal reflection*. Perhaps the most important characteristic is that the fiber will bend around corners to a radius of only a few centimeters without any loss of light. The lowest loss occurs at 1.55 microns, and there is also a loss minimum at 1.31-micron wavelengths (Dutton 1998).

Multimode Step-Index Fiber

Fiber that has a core diameter large enough for the light used to find multiple paths is called *multimode fiber* (see Figure 11). For a fiber with a core diameter of 62.5 microns using light of wavelength 1300 nm, the number of modes is approximately 400, depending on the difference in refractive index between the core and the cladding. The problem with multimode operation is that some of the paths taken by particular modes are longer than other paths. This means that light will arrive at different times according to the path taken. Therefore, the pulse tends to disperse (spread out) as it travels through the fiber. This effect is one cause of *intersymbol interference* (ISI). This restricts the distance that a pulse can be usefully sent over multimode fiber.

One way around the problem of (modal) dispersion in MMF is to do something to the glass such that the refractive index of the core changes gradually from the center to the edge. Light traveling down the center of the fiber experiences a higher refractive index than light that travels farther out toward the cladding. Thus, light on the physically shorter paths (modes) travels more slowly than light on

Figure 11: Multimode step-index fiber

Figure 12: Multimode graded-index fiber

the physically longer paths. The light follows a curved trajectory within the fiber as illustrated in Figure 12. The aim of this is to keep the speed of propagation of light on each path the same with respect to the axis of the fiber. Thus, a pulse of light composed of many modes stays together as it travels through the fiber. This allows transmission for longer distances than in regular multimode transmission. This type of fiber is called *graded-index fiber*. Within this fiber, light typically travels in approximately 400 modes (at a wavelength of 1300 nm) or 800 modes (in the 800 nm band) (Agrawal 2002). A multimode fiber is characterized by its distance multiplied by bandwidth product.

Single-Mode Fiber

Single-mode fibers (also called *monomode fibers*) are optical fibers that are designed to support only a single mode per polarization direction for a given wavelength. As shown in Figure 13, the core diameter is typically between 8 and 9 microns, whereas the diameter of the cladding is 125 microns.

The number of modes allowed in a given fiber is determined by a relationship between the wavelength of the light passing through the fiber, the core diameter of the fiber, and the material of the fiber. This relationship is known as the *normalized frequency parameter*, or *V number*. The mathematical description of the *V* number is given by

$$V = \frac{2 * \pi * NA * r}{\lambda}$$

where NA = numerical aperture, r = core fiber radius (microns), and λ = wavelength (microns).

The electromagnetic wave is tightly held to travel down the axis of the fiber. The longer the wavelength of light in use, the larger the diameter of fiber we can use and still have light travel in a single mode. The core diameter used in a typical single-mode fiber is 9 microns. In practice, it is not quite so simple. A significant proportion (as much as 20 percent) of the light in a SMF actually travels in the cladding. For this reason, the *apparent diameter* of the

Figure 13: Single-mode fiber. The core diameter is typically between 8 and 9 microns, whereas the diameter of the cladding is 125 microns

core (the region in which most of the light travels) is somewhat wider than the core itself. The region in which light travels in an SMF is often called the *mode field*, and its diameter is quoted instead of the core diameter. We cannot make the core too narrow because of losses at bends in the fiber. When the core is especially narrow, the mode spreads more into the cladding. As the core diameter decreases compared to the wavelength (the core gets narrower or the wavelength gets longer), the minimum radius that we can bend the fiber without loss increases. If a bend is too sharp, the light just comes out of the core into the outer parts of the cladding and is lost.

Single-mode optical fiber is an optical fiber in which only the lowest-order bound mode can propagate at the wavelength of interest. SMFs are best at retaining the fidelity of each light pulse over longer distances and exhibit no dispersion caused by multiple spatial modes; thus, more information can be transmitted per unit time, giving SMFs a higher bandwidth in comparison with MMFs. A typical single-mode optical fiber has a core radius of 5 μm to 10 μm and a cladding radius of 120 μm . Currently, data rates as high as 10 Gigabits per second are possible at distances of more than 60 km with commercially available transceivers.

Unconventional Fibers

Photonic Crystal Fiber

Photonic crystal fiber (PCF) or “holey” fiber is the optical fiber having a periodic structure of cylindrical holes running along the length of the optical fiber as shown in Figure 14. The structures of the PCF have been modified since the introduction of such fibers, including the air-silica fiber, photonic band-gap fiber, and hollow-core photonic crystal fiber. The *air-silica fiber* is the most basic structure. It has a silica background and periodic air holes that surround the silica core, so the core has a high refractive index like a traditional optical fiber. As a consequence, *total internal reflection* (TIR) dominates the guiding mechanism. In *photonic band-gap fiber*, on the other hand, air holes are filled with materials that have higher refractive indexes than the core material (Bise et al. 2002). Obviously, it violates the condition for TIR. However, light is still guided via a different mechanism, the so-called Bragg scattering of constructive or destructive scattering. Finally, the *hollow-core photonic crystal fiber* is air-silica fiber with larger air holes in the core region (Cregan et al. 1999). As a result, the

Figure 14: Crosscut view of a photonic crystal fiber

core has a lower refractive index than the cladding, so the guiding mechanism is similar to that of the photonic band-gap fiber.

Holey fibers operating under the TIR principle show significant advantages over their conventional counterparts. For instance, they can be exclusively fabricated out of a single dielectric, thus avoiding interfaces between different materials that might undermine the fiber's performance. The dependence of the cladding's effective index on wavelength permits the manifestation of only a finite number of modes at relatively high frequencies because of the reduction of the difference between the refractive indices of the core and the cladding for increasing frequencies (Birks, Knight, and Russell 1997). Furthermore, it has been theoretically shown and experimentally verified that holey fiber with a triangular lattice of airholes can exhibit endless single-mode operation provided the diameter of the cladding's airholes and the center-to-center spacing of two adjacent holes (lattice constant) are properly chosen (Cregan et al. 1999).

The variation of the cladding's effective index can be optimally turned to advantage, as far as the fiber's dispersion properties are concerned. The wide tailoring of the fiber's design in terms of airhole sizes, shapes, and arrangements provides several degrees of freedom whose proper combination can tune the fiber's dispersion curve. The influence of the design parameters on the dispersion properties of holey fiber has been extensively studied such as both the classical triangular airhole-silica core lattice and other configurations that include additional features—for example, airhole rings of variable diameter and airholes with elliptical cross-sections or doped-silica cylindrical cores (Birks, Knight, and Russell 1997; Saitoh et al. 2003; Ferrando, Silvestre, and Andrés 2001; Hansen 2003). Several types of holey fiber were designed that exhibit favorable dispersion properties, such as zero dispersion at the 1.55- μm operation wavelength and ultraflattened *group-velocity dispersion* (GVD) curves of zero, positive, or negative dispersion over a significant wavelength regime (Crawford, Allender, and Doane 1992; Burylov 1997).

Liquid Crystal Fiber

Nematic liquid crystals are anisotropic materials consisting of rodlike molecules whose axis coincides with the anisotropy's optical axis. The liquid crystal director indicates the local alignment direction and usually varies through the volume of the liquid crystal. When confined in closed cylindrical cavities in the absence of external stimuli, the liquid crystal's director distribution is determined by the physics of elastic theory and the anchoring conditions at the cavity's surface (Saitoh et al. 2003; Ferrando, Silvestre, and Andrés 2001). Under the application of a static electric field, the director's orientation can be controlled because the liquid crystal directors tend to align their axis according to the applied field. In an alternative approach, the properties of nematic liquid crystals can be tuned thermally owing to the dependence of the refractive index values on temperature. The above features have favored their utilization in a number of proposed *opto-electronic* (OE) devices based on photonic crystals (Du, Lu, and Wu 2004; Larsen et al. 2003; Kosmidou, Kriezis, and Tsiboukis 2005; Alkeskjold 2004).

Plastic Optical Fiber

Plastic optical fiber is an optical fiber made from plastic. Traditionally, polymethyl methacrylate is the core material, and fluorinated polymers are the cladding material. The cores of plastic fibers are relatively larger than that of glass fibers (2 mm). The material is a type of plastic and thus quickly absorbs the light traveling through the material. Its lowest loss occurs in the red part of the spectrum rather than in the infrared. Applications for plastic fibers are limited to short-range data transmission. Compared to glass fibers, plastic fibers are less expensive in the overall optical link because of the lower cost of the connector and the splicing used.

Fiber Fabrication

The fiber fabrication process consists of two major stages. The first stage produces a preform, a cylinder of silica of 10 cm to 20 cm in diameter and approximately 50 cm to 100 cm in length. This preform consists of a core surrounded by a cladding with a desired refractive-index profile, a given attenuation, and other characteristics; in other words, this is a desired optical fiber, but on a much larger scale.

In the second stage, the preform is drawn into an optical fiber of the desired size. The preform is made by vapor-phase oxidation, in which two gases—silicon tetrachloride (SiCl_4) and oxygen (O_2)—are mixed at high temperature to produce silicon dioxide (SiO_2):

Silicon dioxide, or pure silica, is usually obtained in the form of small particles ($\sim 0.1 \mu\text{m}$) called *soot*. This soot is deposited on the target rod or tube layer upon layer to form a homogeneous, transparent cladding material. To change the value of a cladding's refractive index, some dopants are used. For example, fluorine is used to decrease the cladding's refractive index in a depressed-cladding configuration.

The soot for the core material is made by mixing three gases— SiCl_4 , germanium tetrachloride (GeCl_4), and O_2 —which results in a mixture of SiO_2 and germanium dioxide (GeO_2). The degree of doping is controlled by simply changing the amount of GeCl_4 gas added to the mixture. The same principle is used for doping other materials.

Because deposition is made by the application of silica layers on top of one another, the manufacturer can control the exact amount of dopant added to each layer, thus controlling the refractive-index profile. The vapor-phase oxidation process produces extremely pure material whose characteristics are under the absolute control of the manufacturer.

OPTICAL FIBER CHARACTERISTICS

The need for high-speed data transmission has meant that optical communication systems have experienced a rapid evolution during the last decade. However, one major impairment restricts the achievement of higher bit rates with standard SMF: chromatic dispersion. This is particularly

problematic for systems operating in the 1550-nm band. CD and PMD can cause intersymbol interference, which is a major obstacle to reliable high-speed data transmission over optical fiber. As both CD and PMD originate in the optical domain, the most effective compensation schemes use optical equalization. Nonetheless, electrical equalization schemes are also being widely considered because they offer several potential advantages, including compactness, flexibility, and low cost (Winters and Gitlin 1990).

CD is the variation in the speed of propagation of a light-wave signal with wavelength. This phenomenon is also known as *group velocity dispersion* because the dispersion is the result of the group velocity being a function of the wavelength.

Attenuation

Attenuation in fiber occurs as a result of absorption, scattering, and radiative losses of the optical energy. Absorption losses are caused by atomic defects in the glass composition, intrinsic absorption by the atomic resonance of fiber material, and extrinsic absorption by the atomic resonance of external particles (such as the OH^- ion) in the fiber. Scattering losses in fiber arise from microscopic variations in the material density and from structural inhomogeneities. There are four kinds of scattering losses in optical fiber: Rayleigh, Mie, Brillouin, and Raman scattering. Radiative losses occur in an optical fiber at bends and curves because of the evanescent modes generated. Figure 15 illustrates the attenuation for SMF with respect to wavelength.

Group Velocity Dispersion and Polarization Mode Dispersion

In SMF there are two types of dispersion: chromatic and PMD. The former is the phenomenon by which different frequencies travel through a fiber with different group velocities, whereas the latter represents a velocity difference between the two orthogonal electric field components of the fundamental mode inside the fiber.

For a single-mode fiber of length L , a specific spectral component at a frequency ω arrives at the other end of the fiber after a propagation delay of $T = L/v_g$, where v_g is the group velocity given by:

$$v_g = \left(\frac{d\beta}{d\omega} \right)^{-1}$$

where β is the mode propagation constant. As a result of the dependence of group velocity on frequency, the different spectral components of the data pulses travel with different velocities along the fiber, arriving at the fiber output dispersed in time. The amount of pulse broadening, as a result of CD, can be quantified as

$$\Delta T \cong \frac{dT}{d\omega} \Delta\omega = \frac{d}{d\omega} \left(\frac{L}{v_g} \right) \Delta\omega = L \frac{d^2\beta}{d\omega^2} \Delta\omega = L\beta_2 \Delta\omega$$

The factor $\beta_2 = d^2\beta/d\omega^2$ is the GVD parameter, which provides a measure of how much a pulse broadens in time as the pulse travels along an optical fiber. Depending on the sign of β_2 , CD is called *positive* ($\beta_2 > 0$) or *negative* ($\beta_2 < 0$).

CD or GVD increases linearly with the fiber length; its effect on the transmitted and received signal is shown in Figure 16. The GVD is governed by material properties (the dependence of the fiber material's refractive index on the light frequency) and waveguide dispersion (wherein Maxwell's equations yield different β 's for different frequencies, depending on the fiber's dimensions). GVD is quantified by a *dispersion parameter*, $D(\lambda)$, that measures the time delay introduced between light at different wavelengths while propagating through a commonly used SMF-28 fiber with a length L :

$$(\tau_{\text{delay}} = D(\lambda)\Delta\lambda L) \text{ and } \beta_1 = \frac{\delta\beta}{\delta\omega} = \frac{1}{v_g} \quad \beta_2 = \frac{\lambda^2 D}{4c\pi}$$

Figure 15: Attenuation for SMF

Figure 16: The overall effect of both GVD and PMD (Guizani et al. 2005)

where β_1, β_2 are the first- and second-order dispersions, v_g is the group velocity, C is the speed of light, $D \approx 17$ ps/nm/km in the 1550-nm communication window, and $D(\lambda)\Delta\lambda$ is the wavelength spread. PMD, on the other hand, is caused by the removal of circular symmetry in a fiber resulting from external factors such as temperature or mechanical stress as well as the lack of perfect symmetry in manufacturing. The fraction of the total power contained in one of the polarizations (γ) governs the severity of the PMD. The overall effect of both GVD and PMD is the broadening of pulses propagating through the fiber; this results in intersymbol interference (Winters and Gitlin 1990). In reality, it affects the envelope of the transmitted pulses. ISI leads to closing of the eye diagram (the eye diagram is created by taking the time domain signal and overlapping the traces for a certain number of symbols) at the output, which in turn causes higher BER and increases input power requirements.

Nonlinear Optical Effects

The refractive index of silica has a weak dependence on the optical intensity, I (optical power per effective area in the fiber), and is given by

$$n = n_0 + n_2 I = n_0 + n_2 \frac{P}{A_{\text{eff}}}$$

where n_0 is the normal refractive index of the fiber material, n_2 is the nonlinear index coefficient, P is the optical power, and A_{eff} is the effective cross-sectional area of the fiber. In silica, the value of n_2 ranges from 2.2 to 3.4×10^{-8} $\mu\text{m}^2/\text{W}$. This nonlinearity in the refractive index is known as *Kerr nonlinearity* and results in a carrier-induced *phase modulation* (PM) of the propagating signal called the *Kerr effect*. It can cause self-phase modulation, cross-phase modulation, and four-wave mixing (Guizani et al. 2005).

Self-Phase Modulation

The local refractive index is a function of the optical intensity of the propagating signal, so the mode propagation constant also depends on the optical intensity. The power-dependent propagation constant, β , can be written as $\beta = \beta_0 + \gamma P$, where β_0 is the mode propagation constant, which is derived by assuming a constant refractive index. The nonlinear coefficient γ is defined by $\frac{2\pi n_2}{\lambda A_{\text{eff}}}$.

Because this nonlinear PM is self-induced, the nonlinear phenomenon responsible for it is called *self-phase modulation* (SPM). As phase fluctuations translate into

frequency fluctuations, SPM and dispersion cause frequency chirping of the optical pulses, which presents a source of error (Guizani et al. 2005).

Cross-Phase Modulation

In WDM systems, where several optical channels are transmitted simultaneously inside an optical fiber, the nonlinear phase shift for a specific channel depends not only on the power of that channel but also on the power of the other channels. Moreover, the phase shift varies from bit to bit, depending on the bit pattern of the neighboring channels. This nonlinear phenomenon is known as *cross-phase modulation* (XPM). Like SPM, XPM may lead to erroneous reception of the transmitted bit sequence (Guizani et al. 2005).

Four-Wave Mixing

Four-wave mixing (WM) is a third-order nonlinearity in silica fiber caused by the Kerr effect. FWM resembles intermodulation distortion in electrical systems. If three optical fields with carrier frequencies f_1, f_2 , and f_3 propagating simultaneously in a fiber, the fiber nonlinearity causes them to mix, producing a fourth intermodulation term that is related to the other frequencies by the relation $f_4 = f_1 \pm f_2 \pm f_3$. FWM is an additional source of ISI (Guizani et al. 2005), but more importantly it causes interchannel interference in WDM systems.

OPTICAL DEVICES

In addition to lasers and LEDs, many other optical devices perform useful and necessary functions in an optical communication system. This section describes some of them. We briefly mentioned some optical devices at the beginning of this chapter. Here we discuss those devices in more detail and also describe other optical devices that find uses in optical fiber communications. Many components already in use in radio and radar systems such as circulators, chirped grating reflectors, and compressive receivers were realized in optical form so that the same system designs could now be used in the optical domain.

Circulators

Circulators are passive micro-optic devices of three or more ports in which the ports can be accessed in such an order that when power is fed into any port it is transferred to the next port, the first port being counted as following the last in order. They are unidirectional devices that direct an optical signal (light) from one port to the next in only one direction at a time. Although the direction of the light may be redirected as needed, it must pass to and from ports sequentially (from port 1 to port 2 before traveling to port 3) as illustrated in Figure 17.

Modulators and Switches

An *optical modulator* is a device that allows manipulating a property of light, often of an optical beam such as a laser beam. Depending on which property of light is controlled, we talk about intensity modulators, phase modulators, polarization modulators, and so on.

Figure 17: Four-port circulator

Most modulators consist of a material that changes its optical properties under the influence of an electric or magnetic field. The following are some modulators types and their possible applications:

- *fiber-optic* modulators, which are often fiber pig-tailed bulk components;
- *acousto-optic* modulators, which are used for switching or continuously adjusting the amplitude of a laser beam to shift its optical frequency or its spatial direction;
- *electro-optic* modulators, which are used for modifying the polarization, phase, or power of a beam or for pulse picking in the context of ultrashort pulse amplifiers;
- *electro-absorption* modulators, which are used for transmitters in OFC;
- *interferometric* modulators (e.g., Mach-Zehnder modulators), which are often realized in integrated optical circuits and used in optical data transmission; and
- *liquid crystal* modulators, which are used, for example, in optical displays and in pulse shapers and often as spatial light modulators (i.e., with a spatially varying modulation).

Optical modulators are used in widely different application areas such as OFC, displays, active Q switching or mode locking of lasers, and optical metrology.

An optical switch may operate by mechanical means, such as physically shifting an optical fiber to drive one or more alternative fibers, or by electro-optic effects, magneto-optic effects, or other methods. Slow optical switches, such as those using moving fibers, may be used for the alternate routing of an optical transmission path such as around a fault. Fast optical switches, such as those using electro-optic or magneto-optic effects, may be used to perform logic operations.

Optical Amplifiers

The transmission distance of any OFC system is eventually limited by fiber losses. Traditionally, OE repeaters were used to overcome this loss by first converting the optical signal into an electric current and then regenerating it using a transmitter. Such regenerators become quite complex and expensive for WDM light-wave systems.

The alternative approach is to use optical amplifiers that amplify the optical signal directly without requiring

its conversion to the electric domain. There are several kinds of optical amplifier. These optical amplifiers have become an integral part of almost all OFC systems installed after 1995 because of their excellent amplification characteristics such as low insertion loss, high gain, large bandwidth, low noise, and low cross talk. The most popular are EDFAs, semiconductor optical amplifiers, and Raman amplifiers.

Fiber Bragg Gratings

An FBG is a periodic perturbation of the refractive index along the fiber length. It is formed by exposure of the core to an ultraviolet optical interference pattern (see Figure 18). The principle of the Bragg grating is illustrated in Figure 19. A part of the incident wave is transmitted at each grating period, and the other part is reflected. For a certain wavelength depending on the period Λ (shown in Figure 18), the reflected waves are in phase. Multiple reflections are not considered in the figure, although they are crucial in fully explaining the device's operation.

The formation of permanent gratings in an optical fiber was first demonstrated by Hill et al. (1978) at the Canadian Communications Research Centre (Maune et al. 2004). They launched intense argon-ion laser radiation into a germania-doped fiber and observed that after several minutes an increase in the reflected light intensity occurred that grew until almost all of the light was reflected from the fiber. Spectral measurements, done indirectly by strain and temperature tuning of the fiber grating, confirmed that a very narrowband Bragg grating filter had been formed over the entire 1-m length of the fiber. This achievement, subsequently called the *Hill gratings*, was an outgrowth of research on the nonlinear properties of germania-doped silica fiber. It established the photosensitivity of germania fiber, which prompted other inquiries several years later into the cause of the fiber photo-induced refractivity and its dependence on the wavelength of the light that was used to form the gratings.

As light moves along the fiber and encounters the changes in refractive index, a small amount of light is reflected at each boundary. When the period of the grating and half of the wavelength of the light are the same, there is constructive interference and power is coupled from the forward direction to the backward direction. Light of other wavelengths destructively interferes with out-of-phase reflections and therefore cannot be reflected and is transmitted instead. The spacing between the grating reflectors determines the wavelength that is reflected. The incoming light is gradually reflected, and the backward-traveling light gradually grows in strength as they are waves coupled by the grating. This is a resonance phenomenon and has some similarities to that in an electromagnetic resonant circuit in electronics. Power from the forward direction is coupled into the resonant circuit and then reflected back. Nonresonant wavelengths are not affected much.

FBGs have proven attractive in a wide variety of optical fiber applications such as:

- narrowband and broadband tunable filters;
- optical fiber mode converters;

Figure 18: Fiber Bragg grating overview

Figure 19: Principle of the Bragg grating (Λ is the grating period)

- wavelength-selective filters, multiplexers, and add-drop Mach-Zehnders;
- dispersion compensation in long-distance telecommunication networks;
- gain equalization and improved pump efficiency in EDFA;
- spectrum analyzers;
- specialized narrowband lasers; and
- optical strain gauges in bridges, building structures, elevators, reactors, composites, mines, and smart structures.

Chirped FBG

The chirped FBG is considered one of the most interesting optical elements to have immediate applications in telecommunications systems. A chirped FBG is used when the spacing of the lines on the grating vary constantly over a miniature range (Figure 20). Shorter-wavelength light

entering the grating travels along it almost to the end before being reflected. Longer-wavelength light is reflected close to the start of the grating (Agrawal 2002). Thus, shorter wavelengths are delayed in relation to longer ones. Because the pulse has been dispersed such that short wavelengths arrive before the long ones, the grating can restore the original pulse shape. It undoes the effects of dispersion (Figure 21). In this sense, it has a similar structure and operates in a similar way to surface acoustic wave chirped reflective gratings developed earlier (Huang, Paige, and Selviah 1986) for use in radar pulse-compression receivers that remove the dispersion on the received pulse.

To show the importance of all of the optical devices discussed herein—the laser, the modulator, the chirped grating, the optical amplifier, the circulator, and the photodetector—an application of an optical link is shown in Figure 21. The electrical signal is transformed into an optical signal by external modulation using a laser source and external modulation, most commonly by means of an

Figure 20: Principle of the chirped grating

Figure 21: Precompensation of chromatic dispersion by using a chirped grating

MZI. The obtained distortion-free optical signal enters a circulator and goes first through a chirped FBG, where it is intentionally deformed to spread the pulses. Then the optical deformed signal recovers its initial shape after propagation through the dispersive fiber, which compensates the chirped FBG effect (Figure 21). Because a standard single-mode fiber operating at 1550 nm causes negative CD ($D = 17$ ps/nm/km), the chirped FBG should first introduce positive dispersion to enable precompensation. Because attenuation is unavoidable over long distances, optical amplifiers should be used.

Filters

In the world of optics, *filter* often is a broad term that is applied to components that filter out part of the incident light and transmit the rest. In current optical systems, frequency filters are used in front of an LED to narrow the line width before transmission in a form of spectral slicing. In WDM networks, filters are extremely important for many uses, such as (1) placing a filter in front of an incoherent receiver to select a particular signal from many arriving signals and (2) controlling which path a signal will take through a proposed WDM network.

Many filtering principles have been proposed, and many different types of devices have been built. The result is that many kinds of active, tunable filters are available that are essential in WDM networks (Dutton 1998).

In dense wavelength-division multiplexing systems, the wavelengths that are not transmitted through the filter normally are reflected, so they go elsewhere in the system. FBGs are probably the most important optical filter in the communications world. One of the simplest filters in principle is based on the Fabry-Perot interferometer. It consists of a cavity bounded on each end by a dielectric stack mirror. If the mirrors are fixed in relation to each other (such as with spacers), it is called an *Etalon*. If the mirrors can be moved in relation to each other, the device is called an

interferometer and is a narrowband tunable filter. However, this mechanical motion is undesirable, so Fabry-Perot filter cavities have been filled with nematic liquid crystal to give a change in optical path length across the cavity when a low voltage is applied; this changes the effective refractive index of the liquid crystal (Day et al. 1995; Kataoka et al. 2004). These tunable narrowband filters, however, only operate for one incident linear polarization of light, so additional birefringent layers were added inside the cavity to make the device polarization-insensitive (Day et al. 1995; Kataoka et al. 2004).

Repeaters

In an optical fiber communications system, repeaters are used to regenerate an optical signal by converting it to an electrical signal, processing that electrical signal, and then retransmitting an optical signal. Such repeaters are used to extend the reach of optical communications links by overcoming losses resulting from attenuation of the optical fiber and distortion of the optical signal. Such repeaters are known as *optical-electrical-optical* (OEO) because of the conversion of the signal (see Figure 22).

Repeaters have largely been replaced in long-haul systems by optical amplifiers (such as EDFA) because one amplifier can be used for many wavelengths in a WDM system, thereby saving money. Note that a device of this class is sometimes called an *optical amplifier repeater*.

Repeaters have been the method of choice for amplifying an optical signal. A regenerative repeater is a full receiver that reconstructs the bit stream and its timing. This bit stream and its timing are used to drive a transmitter. This means that the repeated signal has all dispersion and noise removed. It is said that repeaters perform the “three R’s”: *reamplification*, *reshaping*, and *reclocking*.

So-called 2R repeaters exist but only perform reamplification and reshaping but not reclocking. Repeaters are more complex and more costly than simple amplifiers.

Figure 22: Repeater's components—OE = opto-electrical, EO = electro-optical

They are also highly inflexible because they must be constructed for exactly the wavelength, protocol, and speed of the signal being carried. Because of the high data rates that can be achieved with optical systems, OEO repeaters are expensive to implement; the electronics needed to handle those high data rates are expensive and difficult to construct. Also, because one repeater is required for each wavelength, and many tens of wavelengths may be transmitted down a single fiber, a lot of equipment is required for each fiber. In contrast, an optical amplifier can amplify all of the wavelengths in a single device. An amplifier does not provide the regeneration ability of a repeater, but loss, rather than distortion, is generally the limiting factor in the design of communications systems (Dutton 1998).

CONCLUSION

Since their invention in the early 1970s, the use and demand for optical fiber systems has grown tremendously. OFC now permeate many markets. The most common are telecommunications, medicine, military, automotive, and industrial.

Optical communication applications are widespread, ranging from global networks to local telephone exchanges to subscribers' homes to desktop computers. These involve the transmission of voice, data, and video over progressively shorter distances from thousands of kilometers down to less than a meter within printed circuit boards (Papakonstantinou et al. 2007) in the most recent research.

GLOSSARY

Bit Error Rate (BER): BER is the ratio of bits with errors to the total number of bits that have been transmitted, received, or processed over a given time period. The rate is typically expressed as 10 to the negative power.

Chromatic Dispersion (CD): Different wavelengths travel along an optical medium at different speeds. Wavelengths reach the end of the medium at different times, causing the light pulse to spread. This chromatic dispersion is expressed in picoseconds (of dispersion) per kilometer (of length) per nanometer (of source bandwidth).

Cross-Phase Modulation (XPM): Cross-phase modulation is the change of the optical phase of a light beam caused by the interaction with another beam in a nonlinear medium, specifically a Kerr medium.

Erbium-Doped Fiber Amplifier (EDFA): A purely optical (as opposed to electronic) device used to boost an optical signal. It contains several meters of glass fiber doped with erbium ions.

Fiber Bragg Grating (FBG): A fiber Bragg grating is generally a periodic perturbation of the effective refractive index in the core of an optical fiber.

Group Velocity Dispersion (GVD): Dispersion is a phenomenon that causes the separation of a wave into spectral components with different frequencies due to a dependence of the wave's speed on its frequency. It is most often described in light waves, although it may happen to any kind of wave that interacts with a

medium or can be confined to a waveguide. It is the derivative of the inverse group velocity with respect to either the angular frequency or the wavelength.

Light-Emitting Diode (LED): A light-emitting diode (LED) is a semiconductor device used to transmit incoherent narrow-spectrum light when electrically biased in the forward direction.

Mach-Zehnder Interferometer (MZI): MZI splits an optical signal into two components, directs them down into two separate paths, and then recombines them. By inducing a phase delay between the two optical signals, the resulting interference can cause intensity changes.

Optical Fiber Communication (OFC): Fiber-optic communication system is a fiber-optic link providing a point-to-point connection with a single data channel. The data transmitter can be a semiconductor laser, which can be directly modulated via its drive current.

Opto-Electronic (OE): Optoelectronic devices are electrical-to-optical or optical-to-electrical transducers.

Phase Modulation (PM): Phase modulation is one of the three ways of modulating or altering a signal so that it is able to carry information. The other two are amplitude and frequency modulation. Phase modulation is used in high speed modems.

Polarization mode dispersion (PMD): Light transmitted down a single mode fiber can be decomposed into two perpendicular polarization components. Distortion results due to each polarization propagating at a different velocity.

Single-Mode Fiber (SMF): A single-mode optical fiber is an optical fiber in which only the lowest order bound mode can propagate at the wavelength of interest. Unlike multimode fiber, the conventional SMF has a small core diameter ($< 10 \mu\text{m}$).

Wavelength Division Multiplexing (WDM): A way of increasing the information-carrying capacity of an optical fiber by simultaneously operating at more than one wavelength. WDM modulates each of several data streams onto a different color or wavelength called lambda. Each lambda carries an individual optical signal providing the same bandwidth per channel.

INTRODUCTION

In a point-to-point optical fiber link, the signal, a train of optical pulses, is launched into the fiber by a transmitter module consisting of a laser or *light-emitting diode* (LED) and its associated control and drive electronics (see Figure 1). After attenuation and distortion by its journey through the fiber, the pulse is detected by a receiver module consisting of a sensitive photodiode to convert the optical signal back into an electrical signal, a low-noise preamplifier, and either a variable gain amplifier or a limiting amplifier. The ratio of the received signal to the noise added by the laser and the receiver determines the accuracy with which the determination of the original signal stream can be determined by a subsequent decision circuit. In this chapter, we describe the basic components, design, and functionality of both transmitters and receivers. Although digital transmission

dominates the field of optical fiber transmission, analog transmission is important in remote antenna locations, satellite communications, phased array radar, and cable TV. These and topics related to analog transmission such as linearity are outside the scope of this work, so the interested reader is referred to Cox (2004).

Most data and telecommunication links use a *non-return-to-zero* (NRZ) format, but a *return-to-zero* (RZ) format is sometimes used despite requiring more bandwidth for a given data rate. Our discussion here focuses on systems utilizing these variations of *on-off keyed* (OOK) modulation. Many of the issues involved in the design and characterization of optical transmitters and receivers such as synchronization, line coding, error-correction coding, fiber and transmission impairments, and specific standards are covered elsewhere in this handbook.

In the following, we first will discuss the light sources, modulator, and driver circuits that make up the transmitter.

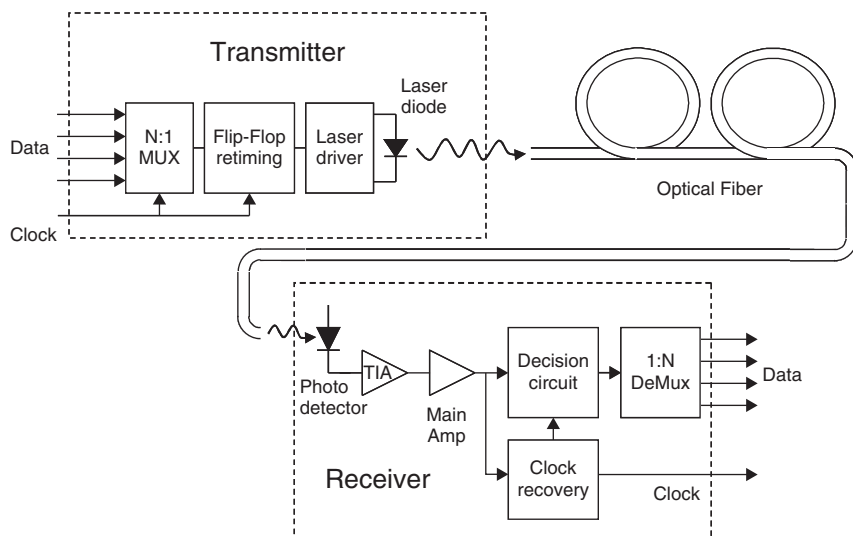

Figure 1: The main elements of a typical point-to-point optical link

Next, fundamental sources of noise encountered in the various stages of an optical link are presented with the intent of allowing the calculation of the *signal-to-noise ratio* (SNR) that determines the achievable error rate in an optical link. Finally, the reception of these signals is treated, starting with the main photodetectors and progressing through representative receiver circuits and system characterization. Both the optical and electronic aspects of these subsystems will be discussed.

OPTICAL TRANSMITTERS

The transmitter subsystem in an optical communication link is responsible for the conversion of the electrical signal into an optical signal. Among the devices used to accomplish this electronic to optical conversion are light-emitting diodes and directly or externally modulated semiconductor lasers. The device choice and approach is driven by cost and performance considerations, chiefly the creation of a faithful replica of the electrical data that is robust to degradation by imperfections in the fiber media and receiver. This becomes translated into a requirement for an emission source whose wavelength lies within a low-attenuation, low-dispersion region of the optical fiber and has a high extinction ratio and low intensity noise. Although the modulated light source is the most important part of a transmitter, state-of-the-art designs must carefully consider the design of the driver circuit and the connection between the driver and the laser. Packaging is also an important issue, requiring an enclosure that is a combination of microwave and optical design approaches. In this section, we survey the various available light emitters, modulators, specifications, and drive electronics used in optical transmitters.

Light Sources

Light-Emitting Diodes

The simplest and cheapest light emitters are LEDs. These are formed from a P-N junction of a direct gap semiconductor such as gallium arsenide (GaAs) or indium gallium arsenide (InGaAs). When a forward voltage bias is applied to the junction, a current flows, resulting in the injection of holes and electrons into the junction region. These carriers then recombine, resulting in the emission of light whose wavelength is characteristic of the band gap of the semiconductor used: 850 nm for GaAs and 1300 nm or 1550 nm for InGaAsP alloys lattice-matched to indium phosphide (InP). For the purpose of achieving good carrier confinement or light emission into a smaller solid angle, the P-N junction is often clad with wider band-gap semiconductor material such as aluminum gallium arsenide (AlGaAs) or InP.

LEDs suffer from three main disadvantages. First, the light that emerges is uncollimated, occupying a large solid angle relative to the acceptance angle of typical optical fibers. LEDs used with large-core fiber can benefit from the use of a lens to capture all of the light, but the inherent low brightness of the sources makes this difficult with small-core fibers. Second, the turnoff time of an LED is limited by the natural recombination time of

carriers in the semiconductor material, typically 5–10 ns for commonly used materials. With the introduction of specific impurities, modulation bandwidths as high as 800 Mbps can be achieved but with reduced light output. These properties make LEDs more attractive for short distance—for example, < 1 km low-capacity < 500 Mbps links. Third, LEDs have a wide spectral bandwidth on the order of 50 nm. This leads to rapid pulse dispersion as well as limits the number of wavelengths that may be used simultaneously on a single fiber.

In resonant cavity LEDs, partially reflective regions above and below the P-N junction form a resonant cavity at the emitted wavelength; they are now becoming available commercially. These have increased brightness because of a reflector behind the active layer. This also results in a narrower linewidth relative to traditional LED structures. The increased light emission allows for longer transmission distances in the face of fiber attenuation. The narrower linewidth allows for higher transmission speeds over longer distances because the pulses are more resistant to spreading in time caused by the chromatic dispersion of the fibers.

New LEDs are also becoming available specifically for use in the shorter wavelength transparency windows of some emerging *plastic optical fibers* (POFs). POF-based link standards are currently targeted at data communications, audiovisual, and automotive applications mostly using 650 nm or 670 nm LEDs, but some are now available that also are optimized for communications use at the 570 and 520 nm POF transmission windows. POF-LED links are typically 10–1000 m long with data rates between 10 Mbps and 250 Mbps.

Laser Diodes

Directly modulated semiconductor lasers greatly surpass LEDs in terms of coupled optical power, narrow optical bandwidth, and switching speed. This enables transmission over much longer distances at higher rates. With the advent of efficient optical amplifiers, it is now possible to reduce or eliminate the impairments resulting from optical attenuation, leaving pulse distortion often as the limiting factor in the attainment of high bit-rate length product fiber links. Optical phase and frequency shifts, referred to as *chirp*, accompany the modulation of semiconductor lasers. These cause spreading and deterioration of the optical pulse as it propagates through dispersive optical fibers. This now becomes the limiting factor in determining the maximum link distance for systems based on these sources. These effects can be reduced by the use of external modulation schemes.

Three basic designs are commonly used in today's systems: *Fabry-Perot* (FP) lasers, *distributed feedback* (DFB) lasers, and *vertical-cavity surface-emitting lasers* (VCSELs). Common to all is a *light versus current* (L/I) characteristic (see Figure 2). Here a relatively small amount of light is emitted below some threshold current; above this value, the light output becomes more intense and rises faster with increasing current. For digitally modulated signals, the current through the diodes is shifted between a current well above threshold and one close to threshold to represent 1's and 0's, respectively. The challenges

Figure 2: Low T_0 laser diode light versus current characteristic showing the effects of self-heating and modulation duty cycle

encountered in transmitter design arise from nonidealities in this characteristic—chiefly, nonlinearities in this relationship at high currents and changes in the threshold current and slope with temperature and aging. In addition, these devices are highly susceptible to variations in the L/I curve caused by back reflections in the optical path (Twu et al. 1992). The relative intensity noise—the optical noise power normalized to the average noise power—can also be adversely affected by optical reflections. Because of this, *optical isolators* often need to be included in high bit-rate systems, further increasing complexity and cost. The problems caused by temperature and aging can in large part be ameliorated by the use of feedback in the driver circuitry and will be discussed later.

The dynamic response of lasers can also be problematic. When switching, they exhibit time delays and ringing. The time delays are a function of the proximity of the bias in the off state to the threshold level: The further below threshold, the greater the delay. The delay τ_d is given in terms of the delay at threshold τ_{th} (typically ~ 2 ns), the peak drive current I_p , the bias current I_b , and the laser threshold current I_{th} as

$$\tau_d = \tau_{th} \ln \left(\frac{I_p}{I_p + I_b - I_{th}} \right) \quad (1)$$

This delay also has a random component because of variations in the build up of the light to its steady state value that results in signal jitter. To reduce this delay,

the laser is often biased at or slightly above its threshold value trading extinction ratio for turn-on time. Alternatively, the laser can be left on continuously, and its light modulated externally.

When a laser is turned on from its fully off state, it will typically exhibit a high frequency oscillation around its steady state value. This ringing results from a natural relaxation resonance within the laser itself. As current builds, optical gain increases, causing an increase in the number of photons in the laser cavity. As the optical power grows, the consequent rapid recombination by stimulated emission strongly reduces the inverted carrier density and optical gain. This then lowers the optical power density in the cavity, leading to an oscillation as this sequence is repeated. This can result in oscillations at transitions in the large signal response and a second-order small-signal modulation response as shown in Figure 3.

The index of refraction in semiconductors has a dependence on the free carrier density. The large variations in carrier density during these oscillations results in a rapid frequency modulation of the light pulse. Quantitative understanding of this phenomenon is gained through the *laser rate equations* (Price and Pedrotti 2002). Pulse distortion results as the different parts of the pulse, which have slightly different frequencies, travel at different speeds through the dispersive fiber medium. Again, as with turn-on delay, relaxation oscillations can be reduced by bias at or slightly above threshold. The turnoff transient is typically a smooth exponential decay that is somewhat slower than the turn-on time. This asymmetry in the rise and fall times gives rise to pulse width distortion in

Figure 3: Laser large signal step response versus time (left) and small signal modulation response versus frequency (right)

which the duration of a logic 1 and logic 0 that are equal in the data are not in the optical signal. This is generally compensated for in the drive electronics.

Fabry-Perot Lasers

Fabry-Perot lasers are constructed as shown in Figure 4 using the reflections from the cleaved facets of the laser chip to form the optical cavity. Such cavities combined with repeated traversals by the optical signal result in narrow emission spectra and much smaller angular emission cones relative to LEDs. The high optical intensities in the cavity also result in short stimulated emission lifetimes and rapid turnoff times, leading to higher modulation bandwidths. The active region of FP lasers is typically much thinner than it is wide. This results in an astigmatic beam with a different divergence angle parallel and perpendicular to the plane of the laser substrate. This can pose challenges for the efficient coupling of their radiation into small core fibers.

Distributed Feedback Lasers

Distributed feedback lasers and the closely related *distributed Bragg reflector* (DBR) lasers incorporate grating structures into the gain regions or end regions respectively as shown in Figure 5. This results in a further narrowing of the emission spectra relative to FP laser diodes. The variation of optical propagation velocity with wavelength in optical fibers—chromatic dispersion—leads to pulse broadening with distance. The restriction of the optical emission bandwidth in DFB lasers results in optical pulses that spread less with distance. This means that for a given pulse length or data rate, the bit stream encoded by a DFB laser can propagate further before impairments because of pulse spreading become important. Links using DFB lasers thus achieve higher bit-rate distance products as compared to FP lasers, albeit with a considerable increase in processing complexity and consequent decrease in yield relative to FP lasers. For a more complete treatment of DFB lasers, see Coldren and Corzine (1995).

Figure 4: Typical structures of simple Fabry-Perot lasers

Figure 5: Distributed feedback laser structure

Vertical-Cavity Surface-Emitting Lasers

In VCSELs, the resonant optical cavity is formed perpendicular to the wafer surface. One type of laser structure is shown in Figure 6. A very high reflectivity mirror is first grown composed of many alternating layers of material with different indexes of refraction, with optical thicknesses of one-quarter the desired emission wavelength, to form a Bragg reflector. The active P-N junction region is grown on top, surrounded by spacer layers, and then capped with another Bragg reflector mirror. Although thick and time consuming to grow by the usual epitaxial techniques, a mirror with exceptionally high reflectivity can be produced. A great number of laser structures exist using a variety of materials systems aimed at different performance goals; see, for example, Wilmsen et al. (2001) for a thorough treatment. Some use semiconductor materials for the reflectors; some use dielectrics, mostly for long wavelength emitters; and some use combinations of the two. Many different approaches have also been taken to provide both optical and carrier confinement to the active region and to reduce the sometimes high series resistance and operating voltage. The earliest VCSELs were made from AlGaAs and its alloys and operated in the 850-nm region. Work is continuing, and VCSELs have now been demonstrated at the important 1300-nm and 1550-nm silica fiber transmission windows as well as the shorter 670-nm and 650-nm wavelengths for use with POF.

VCSELs typically have an especially low threshold current, relatively low power outputs, and circular beams that couple well into optical fiber. These desirable characteristics and the advantages in manufacturing and testing afforded by the ability to batch test the lasers before

dicing, as is typical with integrated circuits, make them attractive and economical devices. Today, they are used mostly in the 850-nm range using multimode optical fiber for local area networks and other short-distance, high-bandwidth applications for which LEDs are not suitable: most notably, in the optical versions of multi-Gigabit Ethernet implementations. This evolving technology is now spreading into single-mode fiber applications in metropolitan area and wide area networks. This technology is not yet mature or widely used in the longer 1550-nm telecommunication bands.

Tunable Lasers

Tunable lasers are of increasing interest with the advent and wide deployment of *wavelength-division multiplexing* (WDM) systems. The hundreds of wavelengths that can be used in such links creates an inventory and maintenance problem for operators that is solvable by the use of a single or a few distinct tunable lasers. Interest in tunable lasers is also being spurred by their usefulness for wavelength provisioning and wavelength-based routing.

DFB and DBR lasers are thermally tunable. With a typical 0.1 nm/°C tuning coefficient, a 50°C temperature change allows ~5 nm of tuning. Wider tuning can be achieved by the variation of the index of refraction in the grating region of a DBR, usually by free carrier injection. Even wider tuning can be achieved by using a similarly tuned grating structure to selectively couple the desired wavelength between two waveguides with similar propagation constants. Wider tuning range is accompanied by lower frequency selectivity, which can be restored by the use of sampled gratings for the reflectors. Sampled gratings with slightly different grating periods allow wide tuning

Figure 6: VCSEL structure

in a relatively simple structure. Tunable VCSELs are also available; to date, most have been realized by the micro-mechanical movement of one of the reflective tuning mirrors. Devices with tuning ranges of more than 100 nm are available in some technologies. The need to simultaneously control several currents, voltages, or both—often adaptively—increases the complexity and challenge of transmitter designs based on these devices. Coldren et al. (2004) provide an overview and tutorial introduction to the state-of-the-art in tunable laser technology.

Modulators

External optical modulation is used when the highest data rates and longest transmission distances are of interest. They can switch faster than a directly modulated laser and have less chirping, which reduces the optical pulse spreading. Two types are most often used in optical communications. Semiconductor-based electro-absorption modulators are popular because of their ease of monolithic integration with the *continuous wave* (CW) laser source, high modulation speeds, and reduced chirp relative to lasers. The most common interferometric modulators, however, are the Mach-Zehnder type; these are typically made of lithium niobate, a nonlinear optical material with a high *electro-optic coefficient*. These provide the most precise control over amplitude and phase of the optical signal and are used in the highest performance applications. A current and more detailed treatment of the operation of and comparison between optical modulators is presented by Li and Yu (2003).

Electro-Absorption Modulators

Electro-absorption (EA) modulators are monolithic semiconductor devices that are most often fabricated on InP substrates and use either the Franz-Keldysh or *quantum-confined Stark effect* (QCSE) to vary the effective band edge of a semiconductor region incorporated into an optical waveguide (Wakita 1997). Both of these effects rely on the change in the electric field in the semiconductor in a reversed biased PIN structure (an example is shown in Figure 7). With care and compromise, these modulators can be designed to be compatible with

regard to growth and fabrication, which can allow for monolithic integration of the CW laser and EA modulator as a single device. The main advantage relative to a directly modulated laser is reduced chirp because the frequency modulation associated with the laser relaxation oscillations is avoided (Koyama and Iga 1988). Some residual and unavoidable chirp will remain as implied on fundamental grounds by the Kramers-Kronig relation for the connection between the index of refraction and absorption. Other advantages can accrue because of superior extinction ratio at the desired data rate, lower drive voltages, small size, higher drive impedance, better temperature stability, and improved linearity.

Mach-Zehnder Modulators

Mach-Zehnder modulators (MZMs) operate by splitting a light beam and directing two beams down two different paths before recombining them. This is illustrated in Figure 8. If the phase of the light traveling down one path can be varied relative to the other by the use, for instance, of an electro-optic material such as lithium niobate, then the beams can be caused to arrive either in or out of phase at the beam-combining junction coupled to the exit waveguide. When in phase, the beams recombine to form a propagating mode in the exit waveguide. When out of phase, their amplitudes cancel, no radiation appears in the exit guide, and the optical power is radiated into the crystal substrate. The phase change is controlled by the application of electrical fields across the insulated waveguides, yielding a capacitive drive impedance. Along with the output impedance of the drive electronics, this capacitance determines the maximum modulation rate. The intrinsic electro-optic response is especially fast. These modulators are characterized according to their V_{π} , the voltage necessary for a relative phase shift of π radians between the waves traveling in the two guides. This is the minimum voltage necessary to change the transmitted signal from fully on to fully off. A typical value is 10 V for a 10-GHz modulator. The V_{π} can be lowered by extending the electrodes along the optical transmission line, but then the drive capacitance of the modulator increases, reducing the bandwidth. The typical ratio of the on-to-off power, the *extinction ratio*, that is practically achieved is better than 20 dB. Better overlap of the optical and applied electrical fields along with differential drive and new materials has been used to reduce V_{π} , and commercial devices are available in the 4–6 V range. This is particularly important for high speed (> 10 Gb/s) operation where the maximum voltage swing provided by transistors is limited by the reduced device geometries necessary for their high-speed operation.

Other materials are also used to realize these types of modulators, including III-V semiconductors, organic nonlinear optical polymers, and silicon. GaAs-based MZMs (which are also based on a bulk electro-optic effect) are demonstrating performance that is close to that achievable with lithium niobate: drive voltages in the range of 5 V but at a smaller size of ~ 3 cm rather than 5–10 cm lengths typical of Lithium Niobate. Using the QCSE in III-V semiconductor quantum wells, index variations arise that can be used to make MZMs. Relative to lithium niobate, much smaller chip sizes can be realized with lower drive voltage

Figure 7: Electro-absorption modulator grown on semi-insulating indium phosphide

Figure 8: Single Mach-Zehnder modulator (top) with intensity versus voltage characteristic (bottom)

requirements, which allows possible monolithic integration with laser and amplifier components. Disadvantages include higher optical loss, lower extinction ratio, more difficult chirp control, and a narrower wavelength range of operation. Polymer-based MZMs have lower dielectric constants, higher theoretical effective bandwidth, compact size, easier and lower-cost processing, and potential for heterogeneous integration. Stability concerns (both thermal and photochemical), relatively higher optical losses, and limited power-handling capability are the main impediments to more widespread commercial application.

Traveling Wave Modulators

For the highest speed operation the modulating signal is launched down a transmission line in which the propagation velocity of the electrical modulating signal matches that of the optical mode in the adjacent waveguide. This allows a significant increase in bandwidth that is limited only by the time over which the velocity and phase matching can be maintained. This approach is referred to as a *traveling wave modulator*; it also allows for a lower V_{π} relative to a bulk electrode approach.

Finally for both types of interferometric modulators, if the electrode geometry is such that the induced phase shifts are equal and opposite along the two optical paths, as is obtained with a differential drive, the resulting amplitude modulated signal emerging from the exit waveguide is free of phase modulation (chirp). If independent control of the electrodes on each path is provided, then adjustable amounts of phase, amplitude modulation and chirp can be provided (Gnauck et al. 1991). This is sometimes useful; for example, for optimum transmission over

certain distances and fibers, a small amount of the proper chirp can actually enhance the transmission distance.

Driver Circuits

The electronic driver circuits are designed to transfer the data signal with high fidelity to the optical emitter or modulator; provide a good impedance match to the optical device and compensate for device nonidealities, temperature variation, and aging. Here we describe circuits that are appropriate to driving LEDs, directly modulated lasers, and modulators.

LED Drivers

Given their relatively low maximum modulation rates and stable output characteristics, LEDs are often driven simply and directly in a single-ended configuration by a current source as shown in Figure 9.

The L/I characteristics for an LED are fairly linear and do not typically suffer from the same drift and degradation as laser diodes. For this reason, and particularly where cost is an issue, simple driver approaches like that shown in Figure 9 are often used.

Figure 9: Simple driver for an LED (bias circuitry not shown)

Laser Drivers

Directly modulated lasers are most naturally driven by current sources because the optical signal above threshold is approximately linearly related to the drive current. The laser is biased with a DC bias current (I_{bias}) that sets the off or zero drive value in the vicinity of the laser threshold current. An AC modulation current then varies between zero and a peak value (I_{mod}). This results in the laser biased at I_{bias} in the zero state and $I_{bias} + I_{mod}$ in the on state representing a logical 1. Typically, a current steering circuit using a differential pair is employed (see Figure 10). These circuits can be effectively implemented using either *bipolar junction transistors* (BJTs) or *field effect transistors* (FETs) and possess the following advantages that justify their popularity:

- The roughly constant current draw of the device minimizes the generation of power supply or ground noise because of inductive or resistive parasitics in the supply lines.
- Such a circuit is insensitive to common mode noise such as power supply noise or ground bounce.
- The modulation current can be easily adjusted by variation of the tail current via V_{mod} as indicated in Figure 10.

Also shown in Figure 10 is a monitor photodiode and feedback circuit implementing automatic power control. The monitor diode is mounted so as to intercept the unused light exiting through the back facet of the laser. The diode and circuitry typically has a rather long response time and so measures the average power produced by the laser. In this particular circuit, the laser bias current is adjusted via this feedback loop. This circuit can thus be used to partially compensate for variations in the laser threshold current that result from temperature and aging. This technique would not work if the average number of 1's and 0's (mark density) varied appreciably within the response time of the bias control circuit. Numerous techniques have been used to compensate for threshold variation with temperature and aging, laser L/I characteristic slope, laser L/I characteristic curvature variation and mark-density changes. Most are implemented by use of feedback control based on some combination of the measurement of the electrical data mark density, the peak and average light output that are used to control the laser DC bias current, and the modulation current. For details and a more exhaustive treatment, see Price and Pedrotti (2002). These monitoring circuits can also be used to indicate approaching end of life for the laser

Figure 10: Simple laser driver output stage

Figure 11: Equivalent circuit of a typical packaged laser diode

diode, allowing preemptive maintenance or switchover to a backup system before an actual failure occurs.

Figure 11 shows an equivalent electrical model for a packaged laser diode. The various parasitic reactances can seriously limit the response speed of the laser. Models such as this can be used in analog circuit simulation programs to simulate the combined performance of the laser, driver circuit, and bias network. The internal carrier dynamics and relaxation oscillations can also be modeled with circuit simulation programs (Wedding 1987). Typically, the sum of the 20 percent to 80 percent rise and fall times should be no more than 0.70 of the bit time to achieve adequate temporal response. Excessively short rise times should also be avoided because, as with relaxation oscillations, they too can lead to undesirable frequency chirp.

The output drive stage is usually preceded by a predriver that consists of several gain stages designed to provide sufficient gain and provide matching between the data source and the low-impedance, high-current load. The signal offset is also controlled by this stage to ensure that the time duration of 1's and 0's is equal. This pulse-width control is used to compensate for pulse-width distortion caused by asymmetric optical turn-on or turnoff delays in the laser. Frequently a flip-flop is provided at the input to allow retiming of the signal with a clean clock. This helps to reduce pulse-width distortion in the incoming data and reduce jitter in the transmitted signal.

Driver-Laser Interface

Most simply, the laser is directly connected to the drive circuit as shown in Figure 12. This approach is well suited to data rates below 1 Gbps, where the laser's parasitic bond wire inductance and capacitance do not pose a serious limitation. Direct drive can be extended to higher frequency by the reduction of packaging parasitics via direct flip-chip mounting of the laser on the driver chip (Pedrotti 1992) or by monolithic integration of the laser with the drive circuitry. This latter approach poses practical fabrication challenges that have so far precluded it from widespread use.

Figure 12: Laser directly connected to the driver chip by a short bond wire

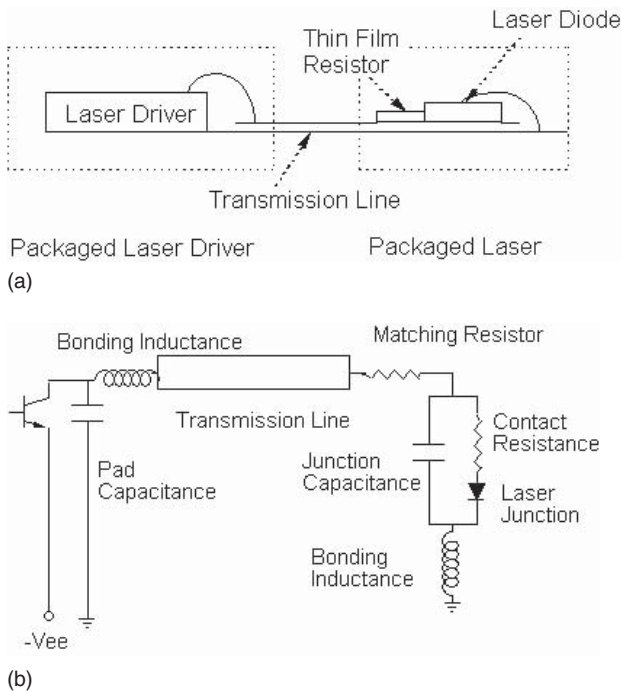

Figure 13: (a) Laser driver connected to a laser diode via a transmission line and matching resistor; (b) schematic diagram of the equivalent electrical circuit

At higher speeds, for separately packaged lasers, the package and bond wire inductance can induce undesirable ringing in the current pulse. One method to alleviate this is to use a transmission line (12–50 Ω) and a matching network between the drive circuit and the low dynamic impedance (3–8 Ω) of the laser diode. The matching is usually provided by a resistor closely mounted in series with the laser diode (see figure 13) with a value chosen to bring the series resistance of the resistor and laser to that of the driving transmission line. This resistance also aids in suppressing inductive ringing. A back termination is often also used to further suppress ringing because of power reflected back to the driver circuit. Both of these measures significantly increase the power dissipation of the transmitter, with the majority of the power consumed in the matching resistors. When this approach is employed, care must be exercised because of the extra heating of the laser by the nearby matching resistor. Often the bias current needed to bring the laser close to its threshold can be supplied through an inductor whose high impedance at the modulation rate ensures that the bias network does not load the transmission line yet has a low DC impedance, reducing the power dissipation in the laser package.

Modulator Drivers

Both Mach-Zehnder and electro-absorption modulators require a voltage drive. Typically, a precisely controlled DC-voltage bias is supplied to adjust the off state attenuation, and then the modulation is supplied as an AC signal summed with this bias.

EA modulators (EAMs) are typically driven single-ended as with laser drivers. The substrate is usually the

cathode and is maintained at a constant voltage. The voltage drive is supplied by driving a current through a parallel resistor mounted close to the device so as to modify the diode reverse bias voltage between the off and on states. The current is supplied by circuits similar to those used with laser drivers. Pulse-width control is often included to compensate for the nonlinear drive characteristic of EAMs that can lead to pulse width distortion.

Mach-Zehnder modulators can be driven either single-ended or differentially. Differential drive is often used because it allows for a reduced absolute voltage swing at the driver output and allows for chirp control. Differential drive can be realized by using both outputs of the current steering stage shown in Figure 10. Automatic bias control can be provided by the injection of a low-frequency pilot tone and optical monitoring of the modulated signal to generate the appropriate feedback signal (Heismann, Korotky, and Veselka 1997).

Packaging

The packaging of optoelectronic components is a challenging interdisciplinary exercise involving materials choices, mechanical design, thermal design, adhesives, electrical bonding, microwave techniques, and optics. Much of the discussion presented here is also relevant to the packaging of receivers and transceivers.

As an example, a rather traditional laser package suitable for high-bandwidth, long-distance data transmission that illustrates many of the packaging concerns and complexity is shown in Figure 14. Here a laser attached to a diamond heat spreader is mounted on a *thermoelectric* (TE) cooler used to stabilize the laser temperature. Behind the rear facet are the monitor photodiode, matching resistor, and transmission line. The laser driver *integrated circuit* (IC) is mounted off the TE cooler to minimize the heat load that it must handle, thus reducing overall power consumption. A ribbon bond connects the laser driver to the transmission line. The electrical signal enters through the high-speed electrical connector, feed through, and transmission line with a controlled 50- Ω impedance throughout. The optical output exits through an optical isolator and is then focused through a *graded index* (GRIN) lens into the optical fiber pigtail. Spherical or more complicated aspheric lenses are sometimes used. Rather than a fiber pigtail, often the optical path is arranged so that a fiber can be inserted directly into a bulkhead fiber connector on the package to ease handling of the packaged part. All of this must be designed to allow hermeticity, precise temperature control, and micron or even submicron optical alignment tolerances over a broad range of environmental conditions. More detailed discussions of techniques, trade-offs, and approaches can be found in Mickelson, Basavanahally, and Lee (1997).

Butterfly packages with controlled impedance lines including laser monitoring and temperature control have often been used at high speeds and where precise wavelength control is desired. Dual in-line packages provide lower cost and lower speed alternatives. The lowest-cost packaging includes an uncooled laser in a TO can that is then mounted using traditional techniques to FR-4 circuit board. Packaging solutions are emerging

Figure 14: Laser package

that combine an inexpensive uncooled package with an impedance-controlled flex circuit for ease of interface to circuit boards at high data rates.

Uncooled Applications

For many data communication applications, the thermoelectric cooler is dispensed with and a greater range of currents are provided by the laser driver to compensate for the changes in the device with temperature. Device design for such uncooled applications seeks to minimize the laser threshold shift (high T_0) and wavelength shift with temperature. Data communication standards in particular such as those for Gigabit Ethernet, 10Gigabit Ethernet and coarse WDM applications have been developed to tolerate the shift in laser properties with temperature. This ability to dispense with the TE cooler results in significant reduction in power consumption, size, and cost relative to, for example, the cooled lasers used in long-haul dense WDM applications.

Hot-Swappable Transceivers

Many modern transceivers are also packaged to allow hot swapping—that is, insertion or removal from the system without powering down. To accomplish this, the pins that make the various electrical connections are staggered. Typically, as a transmitter or receiver submodule is inserted, the shield connections are made first to help avoid *electrostatic discharge* problems. Next, the ground pins come into contact, followed by power, and lastly the signal connections. Current limiting on the power supply lines is provided to ensure that the local module bypass capacitors do not cause power bus voltage sag. Power on reset routines, now realized in dedicated integrated circuits, orchestrate the series of events that occur during insertion or removal to ensure that sensitive components are not damaged and are powered on into well-defined states.

Multisource Agreements

Active work is proceeding in package development with new connector designs, package miniaturization, cost reduction, standardized footprint interfaces and functionality being the primary concerns. Although standards bodies can only define the minimum set of requirements on system components to ensure interoperability between components supplied by different vendors, this

often leaves many details of the component realizations such as form factor, thermal behavior, electromagnetic compatibility, optical connectors, electrical connectors, electrical interface protocols, and pinouts undefined. To facilitate system acceptance and further ease interoperability *multisource agreements* (MSAs) have evolved to provide plug-compatible and interchangeable parts among a variety of manufacturers. For instance, the XENPAK MSA (www.xenpak.org) defines a 10-Gb Ethernet (IEEE 802.3ae) standard compliant transceiver design that additionally defines the hot-pluggable electrical interface (four wide XAUI), pinout, form factor, optical interface, and connector with additional power supply, thermal, electromagnetic interference, and EMC specifications. Other MSAs include the XFP MSA (www.xfpmsa.org) for a hot-swappable OC-192 SONET/STM-64/10-Gigabit Ethernet, protocol agnostic, parallel electrical, small form factor specification, and its related XFI MSA with a serial electrical interface. The X2 MSA (www.x2msa.org), the small form factor, and the related small form factor pluggable MSA, Gigabit interface converter (relevant documents are available through www.sffcommittee.com), the dense WDM MSA (www.hotplugdwdm.org), and the 300PIN MSA (www.300pinmsa.org) are also examples of the many evolving packaging standards that are continually in development.

Performance Evaluation

As various data-transmission standards have emerged, the testing and evaluation of components has become standardized as well. The intention is to ensure interoperability between devices and subsystems made by different manufacturers. Usually, the transmitter is tested using a long run-length pseudo-random data sequence. The resulting optical signal from the transmitter is detected by a wideband photodetector followed by a low-pass filter with prescribed characteristics. The signal is then displayed on an oscilloscope by overlapping successive bits, all synchronized to the underlying clock, to form what is called an *eye pattern* as shown in Figure 15. A mask is overlaid on the eye diagram. To ensure proper signal shape, the signal trace should not enter the masked areas. Software measures the limits on signal characteristics defined in the standard and also such quantities as extinction ratio and jitter.

Figure 15: Eye pattern and mask for testing

For long-distance transmission or when using high-dispersion fiber, the effect of the optical bandwidth must be included. Often the best way to do this is to measure the actual error rate after passage through a test fiber. The signal is first launched through an attenuator and a short length of fiber. The signal is attenuated until a specified error rate is observed (typically, $10^{-9} - 10^{-10} \text{ sec}^{-1}$) and the received power is measured. Next, a long fiber is inserted in the link and the received power measured to attain the same error rate as obtained previously. After the pulse distortion caused by propagation through the fiber, more receive power is needed to attain the same error rate. The ratio of these two values is known as the *dispersion power penalty* and is commonly expressed in dB. Many other system impairments are also characterized in terms of their power penalties using similar techniques, making this a useful method to quantify trade-offs between and among different implementations, subsystem devices, and techniques.

NOISE

Any unwanted signal in an electronic system is commonly referred to as *noise*. Here, however, we would like to distinguish between noise and interference. *Interference* arises from such sources as undesirable coupling between circuit nodes, the power supply, or sources of other electrical or optical signals external to the communication system. Such sources can usually be reduced to negligible levels by suitably grounding and shielding a system; details of these techniques are provided in

Ott (1988). Here we will refer to *noise* as those inherent fundamental signal variations that arise spontaneously within the system itself. Noise can arise in a general communication system in the transmitter, the communication channel, and the receiver. In typical, well-designed optical communications systems, the most significant noise in terms of its impact on signal fidelity arises in the electronic devices that make up the receiver unless optical preamplification is used. The fundamentals of noise as they pertain to optical links, particularly receivers, is presented here (readers who are familiar with the topic can easily skip to the next section).

Noise in electrical circuits fundamentally arises from the discrete nature of electric charge and the random thermal motions of these carriers in resistive materials, the capture and release of carriers at traps, or the random thermal emission of carriers over potential barriers. Here we briefly describe each of these noise sources—known as thermal noise, flicker ($1/f$) noise, and shot noise, respectively—and their typical role in optical data transmission.

Thermal Noise

The random motions of a large number of charge carriers in an isolated resistor lead to a net long-term average current of zero amps through the device and, one would suppose, zero volts across it. However, given the discrete nature of electric charge and its random thermal motion, more carriers may be traveling in one direction or the other at any instant of time; this leads to a non-zero *root-mean-square* (RMS) current through the device. This fluctuating

current leads to a fluctuating voltage across any resistance. The thermal noise power (S) in any resistive element (R) measured in a bandwidth B was shown by Nyquist to be given by:

$$S = 4kTB \quad (2)$$

where k is Boltzmann's constant. This expression, interestingly, is independent of the resistor value and depends only on the temperature and the bandwidth. The spectrum of the noise has a constant power as a function of frequency and is consequently referred to as *white* noise. In some ways, this takes much of the mystery out of low noise design as there are really only two strategies to pursue in reducing the available thermal noise power: (1) reduction of temperature or (2) reduction of bandwidth. Usually and practically, there is only one: bandwidth reduction.

The RMS noise voltage (V_{rms}) across a resistor is given by

$$V_{rms} = \sqrt{4kTRB} \quad (3)$$

and the RMS current (I_{rms}) through it by

$$V_{rms} = \sqrt{\frac{4kTB}{R}} \quad (4)$$

It is easily verified that the product of the two yields the total noise power given above. Note that if the signal is represented by a voltage, then the voltage noise that will corrupt it is reduced by using low resistances. Thus, for those circuit elements with bandwidths that cannot be limited, the available noise voltage can be reduced by using low resistances.

Thermal noise is also present in the resistive channel of *metal-oxide semiconductor field effect transistors* (MOSFETs). The variation of the channel resistance along the length of the channel changes the appearance of the resulting expression, which can be thought of as the sum (integration) of the noise power contributions of a continuously varying set of resistors of different values that make up the channel region. If the necessary integrals are performed, one obtains the expression for the RMS noise current (I_n) in the channel as

$$I_n = \sqrt{4kT\gamma g_m} \quad (5)$$

where γ , the excess noise factor, is equal to $2/3$ and g_m is the small signal transconductance of the FET as determined by its bias state. This result is valid for long-channel devices. For short devices encountered in modern CMOS technology, the overall dependence is similar, but γ typically has a higher value. Figure 16 shows the equivalent circuit model of a noisy MOSFET.

Shot Noise

The discrete nature of electric charge results in an additional source of noise when carriers flow through a potential barrier such as exists in a P-N junction diode, the base-emitter or base-collector junctions of a bipolar junction transistor or through poorly made contacts between dissimilar materials in any electronic device. In these

Figure 16: Circuit model of a noisy MOSFET. The noiseless ideal MOSFET is considered to be in parallel with an effective noise generator

devices, the current flows because of the random emission of sufficiently hot carriers over a potential barrier. As a P-N junction is forward biased, the potential barrier is lowered and more carriers have sufficient energy to be emitted across the junction. The current thus consists of a large number of random charge impulses. The Fourier transform or spectral decomposition of such a current exhibits a white spectrum that is constant across frequency. Although the current through the junction has a constant average value (I_{AV}), it exhibits variations around its average value, whose RMS value (I_{shot}) is given by

$$I_{shot} = \sqrt{2q_e I_{AV} B} \quad (6)$$

where q_e is the charge on the electron. Note that in the absence of an average current, there is no shot noise. This is different from the case of thermal noise, which will be present independently of the current.

Flicker Noise

Flicker noise also known as “one over f” ($1/f$) noise is so called because of the roughly inverse dependence of its power spectral density on frequency. The size of the fluctuations increases as the frequency decreases with a roughly constant power contribution per frequency decade. In electronic devices, it is most often caused by capture and emission processes at carrier traps with widely varying effective trap lifetimes present in the conductive path.

One example of the effect of the contribution from $1/f$ and the other noise sources described above is seen in the differing amounts of noise exhibited by different resistors, with metal film being quieter and carbon composition noisier. Comparing the noise in a metal film and carbon composition resistor, each with the same resistance, the thermal noise in each would be identical but their material dependent $1/f$ contributions could be different. Poor contacts to the resistive elements can also give rise to additional shot noise in resistors.

Typically, $1/f$ noise in MOS devices is attributed to the silicon-silicon dioxide (Si-SiO_2) interface traps over the channel region. Trapped carriers at this interface can be thought of as modifying the effective device threshold voltage at a slow rate as carriers are randomly trapped and released. This causes a variation in the device current that can be modeled as a noise voltage source modulating the gate voltage.

In fact, $1/f$ noise is highly dependent on materials choices and process details between broad classes of

devices. As one example of this, because of the way that P-channel MOS transistors have typically been constructed, the carrier flow in their channels is typically farther away from the traps located at the Si-SiO₂ interface, leading to lower $1/f$ noise relative to N-channel MOS devices.

The amount of $1/f$ noise exhibited by a MOS device can be highly variable within and between process lots as well, and so is often poorly controlled and characterized by manufacturers.

One simple model for the spectral dependence of the flicker noise in MOSFETs is given by a voltage noise source ($V_{1/f}$) in series with the gate that has a RMS value given by the following formula:

$$V_{1/f} = \sqrt{\frac{K}{C_{ox}WLf}} \quad (7)$$

where K is an empirical factor that is dependent on the device design, materials, and processing; C_{ox} is the gate oxide capacitance per unit area; W and L are the width and length of the gate, respectively; and f is the frequency. The noise power can be seen to decrease linearly with the frequency and with the device area WL . Large area devices are often used to reduce flicker noise in MOS designs.

Often, $1/f$ noise is characterized by its *corner frequency*, or the frequency at which the lines representing the $1/f$ noise and the thermal noise intersect on a log-log plot as shown in Figure 17. Bipolar transistors typically exhibit $1/f$ noise that is roughly 10 dB lower than MOS devices.

Combining Noise Sources

In an operating transmitter or receiver all of these noise sources will be acting simultaneously. However, because each source is usually uncorrelated with any other, their effects at any circuit node do not add linearly as one would expect for a linear time invariant circuit using superposition. Rather, statistical analysis shows that they must be added by the sum of the squares—that is, the noise powers add linearly, not their RMS values. The voltage noise at any given circuit node is thus calculated by finding the noise resulting from each source acting independently at that node and then taking the sum as shown in Equation (8):

$$V_{rms\text{total}} = \sqrt{V_{rms1}^2 + V_{rms2}^2 + \dots + V_{rmsn}^2} \quad (8)$$

Figure 17: Power spectral density of $1/f$ and thermal noise showing the corner frequency

Current noise sources are combined in a similar manner. In our treatment of optical transmission links the quantity of greatest concern is the SNR at the decision circuit. This determines the error rate of the system. Conventionally, this is most often and conveniently calculated at the receiver input. This easily allows understanding of the link performance in terms of the optical power and leads to the ability to express impairments in terms of the incurred optical power penalty.

The noise quantity of interest is called the *input referred current noise*. This can be calculated by considering the effect of each noise source independently on the RMS output noise. The various noise voltages are then summed as above, and then the entire RMS output noise is divided by the gain between the input and output. The system can in this manner be assumed noiseless with a single effective noise current source applied at the receiver's input. Often this will be expressed as the noise per root Hz by dividing by the square root of the noise bandwidth of the receiver amplifier. For more in-depth coverage of noise in electrical systems, the interested reader is referred to Motchenbacher and Connelly (1993).

OPTICAL RECEIVERS

Photodetectors

The function of the photodetector is to convert the optical signal into an electrical one. This needs to be done with low noise and high sensitivity. Although many type of photodetectors exist, two are most used in optical fiber communication systems: *PIN diodes* and *avalanche photodiodes* (APDs). These can rapidly and efficiently convert photons into hole-electron pairs and thus create a photocurrent with low noise. Figure 18 shows the dependence of the optical absorption versus wavelength over the range commonly used in optical communications for a number of semiconductors.

Figure 18: Optical absorption and the $1/e$ penetration depth versus wavelength for a number of semiconductors commonly used for photodetectors

Figure 19: Typical responsivity of PIN photodetectors versus wavelength

Photodetectors are commonly characterized by the following quantities.

The internal quantum efficiency (η_i):

$$\eta_i = \frac{\text{Number of Collected Electrons}}{\text{Number of Photons * Entering * Detector}} = [1 - e^{-\alpha W}] \quad (9)$$

The external quantum efficiency (η_e):

$$\eta_e = \frac{\text{Number of Collected Electrons}}{\text{Number of Photons * Incident * on Detector}} = \frac{i_{ph}/q}{P_o/h\nu} = (1 - R_p)[1 - e^{-\alpha W}] \quad (10)$$

And the responsivity:

$$R = \frac{\text{Photo Current (Amps)}}{\text{Incident Optical Power (Watts)}} = \frac{i_{ph}}{P_o} = \frac{q}{h\nu}(1 - R_p)[1 - e^{-\alpha W}] \quad (11)$$

This allows the calculation of the overall device photocurrent for a given illumination as

$$i_{ph} = q \left[\frac{P_o}{h\nu} \right] (1 - R_p)[1 - e^{-\alpha W}] = RP_o \quad (12)$$

In the above expressions, α is the $1/e$ absorption length of the light in the detector active region, W is the width of the absorption region, i_{ph} is the photo current, q is the charge on the electron, P_o is the incident optical power, h is Plank's constant, ν is the frequency of the incident light, and R_p is the reflectivity of the entry surface of the detector. The responsivity vs. wavelength for PIN diodes

realized in a number of different semiconducting materials in shown in Figure 19.

Below we will explore the construction, operation, and noise inherent in these devices.

PIN Diodes

The PIN diode's name reflects its structure: P and N doped semiconductor materials separated by a region of undoped or lightly doped semiconductor referred to as the *intrinsic* (I) layer. In a reverse-biased P-N junction operating below its breakdown voltage, only a small current flows. This consists of thermally generated carriers that, once generated, are rapidly swept by the reverse electric field to the device terminals. If light in which the individual photon energies exceed the band-gap energy of the semiconductor is present, then the photons can be absorbed with the promotion of an electron from the valence band to the conduction band of the semiconductor. The missing electron in the valence band behaves for all intents and purposes like a positively charge particle (called a *hole*), which is analogous to a bubble in a sealed tube of water. The electron promoted into the relatively empty conduction band, now able to easily make transitions to other allowed quantum states, also now becomes mobile. The newly liberated electrons and holes are now free to move in opposite directions under the influence of the electric field imposed by the bias voltage applied to the device. This process is shown in Figure 20.

Two sources of noise are inherent in a PIN diode. One is a shot noise associated with the detection of individual photons. This is sometimes referred to as *quantum noise* because it is associated with the quantized nature of the electromagnetic field. In general, the fluctuations in the number of photoelectrons generated (N_{ph}) is proportional to the square root of N_{ph} . Thus, as the signal increases, so does the noise. The noise, however, increases less rapidly

Figure 20: Photon absorption and carrier transport in a PIN junction diode

than the signal, resulting in a steadily improving SNR with increased illumination. In most systems this quantum shot noise is overwhelmed by other noise mechanisms that end up dominating the signal-to-noise ratio and lead to a more intuitively satisfying linear dependence of the SNR on the received signal. The photon shot noise is calculated using Equation (6) with the average photo current during the 1 or 0 used for I_{AV} .

Even when a PIN diode is not illuminated, some small current can be measured when it is under reverse bias. This current is known as *dark current* and is frequently quoted as a measure of quality for a given photodiode. Although it is indicative of material quality, the shot noise associated with this dark current is seldom the limiting source of noise in an optical data link.

Avalanche Photodiodes

In an APD, the photo-generated carriers can acquire enough energy in the intrinsic region so that they can in turn create more hole-electron pairs by collisions with unexcited carriers. This leads to an increased current relative to a simple PIN diode (see Figure 21).

The APD thus has an inherent gain mechanism. This multiplication process also leads to additional noise beyond the photon shot noise. Known as the *excess noise* or *multiplication noise*, this noise is frequently lower than the thermal and $1/f$ electronic noise in the subsequent receiver circuit. In a chain of amplifying elements, the SNR of the chain is dominated by that of the initial amplifier stage. Even though an APD adds more total noise to the system, its gain results in usually a 6–10 dB improvement in SNR. Despite this advantage, the use of APDs is more limited than one might suppose. This is because of the need to carefully control the bias voltage over process, temperature, and aging in order to keep the diode out of avalanche breakdown. This is a sensitive adjustment that usually involves a feedback system. The construction and yield of APDs is similarly problematic because rather complex doping and material profiles are needed for optimum performance, and defects can easily limit yield. The additional time required for the multiplication process and the often larger device dimensions also result in

Figure 21: Avalanche photodiode

Figure 22: In a waveguide photodetector, light is confined in a small waveguide region to reduce the carrier transit time, allow a small contact with low parasitic capacitance, and thus enable high bandwidth simultaneously with high quantum efficiency

bandwidths somewhat less than can be obtained with a PIN diode. Erbium-doped optical amplifiers also provide an even lower noise source of gain with inherently very high bandwidth, thus supplanting APDs for the more performance-sensitive applications.

Waveguide Photodetectors

The diameter needed for a vertically illuminated photodetector is dependent on the spot size to which the optical mode can be focused. This sets a minimum capacitance, thus setting the maximum speed that the detector can be used with a given preamplifier input impedance. If the detector material has a small absorption coefficient, then the absorption layer must be fairly thick to efficiently detect all of the light. Although this tends to lower the diode capacitance, at high speeds the carrier-transit time can limit the detector-response time. To eliminate the resulting trade-off between responsivity and speed, waveguide detectors can be used (see Figure 22). Here the absorption region is embedded in a semiconductor optical waveguide. The well-confined mode allows the contact area to be small, decreasing the parasitic capacitance; and because the optical power is propagated transversely to the direction of carrier collection, the transit time problem is much reduced. Relatively long absorption lengths can be used without incurring a severe capacitive penalty, thus enabling high bandwidth (~100 GHz) with high efficiency (~50 percent).

Even higher speed operation is possible if the detector electrodes are configured as an electrical waveguide whose mode propagation velocity matches that of the optical signal in what are termed *distributed* photodetectors. In this case, as with waveguide modulators discussed above, the parasitic capacitance is absorbed into the waveguide impedance and the upper bandwidth limit (hundreds of GHz) is then set by the velocity mismatch between the optical and electrical modes.

Transimpedance Amplifiers

Photodetectors are naturally high output-impedance devices, often approximated as a current source for modeling purposes. Signals are usually represented, amplified, and processed as voltages, requiring that the photocurrent be converted into a voltage. This is most often accomplished in the first amplification stage of the receiver by use of a *transimpedance amplifier*. Sometimes called *transresistance amplifiers*, these amplifiers are designed

to accept a current as input and provide a proportional voltage at their output. The gain of a transimpedance stage is thus the ratio of the output voltage to the input current and is expressed in the units of resistance, ohms. Below we explore some of the typical receiver stage specifications, followed by some common amplifier circuit topologies and finally the technologies available for their implementation.

Specifications

The two most important specifications for an optical receiver are its bandwidth and its sensitivity.

The bandwidth must be high enough that excessive pulse broadening does not occur. This can lead to *inter-symbol interference* (ISI) and errors in the reconstructed data. Excessive bandwidth, although enhancing the fidelity of the received pulse, also increases the amount of noise that can corrupt the signal and can lead to data errors. The choice of the correct high-frequency limit is thus a compromise. For many NRZ systems, a good rule of thumb is to use a bandwidth of roughly 70 percent of the desired symbol rate. As an example: If a receiver is being designed for use in a 10 Gigabit-per-second system, the optical receiver should have a bandwidth of roughly 7 GHz.

The lower frequency cutoff is also important for proper system operation, particularly for NRZ signals, which can have a considerable amount of signal power in the low-frequency portion of their spectrum. If the amplifier is AC coupled with a low-frequency cutoff that is insufficiently low, then the DC level of the system will appear to wander in a data-dependent manner. This can cause problems at the decision circuit further down the signal-processing chain, leading to errors as well. For many NRZ systems, a low-end frequency response that is 10^{-4} of the symbol rate is desired. For a 10-Gbps NRZ type system, a low-frequency response below 1 MHz is needed, and often 100 kHz or better is used. AC coupling over such a broad bandwidth can be a challenge and is usually accomplished via a combination of several different types of capacitors in parallel. The required high- and low-frequency cutoffs are ultimately determined by the spectral power distribution of the transmitted signal; this, in turn, is determined by the data, the modulation scheme used, and the type of digital coding used.

Receivers must often tolerate a large range of input light intensity because of the uncertainty of the link length and attenuation over which they will be receiving the signal. Hand tuning is undesirable. In addition, for testing purposes it is often desirable to be able to do *loopback* testing in which the local transmitter output is directly connected to the receiver input. This requires that the receiver have a high saturation or overload power, often characterized by the received power at which the receiver input stage response has declined by 1 dB below that expected from a linear extrapolation from lower power inputs. The difference between the saturation power and the power at which the desired *bit error rate* (BER) is just achieved (sensitivity) is defined to be the *dynamic range*.

Resistor as a Transimpedance

Applying the photocurrent from the detector directly to a resistor is the easiest way to convert the current from

Figure 23: Schematic diagram of a resistor used as the transimpedance. On the right is shown the equivalent model for the sensitivity calculation including the photo current resulting from illumination (I_{ph}), the diode dark current (I_{dark}), the detector's parasitic capacitance, and the resistor (R).

the photodetector into voltage as shown in Figure 23. The transimpedance gain is then just the value of the resistor. The problem with this approach is that to achieve a high transimpedance gain using a large value resistor usually results in an unacceptably low bandwidth because of the large R-C time constant created by the photodetector's parasitic capacitance and the resistor. Some receivers are actually built this way with the bandwidth restored by the use of a high-pass filter as an equalizer.

This simple case illustrates the calculation of the signal-to-noise ratio and the error rate in a received signal. The total signal at the input is just I_{ph} , the diode photocurrent. The detector is assumed to have a parasitic capacitance C_{det} and a dark current of I_{dark} . The noise is the sum of the noise powers from the photon shot noise, the shot noise associated with the dark current, and the thermal noise of the resistor and is given in Equation (13):

$$\langle i_{noise}^2 \rangle = 2qI_{ph}B + 2qI_{dark}B + \frac{4kTB}{R} \quad (13)$$

The associated Q parameter from which the error rate can be calculated is given by

$$Q \equiv \frac{I_{signal\ p-p}}{I_{noise\ rms}(1) + I_{noise\ rms}(0)}$$

if the noise is the same for a 0 or a 1 then (14)

$$Q = \frac{I_{signal\ p-p}}{2I_{noise\ rms}}$$

This quantity can be thought of as a sort of signal-to-noise ratio. For RZ or NRZ signals, however, the noise can be different, depending on whether the intended symbol is a 1 or a 0 because of the associated photon shot noise. If the photon shot noise is negligible, then Q becomes the signal to noise ratio divided by 2. Once Q has been obtained, the error rate and sensitivity of the link can be calculated.

To a good approximation assuming Gaussian-distributed noise, the probability of error is given by

$$P(E) = \frac{1}{\sqrt{2\pi}} \frac{e^{-[Q^2/2]}}{Q} \quad (15)$$

if the decision level has been optimally chosen. So, for example, if Q is 6, the probability of error is $\sim 10^{-9}$. This means that, on average, one bit in a billion would be in error. This is alternately termed the *bit error rate* or *bit error ratio*.

Allied with this is the concept of *receiver sensitivity*. The sensitivity is given as the power required to reach a given BER with a given receiver. The sensitivity is commonly quoted for the 10^{-9} BER but often lower error rates ($\sim 10^{-12}$) are required in practice.

Suppose for the moment that in our simple example receiver that both the thermal and the dark current can be neglected. This leaves the unavoidable photon shot noise as the only noise source. Q is then given by

$$Q = \frac{2I_{ph}}{\sqrt{2qI_{ph}B}} = \sqrt{\frac{2I_{ph}}{qB}} = \sqrt{\frac{2\Phi_{ph}}{B}} = \sqrt{2N_{ph}} \quad (16)$$

where I_{ph} is the average photo current (hence the factor of 2 to get the peak-to-peak value), Φ_{ph} is the average photon flux in number per second, and N_{ph} is the average number of photons received per bit. The bit time has been taken rather crudely as $1/B$, which rigorously should be the noise bandwidth. If, however, a single pole receiver roll-off is assumed to be set to the recommended 70 percent of the bit rate, then this is not far off. Here we can see that with these assumptions a minimum of eighteen photons per bit on average would be needed for a 10^{-9} BER.

More rigorous analysis using the correct Poisson statistics for the photodetection process gives a true quantum noise limited sensitivity for an OOK signal of

$$N_{ph} = \frac{-\ln(2BER)}{2} \quad (17)$$

which for a BER of 10^{-9} gives a required minimum of ten photons per bit. Given this fundamental limit, we can see why as the bit rate increases the required power per bit does as well. The same number of photons are still required, but they must now be supplied in a shorter amount of time.

One case in which both high bandwidth and ease of use sometimes reward this approach is the use of a 50-ohm resistor and a 50-ohm input-impedance, high-speed amplifier as shown in Figure 24. Although seldom used in practical systems, this is easily built and is sometimes useful for testing and laboratory use.

Fortunately, the bandwidth limitation can be overcome by the use of feedback topologies to realize a broadband transimpedance amplifier. An ideal transimpedance amplifier would have zero input and output impedances. The low input impedance ensures that all of the photocurrent flows into the amplifier input, and the low output impedance would be characteristic of a perfect output voltage drive. To realize such an amplifier, we need to sense the output voltage in parallel and feedback a current in shunt with the photodiode input current. With negative feedback, this will have the effect of lowering the output and

Figure 24: Photodiode using a resistor as the transimpedance followed by a voltage amplifier

input impedances by the amplifier loop gain. This can be understood from the more formal analysis of feedback circuits or intuitively by realizing that the action of the voltage sensing at the amplifier output combined with negative feedback will tend to hold the output voltage constant over a wider variation of output load, leading to a lower output impedance when the loop is closed. At the input, the return of the feedback signal as a current in shunt will tend to hold the amplifier input voltage constant over a wide variation of input currents as would be characteristic of a low impedance input. As we will see in the more detailed analysis to follow, the chief advantage of the feedback topology is the ability not only to use a high-value resistor to realize a high transimpedance gain but also to escape the bandwidth limitation via the decrease of the input impedance by the loop gain.

Common Transimpedance Amplifier Topology

Although many topologies have been investigated, the one shown in Figure 25 is one of those most often used.

This amplifier consists of a common source stage followed by a source follower. The output voltage is detected by the resistor R_F and is fed back to the input as a current. The equivalent open loop circuit in which the loading effects of the feedback network are taken into account is shown in Figure 26.

From the figure, we can see that the open loop transimpedance gain is approximately

$$R_{TOL} = -R_F g_{m1} R_D \quad (18)$$

Figure 25: Common transimpedance feedback amplifier topology consisting of a common source stage followed by a source follower stage

Figure 26: Correctly loaded open loop amplifier corresponding to the closed-loop amplifier shown in Figure 25.

The open loop input and output impedances are approximately

$$R_{INOL} = R_F \quad \text{and} \quad R_{OUTOL} = \frac{1}{g_{m2}} \quad (19)$$

The loop gain T of the amplifier is approximately just $-g_{m1}R_D$. Using the usual feedback formalism, this leads to the closed loop values of

$$\begin{aligned} R_{TCL} &= \frac{R_{TOL}}{1+T} = \frac{R_F g_{m1} R_D}{1+g_{m1} R_D} \approx R_F \\ R_{INCL} &= \frac{R_{INOL}}{1+T} = \frac{R_F}{g_{m1} R_D} \\ R_{OUTCL} &= \frac{R_{OUTOL}}{1+T} = \frac{1}{g_{m2} g_{m1} R_D} \end{aligned} \quad (20)$$

for the transimpedance gain R_{TCL} , the input R_{INCL} and output R_{OUTCL} closed loop resistances. Here we can see explicitly that, whereas the transimpedance gain is maintained at R_F , the input impedance is reduced by the loop gain of the open loop amplifier, reducing the bandwidth limitation seen with the use of a single resistor.

Correct treatment of the calculation of such a receiver's sensitivity is complicated and beyond the scope of this chapter. The difficulties arise from the proper inclusion of the noise bandwidths that must be used for the various noise sources obtained by their integration over the receiver's frequency response. The interested reader is referred to a summary treatment by Smith and Kasper (2002) or the rigorous and detailed treatment found in Personick (1973).

Receiver Blocks

The initial transimpedance amplifier is usually followed by a main amplifier as shown in Figure 1, which is implemented as either an automatic gain control amplifier or sometimes as a more simply implemented limiting amplifier. The purpose in each case is to amplify the signal to a predetermined level for further processing. The signal from the main amplifier is split and applied to the clock recovery and decision circuits. The underlying clock that was used to synchronize the data is recovered, usually by use of a phase-locked loop, and applied to the decision circuit, which in its simplest form can be thought of as a flip-flop. When clocked, it generates a digital output that depends on the analog value at the moment it is clocked. For best signal-to-noise performance, the threshold voltage level and clock timing must be set to the middle of the open data eye.

Transmission impairments—such as chromatic dispersion, chirp in the optical pulse, fiber nonlinearity, polarization mode dispersion, and insufficient component electrical bandwidth—can result in significant pulse distortion leading to ISI and limit the usable link length or maximum data transmission rate. Improvements in component performance or fiber over time tend to reduce these problems for new installations, but it is often desirable to use legacy fiber or lower-cost components at ever greater bit-rate distance products. This limitation is addressed in some systems by either pre- or postelectronic

equalization that offers a low-cost, compact, and relatively simple method to increase link span or bandwidth. When combined with forward error-correction codes, these techniques, which were largely developed for lower-speed wireline and wireless applications, yield significant improvements in link performance. Several approaches are outlined here, but for a more thorough and tutorial discussion the interested reader is referred to Azadet et al. (2002).

Electronic Equalization

Four main techniques are being employed in optical links, *maximum likelihood sequence estimators* (MLSEs), *decision feedback equalizers* (DFEs), *feed-forward equalization* (FFE), and *adaptive threshold control*.

Figure 27 shows a block diagram of a receiver using adaptive threshold control. Here the error monitor block senses the errors as a function of the threshold setting. The threshold is then adjusted to the setting that minimizes the errors induced by noise or pulse distortion.

One way that an FFE can be implemented is shown below in Figure 28. The input signal is delayed a number of times by τ , typically on order of the bit time. The delayed signal samples are then multiplied by analog weighting factors and then recombined in the summation block. This process can be thought of as providing an approximation to a matched filter for the channel. Again, an error monitor circuit is used to adaptively compute the tap weights, often with the aid of initial or periodically recurring training sequences.

FFE implementations are often combined with DFEs; an example is shown in Figure 29. For simplicity, the figure shows a single bit realization, although multiple delays and taps are often used. The DFE operates by adjusting the reference input to the differential amplifier, depending on the value of the previous bit. So, for example, if a 1 was previously detected, the amount of ISI that it contributes to the present bit can be subtracted before the decision circuit. Again, the system can be made adaptive by the use of training sequences or by channel estimation followed by continuous error monitoring and adjustment.

MLSE is a technique that was developed in lower-speed applications, principally for disk drives. This technique

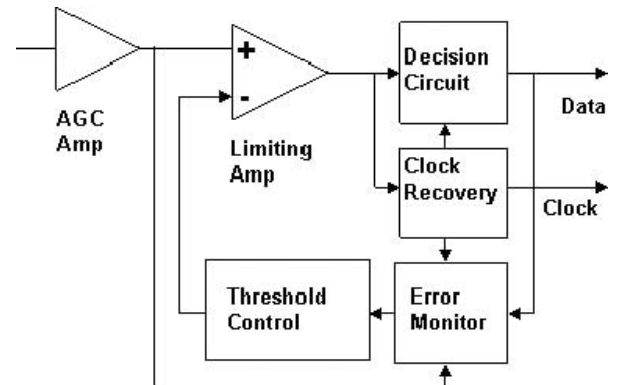

Figure 27: Block diagram of a receiver with adaptive threshold control

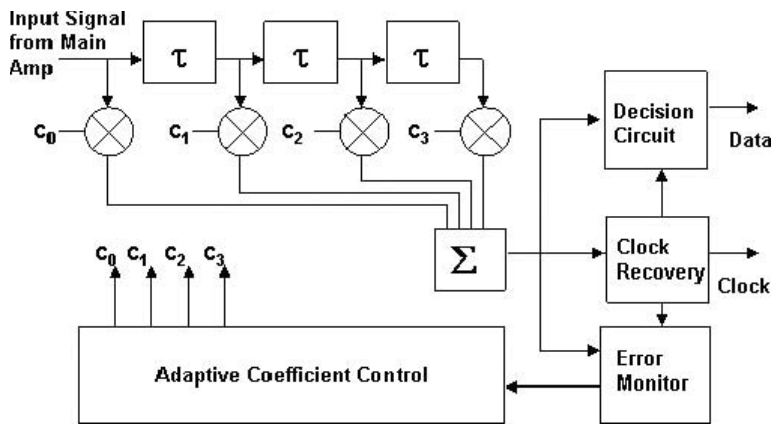

Figure 28: Block diagram of an adaptive feed-forward equalizer using an FIR traversal filter with adjustable tap weights

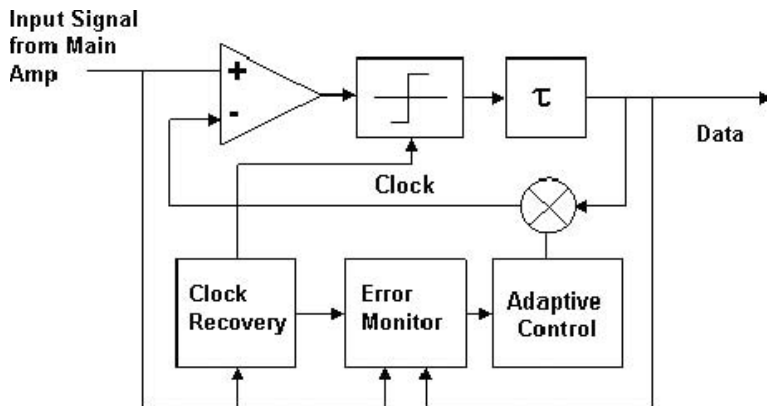

Figure 29: Decision feedback equalizer

makes decisions on the value of not just individual bits but also on sequences. The algorithms used to implement it are often realized digitally, so this approach requires a high-speed analog-to-digital converter with modest resolution. Many standard texts on digital communication treat adaptive equalization and MLSE detection; among them is Proakis (2000).

Electronic Technologies

A variety of circuit technologies are employed to realize transmitter and receiver circuitry. At lower bit rates, CMOS is generally suitable and employed where possible because of its economic advantage in volume production. Higher performance is generally realized by the use of approaches based on silicon BJTs or silicon-germanium (SiGe) *heterojunction bipolar transistors* (HBTs). At the highest bit rates, more exotic processes can be employed using III-V-based semiconductor transistors. The best broadband receiver performance is achieved using InP-based *heterostructure FETs* (HFETs) or *high electron mobility transistors* (HEMTs) that have the virtue of being capable simultaneously of both high F_i and low noise. For laser and modulator drivers for high-bandwidth applications SiGe-based BJTs are often needed. Even this technology becomes inadequate at extremely high bit rates where it is difficult to simultaneously achieve both the necessary F_i and the voltage drive for some modulators. In these cases, GaAs- or InP-based BJTs are often needed.

Good reference works on III-V compound semiconductor-based devices can be found in Liu (1999) and Yuan (1999). Cressler and Niu (2003), Ashburn (2003), and Singh, Oprysko, and Harame (2003) cover the use and development of SiGe HBTs.

Optoelectronic and Photonic Integrated Circuits

The monolithic or hybrid integration of optoelectronic devices such as photodetectors, lasers, and modulators with electronic transistor technologies creates *optoelectronic integrated circuits* (OEICs). This is in contrast to the integration of optical components with optoelectronic devices that leads to *photonic integrated circuits* (PICs). Although demonstrated, monolithic OEIC laser transmitters have not elicited great amounts of interest because of their increased processing complexity with little gain in performance. Hybrid integration via flip-chip bonding of either individual lasers or arrays is used to reduce bonding parasitics and module size. Monolithic OEIC receivers have been more successful, with some reaching commercial production, the most widespread being the integration of GaAs-based MSM detectors with GaAs *depletion mode metal-semiconductor field effect transistors* (D-MESFETs) or HEMTs in an almost completely process-compatible manner. Another natural combination is the combination of PIN detectors with III-V based HBTs. The collector-base junction of the HBT can serve

as a passable photodetector with only minimal process alteration. The most successful PICs to date involve the combination of CW-DFB lasers with EAMs for the generation of low-chirp modulated data streams in the multi-Gigabit per second applications and of spot size converters with DFB lasers to ease optical coupling. Rather large PICs that combine arrayed waveguide multiplexers, optical photodiode monitors, tunable DFB lasers, EAMs, and variable optical attenuators integrating more than fifty devices have produced ten 10-Gb/s optical WDM channels on a single chip (Nagarajan et al. 2005). Such high levels of integration with the attendant reduction in expensive alignment steps could provide the impetus needed to further move PICs and OEICs from the research lab to the marketplace. The device performance compromises that inevitably seem to arise for the sake of monolithic integration indicate that OEICs and PICs will likely have the most success in standards-based markets where performance that is “good enough” can be achieved at lower cost.

SILICON PHOTONICS

Although the dominant semiconductor for electronic applications, silicon is a poor light emitter because of its indirect band gap. This also leads to large photon absorption lengths that translate into large and relatively slow photodetectors. The relatively large band gap also makes it transparent at the important glass fiber telecommunications wavelengths of 1.3 and 1.55 μm , although good performance can be achieved at 850 nm, which is the preferred emission wavelength for low-cost and high-speed VCSELs as well as a region of tolerably low loss in both glass multimode fibers and perfluorinated polymer optical fiber, both important for emerging data communication standards. Despite the apparent disadvantages, significant progress has been reported in Si-based OEICs and silicon photonics with much laboratory work focused on methods to create efficient light-emitting devices. Notable has been the report of almost completely process-compatible integration of WDM multiplexers, demultiplexers, waveguides, couplers, modulators, and detectors in a CMOS semiconductor-on-insulator process (Huang et al. 2006). Progress in light emission and integration of optical components with silicon is also reported by Panicia and Koehl (2005) and discussed in some detail in Pavesi and Lockwood (2004) and Reed and Knights (2004). Zimmermann (2004) provides a detailed look at progress in silicon-based OEICs.

CONCLUSION

In this chapter we have provided a detailed summary of the physical layer components and related issues surrounding the optoelectronic components used in optical data links. The two main components are transmitters (consisting of light-emitting devices, optical modulators, and their associated driver circuitry) and receivers (consisting of photodetectors and electronic amplifiers). The influence of optical fiber transmission properties and fundamental processes such as noise are considered as they pertain to the design of transmitters and receivers

for optical links. Specifications, emerging device trends, electronic equalization, optoelectronic integration, packaging issues, and underlying electronic technologies are also discussed.

GLOSSARY

Bragg Reflector: A reflective structure formed by alternating layers of material with different indexes of refraction. The layer spacing is chosen so that the phases of the reflections from the successive layers all add coherently.

Chirp: A frequency shift associated with the on or off switching of a laser diode or modulator.

Dispersion Power Penalty: The power penalty in decibels associated with the increase in receiver optical power level required to achieve a specified error rate when the signal is subjected to a specified amount of chromatic dispersion.

Electro-Absorption (EA) Modulator: Semiconductor modulators using the Franz-Keldysh effect or the quantum-confined Stark effect (QCSE) to vary the effective absorption edge of the material with an applied electric field.

Electro-Optic Coefficient: A measure of the ratio between an applied electric field and the amount of change in the material's index of refraction. This property depends on the material's field orientation, crystal structure, and propagation direction.

Extinction Ratio: The ratio of maximum to minimum attenuation for an amplitude modulator. The term also applies to the ratio (in decibels) of the average optical energy in a logic 1 level to the average optical energy in a logic 0 level of a digitally modulated optical signal.

Eye Pattern: A signal built up by overlapping traces that correspond to all possible sequences of a digital waveform.

Jitter: Random or systematic variations in the arrival times of pulses or transitions in digitally transmitted data. Seen as a horizontal spreading of an eye pattern at the crossover point.

Laser Rate Equations: Set of equations describing the dynamic behavior of electron and photon population densities in a laser under modulation.

Light versus Current (L/I) Characteristic: Plot of light output versus current in a laser.

Mach-Zehnder Modulator (MZM): A two-path optical interferometer that uses phase shifts to provide amplitude modulation.

Non-Return to Zero (NRZ): Digital format in which the logic 1 or 0 pulses occupy the whole bit period (*see also* Return to zero).

Optical Isolator: A device that utilizes the Faraday effect to allow transmission through the device in one direction only; used to isolate lasers from the effects of reflections from external index discontinuities.

Plastic Optical Fiber (POF): Fiber typically based on polymethyl methacrylate but increasingly composed of perfluorinated polymers.

Relaxation Resonance: Internal resonance in a laser diode between electrons and photons.

Return to Zero (RZ): Digital format in which the logic 1 pulses occupy half (or a fraction) of the bit period.

Thermoelectric (TE) Cooler: Device that utilizes the Peltier effect to remove heat from one surface to the other. The direction of current flow determines the direction of heat flow so that the same device can be used to heat or cool as necessary.

$V\pi$: For phase modulators, the voltage change required to give a phase shift of π radians (180 degrees). In a Mach-Zehnder modulator, this is the minimum voltage needed to change from maximum to minimum extinction.

INTRODUCTION

It is well known that signals propagating over optical fiber networks are significantly distorted because of a combined effect of amplifier noise accumulation, fiber dispersion, fiber nonlinearity, and inter- or intrachannel interactions. This results in serious limits in both capacity and range of the system transmission. This is especially the case in advanced optical networks based on *wavelength division multiplexing* (WDM), where many channels at different wavelengths and each carrying signals of as much as 40 Gbit/s are sent through long stretches of fiber and are traversing many optical amplifiers and switches. Regardless of the transmission formats [return to zero (RZ), NRZ, or chirped RZ], the induced distortion is reflected in four main types of signal degradation: intensity noise, timing jitter, pulse-envelope distortion (Leclerc, Lavigne, and Chiaroni 2002), and phase noise (Boscolo, Bhamber, and Turitsyn 2006). *Intensity noise* might be more accurately referred to as the uncertainty in the energy content of a given bit slot. Fiber chromatic dispersion coherently mixes the contents of adjacent bits, optical amplification causes beat noise with spontaneous emission, and fiber nonlinearities introduce information-dependent power transfer between WDM channels, all resulting in irreversible bit energy fluctuations.

Timing jitter is the uncertainty in the pulse-mark arrival time, or a synchronization default with respect to the bit stream. The main causes for timing jitter are nonlinearities of *self-phase modulation* (SPM), *cross-phase modulation* (XPM), *polarization-mode dispersion* (PMD), and, for RZ formats, the Gordon-Haus and electrostriction effects (McKinstry, Santhanam, and Agrawal 2002).

Pulse envelope distortion can be viewed as an irreversible change in the pulse envelope that increases the probability of symbol detection error. A most obvious pulse distortion effect is the fill-up of 0 symbol spaces by *amplified spontaneous emission* (ASE), thus reducing the on-off extinction ratio. Fiber nonlinearities (SPM, XPM), *four-wave mixing* (FWM), stimulated Raman scattering, and PMD are the essential causes of pulse-envelope distortion.

Phase noise is referred to as *bit-to-bit phase fluctuation*. In fiber-optic transmission systems, phase noise is added by ASE from optical amplifiers. Moreover, intra- and inter-channel nonlinearities resulting from the Kerr effect in the fiber, such as SPM and XPM, convert amplitude noise (variation of the signal amplitude) to phase noise. As a result, amplitude noise from ASE, dispersion-induced pattern effects, and nonlinearities such as four-wave mixing all introduce nonlinear phase noise. For high-performance fiber-optic transmission, phase-sensitive modulation formats such as *differential phase shift keying* (DPSK) have recently emerged as a promising alternative to conventional *on-off keying* (OOK). The DPSK format carries the information in optical phase shifts of either zero or π between adjacent bits. Unlike the OOK signals, the DPSK signals are sensitive to phase noise. In DPSK transmission systems, phase noise limits the system performance (Boscolo, Bhamber, and Turitsyn 2006).

To limit the above impairments, an efficient and powerful solution regenerates signals at intermediate nodes. This can be realized in two ways for given system impairments from amplifier noise and fiber nonlinearities after some transmission distance. The first, the electronic regeneration, consists of segmenting the system into independent

Figure 1: Basic setup of electro-optical regenerator

trunks with full electronic repeaters or transceivers at interfaces. The second is inline optical signal regeneration, which performs the same signal-restoring functions as the electronic approach but with reduced complexity and enhanced capabilities. Several other methods have also been adopted so far: improving the transmission format (e.g., chirped RZ versus NRZ in submarine systems) or reducing power levels (Mu et al. 2002). At the terminal side, the introduction of error-correcting codes has made possible high levels of received signal quality (*bit error rate*, or BER, $< 10^{-7}$), while allowing relatively substantial signal degradation through the transmission line.

Electronic regeneration has been widely used in the networks being deployed today. In electronic regenerators (as seen in Figure 1), the incoming optical signal is converted to the electrical domain by means of a high-speed photodiode. Signal regeneration or processing is then achieved using broadband radio frequency circuitry, after which the regenerated electrical signal is converted back in the optical domain using an electro-optical modulator coupled with a laser diode. As seen in Figure 1, complete integration of such an architecture is rather complex. As the bit rate increases, electronic regenerators become highly expensive and physically more difficult to realize because of the electronic bandwidth bottleneck.

Optical signal regeneration is a promising technique in the evolution of high bit-rate systems, thanks to its strong potential for compact integration and especially high bandwidth. Optical signal regeneration has been one of the most attractive fields of optical fiber communications research. It is now generally accepted that optical signal

regeneration will be the key technique in future photonic networks that require both high-speed optical signals to be transmitted at high qualities over long distances and flexible interconnect of optical network nodes.

In optical signal regeneration, there are three basic signal-processing functions: *reamplifying*, *reshaping*, and *retiming*, hence the generic acronym *3R* (see Figure 2). Thus, optical amplification (such as with erbium-doped fiber amplifiers, EDFAs) provides a mere *1R* signal-processing function. When retiming is absent, we usually refer to the regenerator as a *2R* device, with only reamplifying and reshaping capabilities. A device with the full *3R* capabilities is called a *3R regenerator* and requires clock extraction. There are various ways to define optical signal regeneration. It can refer to pure optical-to-optical signal processing. The *all-optical* label usually refers to the case where the regenerator subcomponents are optically controlled.

This chapter reviews current technology alternatives for optical signal regeneration, considering both theoretical and experimental performance. The second section briefly gives the general principle and the qualification of optical signal regeneration. The third section focuses on regeneration techniques based on the nonlinearities of *semiconductor optical amplifiers* (SOAs). The fourth to seventh sections concern regeneration techniques using multisection lasers, *saturable absorbers* (SAs) or electro-absorption modulators, synchronous modulation, and *nonlinear optical loop mirrors* (NOLMs), respectively. The eighth section discusses other potential implementations of optical signal regeneration.

Figure 2: 3R regeneration—reamplification, reshaping, and retiming

THE GENERIC PRINCIPLE AND QUALIFICATION OF OPTICAL SIGNAL REGENERATION

The Generic Principle of Optical Signal Regeneration

Optical signal regeneration has been realized based on different principles: for example, on nonlinear optical gates, synchronous modulation, self-phase modulation, and so on. Optical signal regeneration using nonlinear optical gates has attracted the most interest in the last decade. The generic principle of an optical signal 3R regeneration based on the nonlinear optical gates is illustrated in Figure 3a. A nonlinear gate can be defined as a three-port device in which the second input port is used as a “decision” control such as in SOA gates. It can also be a two-port device, where the input signal acts as its own control, such as in SA gates. The noisy signals to be regenerated are first launched into the reamplification block. Part of the output signal is extracted to recover a synchronized clock signal, while the remnant is fed to the decision block for simultaneous reshaping and retiming. The end block, the decision gate, performs reshaping and retiming and is the regenerator’s core element. Ideally, it should also act as a transmitter capable of renewing or restoring optical pulse shapes. In fact, the nonlinear

optical gates exhibiting a nonlinear transfer function, as shown in Figure 3b, can also be used as an optical 2R regenerator. At low input powers, the output of the device remains at a low and steady level. Once the input power exceeds a certain power level—that is, the decision threshold—the output rises rapidly up to a steady high level. When the noisy signals to be regenerated are launched into the device, the intensity noise at both 0 and 1 symbols is thus suppressed (i.e., the noise is redistributed) and the *extinction ratio* (ER) is simultaneously improved. The input noisy signals are regenerated.

Figure 4 further illustrates the principle of operation of the optical 3R regenerator based on a nonlinear optical gate. The incoming and distorted signals trigger the nonlinear gate, thus generating a switching window, which is applied to a newly generated optical clock signal so as to reproduce the initial data stream on the new optical carrier.

Clearly, the nonlinear transfer function of the device is the key parameter that governs regenerative properties. It has been shown theoretically that the highest regeneration efficiency (as obtained when considering the less-penalizing concatenation of regenerators) is achieved with an ideal step function (Öhlén and Berglind 1997). Figure 5 shows the theoretical evolution of BER with the number of concatenated regenerators for regenerators having different nonlinear transfer functions. The calculation,

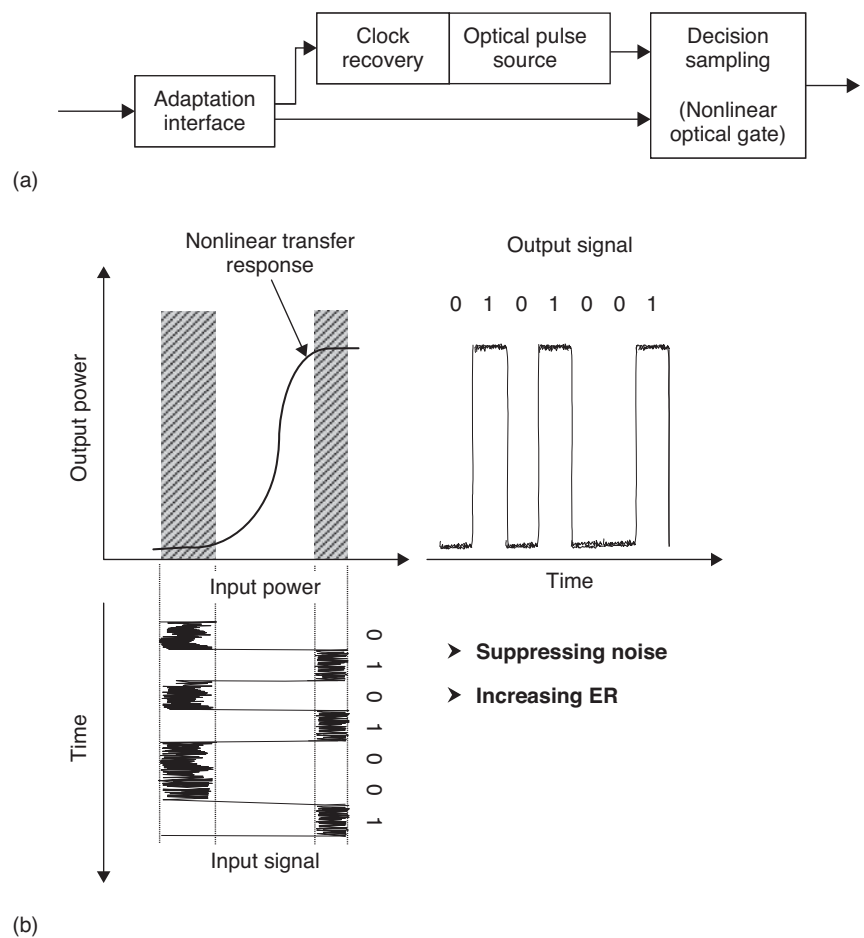

Figure 3: (a) Generic principle of an optical 3R regenerator based on nonlinear optical gates; (b) operating principle of an optical gate with a nonlinear transfer function

Figure 4: Operation principle of the optical 3R regenerator based on a nonlinear optical gate

however, does not account for dynamic effects or jitter impact in the regenerator cascade. The degree of nonlinear function is characterized through the factor γ , which changes the shape of the nonlinearity from a step function ($\gamma = 0$) to a linear function ($\gamma = 1$). The noise level is adjusted so that the output bit error rate is fixed to 10^{-12} after a single regenerator. As seen in the figure, the smaller the factor γ , the lower the BER and the larger the cascade can be. The optical regenerator with quasi-ideal nonlinear function is therefore of great importance. Different nonlinear optical transfer functions approaching more or less the ideal can be realized in various media such as fiber, SOA, *electro-absorption modulator* (EAM), and laser.

Optical signal regeneration can also be achieved through in-line *synchronous modulation* (SM) associated with *narrowband filtering* (NF) (Leclerc et al. 2003). Modulation can be made on signal intensity (*intensity modulation*, IM) or phase (*phase modulation*, PM), or a

combination of both. The SM regenerator includes a *clock recovery* (CR) block, a modulator, and an optical filter. Regeneration through SM-NF intrinsically requires nonlinear (soliton) propagation in the trunk fiber following the SM block. More solutions of optical signal regeneration have been proposed recently. A simple optical regeneration system based on self-phase modulation, which was firstly suggested by Mamyshev (1998), is highly attractive. Optical signal regeneration using a nonlinear optical loop mirror is also an attractive approach. More detailed descriptions of these kinds of optical signal regeneration will be given in following sections.

Qualification of Optical 2R Regeneration

The qualification of the regenerative capabilities of an optical signal regeneration device basically consists of the evaluation of a limited number of key parameters such as extinction ratio, power fluctuations, power penalty, and polarization sensitivity. This is practically accomplished by measuring the eye diagrams and BERs. The ER is here defined as $P_s(1)/P_s(0)$, the ratio of the powers (electrical) for 1 symbols and 0 symbols. As mentioned in the previous section, the fill-up of 0 symbol spaces by the ASE degrades the ER. ER improvement achieved with a 2R device proves its regenerative capability. (Note that a mere optical amplification cannot result in any ER improvement.) The BER is defined as the probability of incorrect identification of a bit by the decision circuit of the receiver—that is, the sum of the probabilities of a 1bit being read as 0 and vice versa. The BER is the ultimate test for a digital transmission link. A transmission link is typically characterized by BER as a function of received power. The minimum average power required at the receiver to get a given BER (typically, 10^{-9} or 10^{-10}) is referred to as *receiver sensitivity*. For a given BER and because of transmission impairments, any additional power required at the receiver is called a *power penalty*. Improvement of receiver sensitivity (negative power penalty) for degraded input signals or lower power penalty for “perfect” input signals, because of the insertion of the device, also proves the regenerative capability of the regenerator.

Certainly, validation of the structure and operation margins, the high bit-rate potential, and cascadability

Figure 5: Evolution of the BER with concatenated regenerators for different nonlinear transfer function (i.e., γ parameter)

issues are also important aspects of the qualification of the 2R regenerators. Note that optical regenerators cannot “correct” errors but can only avoid accumulating noise and other impairments. Ideally, the optical regenerator should be tested also in a recirculating loop (Lavigne et al. 2002), especially for 3R regenerators. In that measurement, one might qualify regeneration performance through the evolution of the receiver sensitivity penalty at fixed BERs with respect to key relevant parameters such as *optical signal-to-noise ratio* (OSNR). Evaluation and comparison of regenerative properties then amounts to measuring the minimum OSNR, corresponding for example to a 1-dB penalty on the receiver sensitivity with respect to the first lap, which is tolerated by the regenerative apparatus throughout the cascade. This measurement then reflects the accumulated effects of all degrading factors occurring in the transmission, such as chromatic dispersion, timing jitter accumulation, and amplifier noise, and hence enables the extraction of the actual regenerative performance of the tested device.

In the following sections, we describe current solutions to realize the optical signal regeneration mentioned above. The issue of characterization and performance evaluation is also addressed. As mentioned in the previous section, a key element of optical regenerators is the nonlinear gate, which performs the decision in the optical domain. Such gates have been extensively investigated. This type of decision element uses either monolithic SOA-based (or laser-based) or fiber-based devices. So, in the following sections, we mainly focus on the realization of decision elements (or 2R regenerators) using SOA-based devices, saturable absorbers, electro-absorption modulators, multisection lasers, and fiber-based devices such as nonlinear optical loop mirrors. Some optical 3R regenerators will be given as examples.

OPTICAL SIGNAL REGENERATION BASED ON NONLINEARITIES OF SEMICONDUCTOR OPTICAL AMPLIFIERS

The semiconductor optical amplifier is a prominent key device that acts as the nonlinear element in optical signal regeneration. Because of the maturity of this device technology, market costs are decreasing and integration with other active and passive devices is possible. SOA-based subsystems are being developed to give feasible alternatives for optical signal regeneration. To implement optical signal regeneration, the phenomenon most often used is the SOAs nonlinear gain behavior: the cross-gain modulation and the cross-phase modulation. Another important nonlinear phenomenon, the *nonlinear polarization rotation* (NPR), has also become more attractive and has recently been used for optical signal processing. The four-wave mixing is also an important nonlinear phenomenon of SOAs, but it is less used because of its complex hardware setup and operation, although it presents a high-speed response. All of them—XGM, XPM, NPR, and FWM—are reached under saturated optical gain conditions during SOA amplification, obtained by injecting

either high-input optical powers or electronic bias current into the SOA active cavity or by doing both simultaneously. The first nonlinear process, XGM, is the easiest to implement but the one with the slowest response, so it has the worst converted eye-opening performance. It can be used to cover bit rates not higher than 5 Gbit/s and with a clear input pulse's shape format, because XGM depends on extremely deep carrier density modulation. So, the implementations of optical signal regeneration given in this section will focus on those based on the SOAs XPM and NPR.

Optical Signal Regeneration Using SOA-Based Interferometers

The optical regeneration using SOA-based interferometers is based on a XPM-induced phase shift. Two basic structures have been explored to realize optical regeneration with monolithic SOA-based interferometers, namely, the *Mach-Zehnder interferometer* (MZI) and the *Michelson interferometer* (MI) as shown in Figure 6 and Figure 7, respectively (Leclerc, Lavigne, and Chiaroni 2002). In these structures, both an input signal carried by wavelength λ_1 acting as a pump signal and a local *continuous wave* (CW) signal carried by wavelength λ_2 acting as a probe signal are used. In the Mach-Zehnder interferometer, injection of the signal at λ_1 induces a phase shift through XPM in SOA2, the amount of which depends on the power level $P_{in}(\lambda_1)$. The probe signal at λ_2 is injected into the interferometer, where it splits equally in the two interferometer arms and then recombines at the output, either constructively or destructively depending on the phase difference between the interferometer arms. The phase difference is determined by both a XPM-induced phase shift in SOA2 and a static phase shift in SOA1 and SOA2, as well as changes with $P_{in}(\lambda_1)$. Therefore, the output of the interferometer changes nonlinearly with increasing input signal power as seen in Figure 3b. As explained previously, the nonlinearity of the transfer function induces noise redistribution, resulting in a narrower distribution for marks and spaces and an improvement of the data ER. The interferometer operates as an all-optical 2R regenerator. In the MI, the probe signal is coupled to the interferometer via a circulator and is back-reflected in two SOAs. As in the previous case, only SOA2 induces XPM. The MI type has higher speed potential compared to the MZI type, mainly because of the fact that back reflection doubles the interaction length. The optical bandpass filters in these structures are used for removing the pump signal (wavelength λ_1).

An alternative implementation of the 2R regenerator using an SOA-based interferometer is similar to the previous one but no local CW signal is needed (Wolfson et al. 2000). In this 2R regenerator, a nonlinear phase difference between the two interferometer arms is the result of an SPM (i.e., the phase shift induced by the input signal itself) in both SOAs, which are now asymmetrically biased.

All of the 2R regenerators using SOA-based interferometers have a high integration potential and open the possibility to integrate complex optical functions for optical signal processing. The implementations using SPM

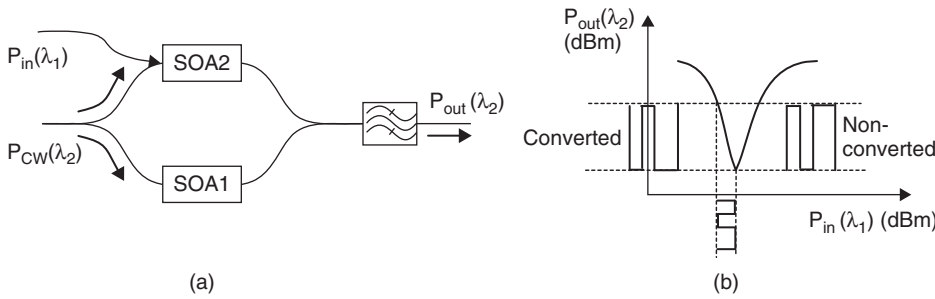

Figure 6: Principle structure of the 2R regenerator based on a Mach-Zehnder interferometer with SOAs in both arms

Figure 7: SOA-based Michelson interferometer for 2R regeneration

are simple and cost-effective. The 2R regenerators based on wavelength conversion are more complex because of the probe laser, but they can be easily upgraded to full 3R regeneration if the CW signal at λ_2 is substituted by an optical clock signal. Reshaping and retiming can then be simultaneously obtained using sampling (Chiaroni et al. 1997). Optical regeneration (2R or 3R) based on MIs or MZIs has been demonstrated at 10 Gbit/s (MZI) (Lavigne et al. 1998) and at 20 Gbit/s (MI) (Jepsen et al. 1998). With a differential mode of the SOA-based MZI, the bit rate can be improved to 40 Gbit/s or beyond (Ueno, Nakamura, and Tajima 2001). An asymmetric MZI with a *multimode interference semiconductor optical amplifier* (MMI-SOA) has been proposed (De Merlier et al. 2002) in which the SOA in one arm is replaced by a one-by-one MMI-SOA. This device has the advantage of being small and easy to fabricate, and it also gives a better regeneration characteristic than the above mentioned interferometers. Regeneration at 2.5 Gbit/s has been experimentally demonstrated. In addition, the SOA-based ultrafast nonlinear interferometer is an attractive approach for exceptionally high-speed optical regeneration (Thiele, Ellis, and Phillips 1999).

Optical Signal Regeneration Using Gain-Clamped SOAs

As seen in the previous section, the SOA-based MZI is one of the most attractive implementations of all-optical 2R regeneration because of its high integration potential. This device, however, suffers from a rather slow nonlinear transfer function, which results in limited regeneration efficiency. An all-optical 2R regenerator that has a steep nonlinear transfer function and gives the same benefits

as SOA-based devices would be a highly promising component for the all-optical networks. An all-optical 2R regenerator using an MZI with *gain-clamped SOAs* (GCSOAs) in both arms that does possess all of these features has been proposed and experimentally demonstrated (Zhao, Morthier, and Baets 2002). The operation of this regenerator is based on the specific property of a GCSOA (its amplification in the linear regime is independent of the injected current), whereas the saturation power increases linearly with the injected current. The regenerator has a Mach-Zehnder interferometric structure with gain-clamped SOAs in both arms. The operation of this regenerator is based on the specific property of a GCSOA that its amplification in the linear regime is independent of the injected current, whereas the saturation power increases linearly with the injected current. The two GCSOAs in the Mach-Zehnder interferometer are, in principle, identical and have different biases applied to them. In the linear regime, both arms of the MZI give the same signal gain and a phase delay that differs by a constant. As a result, a completely destructive interference below the input saturation powers of both GCSOAs is obtained at the output of the MZI. Beyond the saturation power of both GCSOAs, the phase difference between both arms is also constant but now different, and the output powers from both GCSOAs are saturated such that a constant output power is also obtained at the output of the MZI and hence a digital-like decision characteristic is achieved with the MZI regenerator. Figure 8 shows the measured static transfer characteristic of the regenerator. The bias currents applied to the two GCSOAs are 140 mA and 145 mA, respectively, and

Figure 8: Measured static transfer characteristic of the all-optical 2R regenerator; injected current to the two GCSOAs is 140 mA/145 mA, and signal wavelength is 1553.3 nm

Figure 9: Eye diagrams with and without the 2R regenerator for signals with different extinction ratios at 2.5 Gbit/s [pseudorandom binary sequence (PRBS) = $2^{23} - 1$, RZ format]; signal wavelength is 1553.3 nm

the signal wavelength is 1553.3 nm. As we can see, the optical transfer characteristic has a true digital-like shape. For both a logical 1 (high power level) and a logical 0 (low power level) quasi-perfect regeneration is achieved, which is consistent with the simulation result described in the previous section. The output power shifts from the low to the high level over an input power range of approximately 0.2 mW at a threshold power of 1.0 mW. This means that under static conditions an output extinction ratio of 15 dB can be obtained for an input extinction ratio of less than 1 dB.

The eye diagrams with and without the 2R regenerator for the input ERs of 2 dB, 5 dB, and 9 dB are demonstrated in Figure 9, showing the regenerative capabilities of the 2R regenerator under dynamic operation. Clearly, the input signal is regenerated. Both the power level and the noise at the logic 0 are tremendously suppressed, and a strong improvement of the ER is demonstrated. For the input signals with ERs of 5 dB and 9 dB, improvement of 8 dB in ER is obtained. Even for a seriously deteriorated input signal with almost closed eyes (input ER = 2 dB), clearly opening eyes can be obtained with the 2R regenerator, and an ER improvement of 7 dB is still achieved. As the noise at the logical 0 is strongly suppressed after the 2R regenerator, there is no doubt that an improvement in the *signal-to-noise ratio* (SNR) and thus an improvement in receiver sensitivity can be achieved, although no significant intensity noise suppression at the logical 1 is observed.

Optical Regeneration Using Nonlinear Polarization Rotation in SOA

Nonlinear polarization rotation, which is induced by nonlinear effective birefringence, is one of the important

nonlinearities in SOAs. For a linearly polarized injected light beam, the state of polarization of the output from the SOA will be different from that at the input but will not change with varying input power level in the linear regime. Although the polarization state of the output in the linear regime is independent of the input power level, it changes rapidly when the SOA becomes saturated because of birefringence effects and transverse electric and transverse magnetic conversion effects (Zhao et al. 2002).

The optical regenerator based on NPR consists of an SOA followed by a polarization controller and a polarizer, as shown in Figure 10 (Zhao et al. 2003). For a linearly polarized injected light beam, the state of polarization

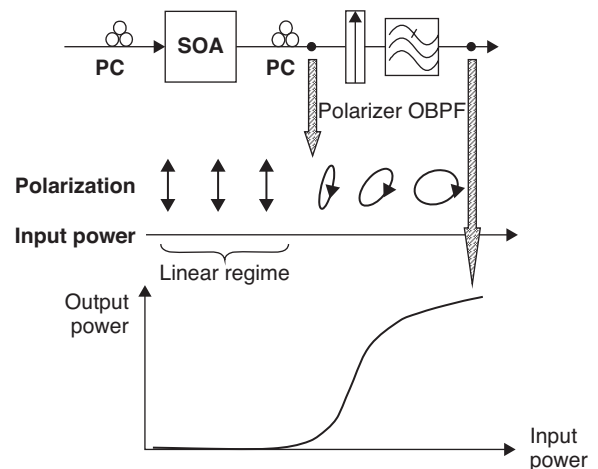

Figure 10: Structure of the 2R regenerator based on polarization rotation in a single SOA

Figure 11: Eye diagrams with and without 2R regenerator for different input signal ER

at the output of the SOA will not change with varying input power level in the linear regime. Hence, by setting the polarizer to block the output beam, a minimal output power (or a logical 0) is obtained below the saturation power of the SOA. Beyond the saturation power of the SOA, the state of polarization of the output from the SOA is changed because of the nonlinear birefringence effects. Both the orientation (i.e., azimuth) and the ellipticity of the polarization vary rapidly with the input power. The polarizer can no longer block the output from the SOA. Hence, a high power level (or a logical 1) is obtained at the output of the polarizer. At the same time, the SOA is saturated and its gain quickly drops with increasing input power, and thus the high power level of the output becomes saturated. As a result, an optical regeneration is realized.

Figure 11 shows the eye diagrams with and without the 2R regenerator for 10 Gbit/s [*non-return to zero* (NRZ), $2^{31}-1$ pseudorandom bit sequence (PRBS)] and 2.5 Gbit/s (NRZ, 2^9-1 PRBS), respectively. Clearly, the input signal is regenerated. The eyes become much more open after the 2R regenerator. Figure 12 contains the results from the bit error rate measurement for 2.5 Gbit/s. A receiver sensitivity improvement of more than 3 dB has been obtained at a BER of 10 for a degraded signal. For 10 Gbit/s, a power penalty of 0 dB was found at a BER of 10, and no receiver sensitivity improvement has been obtained. This is because of a polarization relaxation and the induced pattern effect at the falling edge of the signal, as seen in Figure 11, as the SOA used here is not specifically designed for the application proposed above. SOAs with high speed and weak polarization relaxation effects could be fabricated that are better adapted to the optical regeneration based on the nonlinear polarization rotation.

The advantages of this new scheme of all-optical 2R regeneration are its immunity against small signal distortion in the 0 level and a potentially large ER improvement. This results from the flat gain response for small signal

Figure 12: BER measurement results with and without 2R at 2.5 Gbit/s—input ER, 3 dB; input power, 3 dBm

powers and the sudden drop in gain as soon as the linear power range is exceeded. The features of simple configuration, stable operation, and high regenerative capabilities make this new scheme a promising technique for all-optical regeneration in future optical networks.

Optical Signal Regeneration Based on Gain Saturation of Quantum Dot SOA

SOAs can suppress noise and fluctuation when optical signals are on (on level) by utilizing a characteristic known as *gain saturation*, in which the optical gain (amplification rate) falls when a signal is too intense. However, conventional SOAs typically had slow gain saturation response speeds requiring several nanoseconds, thereby impacting the subsequent signal and making such SOAs unusable in all-optical regenerators. Technology developed recently for a new SOA significantly accelerates the response speed of gain saturation (Fujitsu Corporation 2005). It was achieved by observing and focusing on the

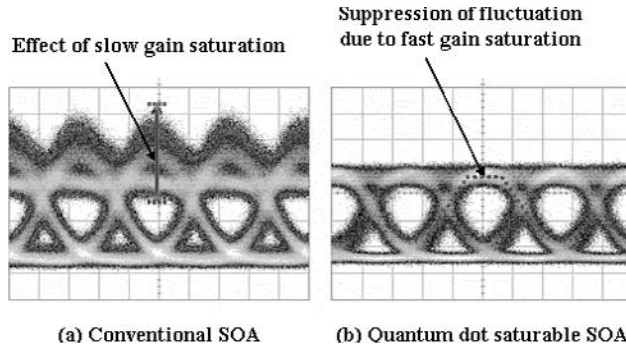

Figure 13: Comparison of output waveform between a conventional SOA and the newly developed quantum dot SOA (signal wavelength = 1550 nm, signal transfer speed = 40 Gbit/s)

extremely fast speeds of gain saturation when *quantum dots* were used. By employing quantum dots, gain saturation response time was accelerated to a few picoseconds, one-thousandth the time that was required with conventional SOAs. In addition, through improvements in crystal growth technology of quantum dots and by designing a new device structure, a quantum dot SOA was realized that easily enables gain saturation while achieving high optical gain and high optical output.

By using the new SOA, successful waveform reshaping and suppression of fluctuations of high-speed optical signals at 40Gbit/s were achieved (see Figure 13). Unlike conventional SOAs in which waveform degradation occurred because of slow response time, such waveform degradation is not observed with the quantum dot SOA. By intentionally adding noise to the input signal, significant suppressing of output signal noise was demonstrated. When the input signal was amplified by thirty times (15 decibels), the noise-to-signal ratio was reduced by 40 percent.

The quantum dot SOA will be further optimized. Development of a function to suppress fluctuations when signals are off (off-level fluctuations) and a retiming function are ongoing. The realization of an all-optical 3R regenerator using practical technology is expected in the next four or five years.

Optical Signal Regeneration Based on XPM-Induced Chirp Filtering

The basic scheme for optical signal regeneration based on the XPM-induced blue-shift chirp filtering is composed of an *ultralong SOA* (UL-SOA, length of the SOA $L_z = 10$ mm) and a common WDM short-band filter [free spectral range (FSR) of 25, 50, or 100 GHz, with a super-Gaussian-like or a sin-square-like frequency response], as illustrated in Figure 14 (Gallep and Conforti 2004).

As a modulated channel λ_2 propagates inside the extremely long SOA cavity, under high optical gain (just below initial lasing oscillations) it induces gain saturation and phase modulation because of charged carrier's modulation. Simultaneously, the amplification induces XGM and XPM in a co-propagating CW channel λ_1 (Figure 14). Because of the long cavity, the induced chirp correspondent to the XPM can be as high as 10 GHz to 20 GHz (positive),

Figure 14: Optical signal regeneration based on channel blue-shift chirp filtering (induced by XPM in UL-SOA amplification)

showing also residual Fabry-Perot oscillations and bit-pattern dependence. By passing the composite output optical signal (the amplified channels λ_1 and λ_2) with the amplified spontaneous emission noise through an abrupt optical filter, the converted signal is obtained when the λ_1 wavelength is rightly positioned at the filter's low-frequency edge, and the modulated channel (λ_2) is positioned out of the bypass window. With this scheme, the second channel and the ASE are totally rejected, and the first channel is also highly attenuated but in such time periods that it presents a huge positive optical chirp induced by the modulation code in λ_2 . So the SOA XPM induced chirp (frequency modulation) in the CW channel is transformed in amplitude modulation (FM-AM conversion). In this way, a λ_1' ($\lambda_1 + \sim \text{FSR}/2$) output channel is obtained with pulses varying from Gaussian-like format (input pulse's shape, low SOA gain) to super-Gaussian-like format (filter response's shape, high SOA gain). Because of the abrupt S-like profile in the edge of the filter band, the scheme enables optical 2R regeneration.

It has been shown both theoretically and experimentally that the gain recovery in a long SOA is much faster than in the short one because of the strong ASE in the longer SOA (Girardin, Guekos, and Houbavlis 1998). The UL-SOA has a high-speed potential in optical signal regeneration (Zhao et al. 2005; Bramann et al. 2005).

OPTICAL SIGNAL REGENERATION BASED ON NONLINEAR ABSORPTION DEVICES

Optical Signal Regeneration Using a Saturable Absorber

A saturable absorber has a highly nonlinear transfer function, as shown in Figure 15 (note that the y-axis does not refer to the output power there). When illuminated with an optical signal with instantaneous peak power below some threshold P_{sat} , the photon absorption of the SA is high and the device is opaque to the signal. Above P_{sat} , the SA transmission rapidly increases and saturates to an asymptotic value near unity (passive loss neglected). Obviously, such a nonlinear transfer function of the SA makes it possible to use it for 2R optical regeneration (when used together with an optical amplifier).

The SA-based 2R regenerator can reduce the ASE noise level in the 0 symbols, resulting in a higher signal ER and hence improving the system performance. However, because SAs do not provide effective control of amplitude fluctuations, they must be associated with a means of control for marks (1 symbols). This can be accomplished

Figure 15: Transfer function of a saturable absorber

by using a cascaded SOA or a narrowband optical filter with nonlinear (soliton) propagation. The SA-based device is simple and has the capability of operating at high bit rate. A 2R regenerator operating together with both an optical filter and nonlinear propagation has been demonstrated at 20 Gbit/s with a specially designed fast SA device (the multiquantum-well microcavity SA) (Leclerc et al. 2000, "Demonstration"). Quite recently, SA-based optical signal regenerators operating at 40 Gbit/s and beyond have been reported. The disadvantages of the SA-based devices are the high-input power requirements and high insertion loss. Further research on SA-based regenerators should address the reduction of saturation energy, the recovery time, the insertion loss, and an increase in the dynamic extinction ratio.

Optical Signal Regeneration Using an Electro-Absorption Modulator

Similar to saturable absorbers, electro-absorption modulators exhibit nonlinear optical transmission characteristics and thus are potential candidates for optical signal regeneration (Cho, Mahgerefteh, and Goldhar 1999). Nonlinear optical transmission in a reverse-biased EAM is achieved by using an intense input optical pulse to produce a large number of photo-generated charged carriers in the highly absorptive waveguide. Drift and diffusion of these photo-generated charged carriers distort and screen the electric field and substantially decreases the absorption coefficient. Reduction of the electric field by the intense pulse significantly decreases the absorption and creates a transmission window for the pulse. Optical

noise such as ASE noise from optical amplifiers, which is not as intense as the data, does not substantially affect the electric field and therefore is absorbed. The recovery time of the absorption after the intense pulse is significantly less than the bit period (50 ps) under high reverse biases. Obviously, the EAM can be used for noise reduction as well as enhancement of extinction ratio. The EAM-based optical signal regenerative devices are especially attractive for high data-rate operation. Optical 2R regeneration at the receiver of 10-Gbit/s RZ data transmitted over 30,000 km using the EAM has been demonstrated (Cho et al. 2000). Recently, optical 3R regeneration using a traveling-wave EAM was proposed and demonstrated (Chou et al. 2005). All of the required functionalities such as clock recovery, pulse generation, and nonlinear decision are implemented with the same device, leading to a highly compact configuration. With a degraded 10 Gbit/s RZ input, 1.0 dB of negative power penalty and 50 percent timing jitter reduction are obtained after regeneration.

OPTICAL 2R REGENERATION USING MULTISECTION LASERS

Recently, two approaches using multisection lasers—namely, the Q-switched, laser-based 2R regenerator and the *distributed feedback* (DFB) laser-based 2R regenerator—have been investigated. The Q-switched, laser-based device consists of three sections: a lasing DFB section, a passive phase tuning, and a second lasing section pumped at transparency and used as a reflector section as seen in Figure 16 (Brox et al. 2001; Möhrle et al. 2002). The combination of passive phase tuning and reflector sections allows the control of the back-reflected signal in amplitude and phase.

The DFB laser integrated with an SOA is shown in Figure 17. In this device, lasing is turned off because of the

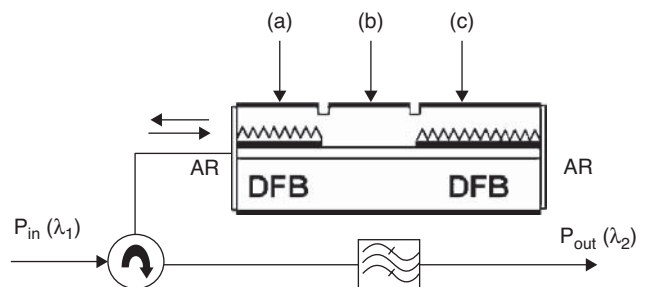

Figure 16: Q-switched, laser-based optical regenerator—(a) laser section, (b) phase tuning section, (c) reflector section

Figure 17: Optical regenerator using a DFB laser integrated with a SOA

gain saturation induced by the injection of a high-power signal (Owen et al. 2000). Both of the two structures deliver optical 2R regeneration through wavelength conversion. The output laser power exhibits a sharply nonlinear response, which results in an efficient optical regeneration.

OPTICAL SIGNAL REGENERATION BASED ON SYNCHRONOUS MODULATION

The use of synchronous modulation for signal reshaping and retiming was first proposed in 1991 (Nakazawa et al. 1991). In that approach, inline synchronous modulation is used to extend the soliton data-transmission distance. Recently, optical signal regeneration based on the inline synchronous modulation technique has been intensively investigated. As mentioned in previous section, SM-based optical signal regenerator includes a CR block, a modulator, and an optical filter (see Figure 18). Regeneration through SM intrinsically requires nonlinear (soliton) propagation in the trunk fiber following the SM block. Therefore, the approach can be referred to as *distributed* optical regeneration, whereas the regeneration described in previous sections can be termed *lumped* regeneration, where 3R is completed within the regenerator and is independent of line transmission characteristics.

In the SM-based optical regeneration, the control effects of modulation over optical pulses are the key points. Both intensity modulation and phase modulation reduce timing jitter regardless of its physical origin (Gordon-Haus, XPM, pulse-to-pulse interactions, or polarization-mode dispersion-induced jitter). However, jitter reduction through PM relies on a time-position-dependent frequency shift of the RZ pulses, resulting in velocity changes because of chromatic dispersion, whereas jitter suppression through IM uses self-forming properties of soliton pulses, which induces detrimental energy fluctuations. These can be efficiently controlled by narrowband filtering. The principle is as follows. In the absence of chirp, the soliton temporal width scales like the reciprocal of its spectral width (Fourier transform limit) times its intensity (fundamental soliton relation). Thus, an increase in pulse intensity corresponds to both time narrowing and spectral broadening. Conversely, a decrease in pulse intensity corresponds to time broadening and spectral narrowing. Thus, the filter causes higher loss when intensity increases, and lower loss when intensity decreases. The filter thus acts as an automatic power control in feed-forward mode, which causes power stabilization. A 1 million km soliton transmission at 10 Gbit/s by synchronous modulation has been experimentally demonstrated.

The optical signal regeneration based on SM associated with NF requires soliton-like pulses; without them, time and intensity noise cannot be controlled. As a result, regeneration and transmission cannot be designed independently from each other. To solve this problem, an improved approach, known as *black-box optical regeneration* (BBOR), was proposed (Dany et al. 1999). The BBOR technique includes an adaptation stage for incoming RZ pulses in the SM-based regenerator, which ensures high regeneration efficiency regardless of RZ signal format (linear RZ, DM-soliton, C-RZ, etc.). This is achieved using a local and periodic soliton conversion of RZ pulses by means of launching an adequate power into some length of fiber with anomalous dispersion. The BBOR approach has been experimentally demonstrated in a 4×40 -Gbit/s DM loop transmission (Leclerc et al. 2000, "Simultaneously"). The experimental results show that at 10,000 km the asymptotic factors of the four channels were measured to be greater than 14.5 dB (5×10^{-8} BER) for $2^{31} - 1$ coding length. The associated system penalty at 10,000 km is only 2 dB compared to a single-channel 40 Gbit/s measurement with SM-NF-based regeneration. Quite recently, 10-Gbit/s RZ transmission over a record distance of 1.25 million kilometers (10,000 loops) using in-line, all-optical 3R regeneration was reported (Zhu et al. 2006).

OPTICAL SIGNAL REGENERATION WITH NONLINEAR OPTICAL LOOP MIRROR

The NOLM is a fiber Sagnac interferometer that has a nonlinear transfer function (a nonlinear input-output power characteristic with slopes larger and smaller than 1). It consists of a fiber coupler and a fiber loop connected to the two output ports of the coupler (see Figure 19a). The phase shift in the interferometer is induced through Kerr effect in the optical fiber. An incoming laser pulse is split into two counterpropagating pulses with different peak powers. Because of the Kerr nonlinearity, these two pulses experience different nonlinear phase shifts that correspond to their peak power. After one round trip, the two pulses interfere at the coupler. This interference is power-dependent and leads to a nonlinear transfer characteristic (see Figure 19b). The flattened region has a slope significantly smaller than 1 and is suitable for signal regeneration in terms of noise reduction. Thus, the SNR is enhanced and bit errors can be reduced.

The NOLM-based optical signal regeneration has been intensively investigated in recent years. Different NOLM configurations have been proposed: for example, dispersion imbalanced NOLM, including dispersive fiber and *highly nonlinear fiber* (HNLF); and imbalanced NOLM,

Figure 18: Optical signal regeneration based on synchronous modulation

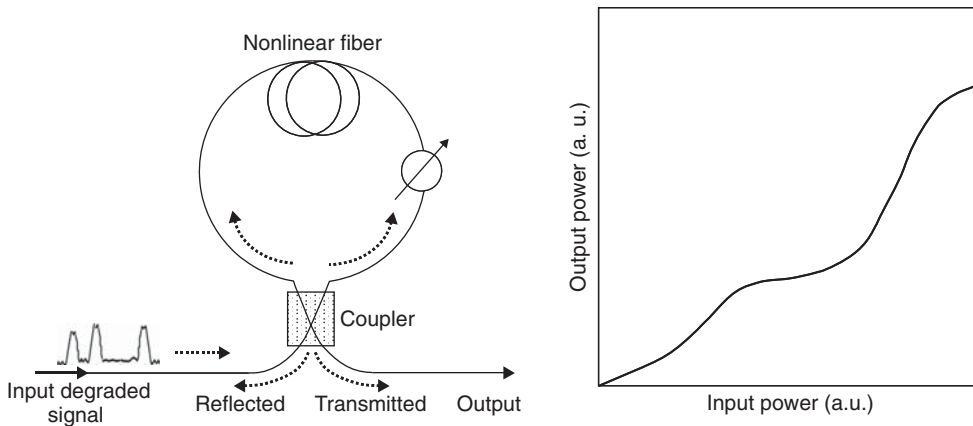

Figure 19: Nonlinear optical loop mirror used for optical signal regeneration

including a HNLF and an attenuator. The common NOLM approach is to use a rather symmetric splitting ratio of the coupler (e.g., 60:40) to compress the noise on the 0 bit while a highly asymmetric NOLM (e.g., 95:5) reduces the noise on the 1 bit. The lower noise suppression on the 0 bit is still good enough for pedestal suppression. The optimum splitting ratio for noise reduction with an asymmetric NOLM needs to be analyzed in the design of a NOLM-based optical signal regenerator. A large number of experimental demonstrations of optical signal regeneration using NOLM technique have been reported in the past years. For example, all-optical, all-passive signal regeneration by reducing the noise imposed on the signal by optical amplification by 12dB with an asymmetric NOLM was experimentally demonstrated (Meissner et al. 2003). An all-optical pulse regenerator suitable for 160-Gbit/s transmission systems, including three stages based on NOLM, was proposed recently (Bogoni et al. 2004). The regeneration was realized based on the idea of splitting the regeneration process in three different steps using easy and well-known ultrafast subsystems. In the first stage, the noise on the spaces is reduced. The second stage transfers the information carried by the input data signal to a clock signal, introducing a logic inversion that transforms the noisy marks into noisy spaces. Finally, the third stage suppresses the residual noise on the spaces. That approach offers advantages in terms of maximum bit rate of the signals that can be regenerated. Experimental results show the suitability of the proposed scheme for the regeneration with a bit rate of 160 Gbit/s. A factor increase from 3.2 to 6.3 was measured for the eye diagram.

The optical signal regeneration mentioned above shows excellent regenerative properties using on-off keying. In fact, the NOLM approach can be upgraded to regeneration of optical signal using phase-encoding modulation formats. A NOLM-based 2R-regenerator, which is capable of regenerating signals modulated in phase-sensitive modulation formats, was recently reported (Striegler et al. 2005). In the advanced system, the key element was a directional attenuator inserted into the NOLM. Numerical simulations show promising performance of the system and capability for the regeneration of RZ-DPSK-modulated signals. The results indicated that regeneration of signals modulated in other phase-sensitive modulation formats

such as duobinary coding, carrier-suppressed RZ, or RZ-DQPSK was also possible.

The key advantage of NOLM-based optical regeneration lies in the near-instantaneous (fs) response of the Kerr nonlinearity, making it highly attractive for ultrahigh bit-rate operation (160 Gbit/s). On the negative side, major limitations come from environmental instability, strong polarization dependence, and difficult integration, mainly because of the requirement of relatively long (kilometer scale) fiber lengths. Polarization-insensitive NOLMs have been realized, although with the same drawbacks concerning integration. The NOLM has promising potentialities for all-optical signal regeneration. With recent developments in HNLFs, however, the required NOLM fiber length could be significantly reduced, dramatically reducing environmental instability.

OTHER POTENTIAL IMPLEMENTATIONS OF OPTICAL SIGNAL REGENERATION

Optical Signal Regeneration Based on Self-Phase Modulation

The operating principle of SPM-based optical signal regeneration is illustrated in Figure 20 (Raybon 2003). An optical pulse launched into the HNLF produces a

Figure 20: Generic principle of optical signal regeneration based on self-phase modulation with bandpass filter

broadened optical spectrum because of the SPM in the fiber. Different intensity pulses give rise to different spectral broadening. An optical filter shifted in wavelength away from the input wavelength acts as an optical decision gate. Shifting the center wavelength of the filter sufficiently far from the input wavelength results in a suppression of noise in the 0's. Similarly, high-intensity pulses give rise to larger spectral broadening, and these components are shifted outside the decision window, resulting in a clamping of fluctuations in the 1's. The regenerated signal is converted to a new wavelength, and the output pulse width is determined by the spectral width of the optical filter. The 2R regenerator provides signal reshaping on one wavelength at a time. Because of the single wavelength nature of the regenerator, its usefulness has been demonstrated both in the transmitter and receivers before and after wavelength multiplexing. The main advantages of the system is the high speed, because of the all-optical nature, the ability to counteract signal distortion regardless of the origin, and the relative simplicity of the experimental configuration. Experiments operating at 160 Gbit/s have utilized this type of regenerator successfully (Mikkelsen et al. 2001). Also, previous experiments at 40 Gbit/s have shown improvements in receiver performance using the regenerator after wavelength have been demultiplexed.

Optical Signal Regeneration Based on Pump-Modulated Four-Wave Mixing

Pump-modulated FWM is a promising technique for optical signal regeneration because of its high-speed performance and the capability to maintain the same logical polarity. Recently, the possibility of 2R regeneration based on pump-modulated FWM using *dispersion-shifted fiber* (DSF) has been demonstrated both theoretically and experimentally (Bogris and Syvridis 2003). The regenerative characteristics of pump-modulated FWM in DSF result from the fact that the OOK modulation for the information encoding is applied on the pump wave and the optical power of the FWM product (the regenerated signal) depends on the square of the pump input optical power, as showing in the following equation (Argyris et al. 2003):

$$P_c(L) = \eta \gamma^2 P_p^2 P_s \cdot \exp(-\alpha L) \cdot \left(\frac{[1 - \exp(-\alpha L)]^2}{\alpha^2} \right)$$

where P_c , P_p , and P_s are the optical powers of the product, pump, and signal wave, respectively; L is the fiber length; η is the FWM conversion efficiency; γ is the nonlinear fiber coefficient; and α is the fiber attenuation coefficient. Obviously, the dependence of the product wave optical power on the square of the pump wave optical power is translated in a logarithmic scale in a multiplication factor of 2. Thus, in a pump-modulated scheme, the ER of the product wave in dB is twice as much as the pump wave ER.

The regenerative properties of the FWM in the DSF can be also confirmed by the transfer function of the system, giving the dependence of the product wave power

on the pump wave power. It has been also shown that the conversion efficiency and the consequent mixing product optical power versus input optical power, under certain operating conditions, saturate when the input optical power is higher or lower than certain value ranges (Bogris and Syvridis 2003). This behavior can be depicted in the corresponding transfer function of the so-called S-shaped function. Two variations of a fiber FWM-based regenerator have been proposed: a single- and a double-stage scheme. In the single-stage approach, the operating conditions of the mixing process are properly adjusted to achieve a compromise between extinction ratio improvement and noise suppression. On the contrary, in the double-stage regenerator, the first stage is adjusted for maximum extinction ratio improvement while the second is used mainly for noise suppression. This dual-stage regenerator transfer function exhibits much broader horizontal regimes for noise suppression and a much steeper intermediate part for extinction ratio enhancement. Note that a bandpass filter is required to extract the regenerated signal and suppress the unwanted output waves at the output of the DSF in the pump-modulated FWM scheme of optical signal regeneration.

The optical signal regeneration scheme utilizing the pump-modulated FWM in DSF generally need a long segment of fiber, and the pump wavelength should be placed near the zero dispersion point of the DSF to maintain the phase-matching condition of FWM. The adoption of high nonlinear DSF can effectively shorten the required fiber length to approximately 1 km, but the dispersion of the fiber still limits the flexibility of operating wavelength. Recently, widely wavelength-tunable FWM using a dispersion-flattened nonlinear photonic crystal fiber has been demonstrated (Chow et al. 2005). With the use of pump-modulated FWM, an improvement of 6 dB in extinction ratio has been shown for a degraded 10-Gbit/s signal, and a power penalty improvement of 3 dB was measured at the 10^{-9} BER level.

Optical Signal Regeneration of Differential Phase Shift Keying Transmission

Most of the regenerators studied so far have been designed to regenerate OOK signals without particular attention to preservation of the signal phase. All-optical regeneration of DPSK transmission by low-complexity and cost-efficient devices that can handle binary phase information would be an attractive technique to improve the performance of DPSK systems. A phase-preserving, all-optical 2R regeneration scheme for phase-encoded signals that exploits a new design of NOLM based on distributed *Raman amplification* in a loop (RA-NOLM) has been proposed (Boscolo, Bhambher, and Turitsyn 2006). It was demonstrated numerically that the combination of the RA-NOLM with narrow spectral filtering provides an additional phase-limiting function in DPSK signal transmission by suppressing the accumulated ASE-induced phase noise. Phase-preserving DPSK signal regeneration using a novel design of a NOLM based on Raman amplification in a loop has been presented at the 40-Gbit/s data transmission rate.

CONCLUSION

The current status of some of the most often investigated technologies and solutions for optical signal regeneration have been reviewed. A variety of solutions were described, including SOA-based nonlinear interferometers and gates, multisection lasers, saturable absorbers, electro-absorption modulators, synchronous modulators, nonlinear optical loop mirrors, HNLF-based self-phase modulation, and fiber-based, pump-modulated, four-wave mixing. Among the solutions, those based on SOAs offer the highest integration potential and have been the focus of much research on optical signal regeneration. They also open possibilities for more complex optical signal processing.

GLOSSARY

Bit error rate (BER): The fraction of bits transmitted that are received incorrectly.

Cross-gain modulation (XGM): A nonlinear optical effect in which the intensity modulation of one wavelength modulates the gain of an active optical device such as a semiconductor optical amplifier (SOA), where another wavelength is propagating and is amplified with modulated gain.

Cross-phase modulation (XPM): A nonlinear optical effect in which the intensity modulation of one wavelength modulates the index of refraction in a material where another wavelength is propagating and therefore modulates its phase.

Electro-absorption modulator (EAM): A chip-level modulation device that modulates light from a laser that is separate from it but may be fabricated on the same wafer. Turning the current on causes absorption of the light.

Extinction ratio (ER): The ratio of the low or off optical power level to the high or on optical power level.

Eye diagram: Shows the proper function of a digital system; the "openness" of the eye relates to the BER that can be achieved.

Four-wave mixing (FWM): A nonlinearity common in optical devices and systems where multiple wavelengths mix together to form new wavelengths called *interfering products*. Interfering products that fall on the original signal wavelength become mixed with and muddy the signal, causing attenuation. Interfering products on either side of the original wavelength can be used for optical functionality such as optical wavelength conversion or optical signal regeneration.

Jitter: Small and rapid variations in the timing of a signal or waveform resulting from noise, changes in component characteristics, voltages, circuit synchronization, and so on.

Mach-Zehnder interferometer (MZI): An interferometer that splits an optical signal into two components and directs them down two separate paths before recombining them. By inducing a phase delay between the two optical signals, the resulting interference can cause intensity changes. Such a device can modulate the optical power from 100 percent (constructive interference) to 0 percent (destructive interference).

Noise figure: The ratio of the output signal-to-noise ratio to the input signal-to-noise ratio for a given element in a transmission system. Used for optical and electrical components.

Non-return to zero (NRZ): A common means of encoding data that have two states termed *zero* and *one* and no neutral or rest position.

Optical signal regeneration: A technology whereby a degraded signal is restored to its original quality. A technology that consists of *reamplification*, *retiming*, and *reshaping* is called *optical 3R regeneration*. When retiming is absent, the optical regeneration is referred to as *2R regeneration* with only reamplifying and reshaping capabilities. *Reshaping* refers to the suppression of noise and fluctuation of optical signals to reshape signal waveforms. *Retiming* reduces timing fluctuations known as timing jitter, and *reamplification* amplifies optical signals. When these processes do not involve conversion to electronic signals, they are referred to as *all-optical 3R regeneration*.

Phase noise: Rapid, short-term, and random fluctuations in the phase of a wave. It is also referred to as *bit-to-bit phase fluctuation* caused by time domain instabilities in an oscillator, *amplified spontaneous emission* (ASE) from optical amplifiers, and intra- and interchannel nonlinearities resulting from the Kerr effect in the fiber.

Polarization: The direction of the electric field in the light wave. If the electric field is in the y-axis, the light is said to be vertically polarized. If the electric field of the light wave is in the x-axis, the light is said to be horizontally polarized.

Receiver sensitivity: The minimum acceptable value of received power needed to achieve an acceptable BER or performance. It takes into account power penalties caused by the use of a transmitter with worst-case values of extinction ratio, jitter, pulse rise times and fall times, optical return loss, receiver connector degradations, and measurement tolerances. The receiver sensitivity does not include power penalties associated with dispersion or back reflections from the optical path; these effects are specified separately in the allocation of maximum optical path penalty.

Return to zero (RZ): A common means of encoding data that has two information states called *zero* and *one* in which the signal returns to a rest state during a portion of the bit period.

Semiconductor optical amplifier (SOA): A semiconductor device that amplifies an optical signal through the stimulated emission of stored carriers in a semiconductor. The carriers are usually supplied by electrical current.

Signal-to-noise ratio (SNR): A measure of signal quality as the ratio of total signal to total noise. This effectively shows how much higher the signal level is than the noise level.

INTRODUCTION

The fundamentals of light as a propagating electromagnetic wave are presented in the initial part of this chapter. Semiconductor materials and their band-gap energy are introduced, leading to a discussion on the choice of materials for different emission wavelengths. The properties and the principles of laser emission are reviewed along with basic operation of laser diodes. Understanding the structure of *light-emitting diodes* (LEDs) and *laser diodes* (LDs) is important in selecting optical sources for specific applications in optical networks and communications, especially when considering the cost and effectiveness of the source. The resolution in data writing and reading for optical disks depends on the wavelength and the numerical aperture of the source. The optical resolution is discussed and the use of short wavelength laser diodes aimed to increase the data storage capacity of optical disks is introduced. Finally, the discussion on criterion of bit-rate distance products in choosing a proper source for a fiber link is presented.

OPTICAL SIGNALS

Optical signals are modulated electromagnetic waves known as *light*. The frequency range of light used in optical communications and networks is approximately from 200 THz (1.5 μm wavelength) to 1000 THz (300 nm wavelength).

The speed of light v is related to the *magnetic permeability* μ and the *electric permittivity* ϵ of the medium in which it is propagating as

$$v = \frac{1}{\sqrt{\mu\epsilon}} \quad (1)$$

In a vacuum, the speed of light is $c = \frac{1}{\sqrt{\mu_0\epsilon_0}} \approx 3 \times 10^8 \text{ ms}^{-1}$, where $\mu_0 = 4\pi \times 10^{-7} \text{ H/m}$ and $\epsilon_0 = 8.85 \times 10^{-12} \text{ F/m}$ are the permeability and the permittivity of a vacuum, respectively.

The *refractive index* n of a medium is defined as the ratio of the speed of light in vacuum c to the speed v in the medium.

$$n = \frac{c}{v} \quad (2)$$

In optical materials, $\mu \approx \mu_0$ and hence $n = \sqrt{\epsilon_r}$, where $\epsilon_r = \epsilon/\epsilon_0$ is the relative permittivity of the optical material.

Light is a *transverse electromagnetic wave*, and it is characterized by electric and magnetic fields that are orthogonal to each other as well as perpendicular to the direction of propagation. For a signal propagating in the z -direction, the electric field $\vec{E}(z,t)$ can be expressed as the vector sum of x - and y -components of the *electric field* (E-field) propagating in the z -direction:

$$\vec{E}(z,t) = \vec{E}_x(z,t) + \vec{E}_y(z,t) \quad (3)$$

The x - and y - components of $\vec{E}(z,t)$ propagating in the z -direction can be presented as

$$\vec{E}_x(z,t) = \hat{x}E_{0x} \cos(\omega t - kz + \theta_x) \quad (4)$$

Figure 1: Electric field linearly polarized in the x-direction and propagating in the z-direction

$$\vec{E}_y(z, t) = \hat{y}E_{0y} \cos(\omega t - kz + \theta_y) \quad (5)$$

where $\omega = 2\pi f$ is the angular frequency of the electric field; $k = \frac{2\pi}{\lambda}$ is the propagation constant; f and λ are, respectively, the frequency and wavelength of the propagating electric field; θ_x and θ_y are initial phase angles; whereas E_{0x} and E_{0y} are the amplitudes of x- and y-components of $\vec{E}(z, t)$, respectively. Hence,

$$\vec{E}(z, t) = \hat{x}E_{0x} \cos(\omega t - kz + \theta_x) + \hat{y}E_{0y} \cos(\omega t - kz + \theta_y) \quad (6)$$

Polarization is defined as the orientation of the electric field $\vec{E}(z, t)$ in three-dimensional space. *Linearly polarized* light has the E-field in one direction only. The E-field in Equation (4) is linearly polarized in the x-direction while propagating in the z-direction as shown in Figure 1. Likewise, the wave expressed in Equation (5) is linearly polarized in the y-direction while propagating in the z-direction.

The E-field in Equation (6) is *randomly polarized* because the resultant direction of $\vec{E}(z, t)$ depends on the phase difference $\theta = \theta_x - \theta_y$ as well as on the amplitudes E_{0x} and E_{0y} of x- and y-components of $\vec{E}(z, t)$. It can be shown that $\vec{E}(z, t)$ is *elliptically polarized* if $E_{0x} \neq E_{0y}$ and $\theta = \theta_x - \theta_y \neq 0, \pi$. If $E_x = E_y$ and $\theta = \theta_x - \theta_y = \frac{\pi}{2}$, then the light wave is *circularly polarized*. The polarization as a function of the phase difference $\theta = \theta_x - \theta_y$ with $E_{0x} < E_{0y}$ is summarized in Figure 2. The arrowheads show the directions of rotation of the E-field as the optical wave propagates (out of the page in Figure 2). The E-field makes one complete rotation as the wave propagates one wavelength forward. The optical wave is linearly polarized at $\theta = 0, \pi, 2\pi$. It is elliptically polarized at $\theta = \pi/4, \pi/2$, and $3\pi/4$, and the E-field makes one complete rotation anticlockwise (looking back into the source) as the wave advances one wavelength. The wave is elliptically polarized at $\theta = 5\pi/4, 3\pi/2$, and $7\pi/4$ with clockwise rotation.

If $E_{0x} = E_{0y}$ and at $\theta = \pi/2$, then the resultant E-field rotates anticlockwise in a circular path (looking back into the source) and is said to be *left-circularly polarized*. At

Figure 2: Polarization as a function of phase difference $\theta = \theta_x - \theta_y$ with $E_{0x} < E_{0y}$ (Hecht 2002).

$\theta = 3\pi/2$, the resultant E-field rotates clockwise and is referred to as *right-circularly polarized*.

The *polarization mode dispersion* (PMD) in fibers denotes the effect of widening of optical signal pulses when the optical signal propagates along the fiber because of different propagation speeds in each polarization direction. It is difficult to mitigate the PMD effect in optical fiber communication systems as the PMD is not a constant, but is a randomly varying parameter and depends on temperature variation and stress on the fiber.

SEMICONDUCTOR MATERIALS

Semiconductors are materials where all of the energy states in the valence band are filled with electrons while the conduction band is empty at 0 Kelvin. At room temperatures, some of the electrons in the valence band get thermal energy and thus can jump across the energy band gap into the conduction band. The unfilled energy states left behind in the valence band are called *holes*.

Direct and Indirect Band Gaps

The plots of energy band against the momentum vector k are shown in Figure 3 for direct band-gap and indirect band-gap semiconductor materials (Verdeyen 1995).

When an electron in the conduction band recombines with a hole in the valence band, a *photon* of energy $h\nu \geq E_g$ is emitted, where h is the Planck's constant, and E_g is the energy band-gap (atomic energy levels and light emission will be discussed below in the "Fundamentals of Laser" section). The probability of this transition is high in *direct band-gap semiconductor materials* (Verdeyen 1995), where the momentum of the electron is equal to the momentum of the hole and the total energy is conserved. The conduction band minimum energy E_c and the valence band maximum energy E_v occur at the same momentum values.

In an *indirect band-gap* semiconductor material, the conduction and the valence band levels E_c and E_v occur at different k values, and the probability of emission of photons by recombination is especially low because it needs a third particle with appropriate energy for the conservation of momentum.

Therefore, only direct band-gap materials are used for the high emission of photons. The direct band-gap materials are the *group III-V* materials, some of which are gallium arsenide (GaAs), indium phosphide (InP), indium arsenide (InAs), and gallium nitride (GaN).

The probability of occupation of electrons at energy level E_2 (E_1) in the conduction (valence) band is given by the *Fermi-Dirac distribution* (Agrawal 2002):

$$f_c(E_2) = \frac{1}{1 + \exp[(E_2 - E_{fc}) / kT]} \quad (7)$$

$$f_v(E_1) = \frac{1}{1 + \exp[(E_1 - E_{fv}) / kT]} \quad (8)$$

where E_{fc} and E_{fv} are the Fermi energy levels in the conduction band and the valence band, respectively, k_B is the Boltzmann constant (1.380×10^{-23} J/K) and T is the

Figure 3: Energy band against the momentum vector k for (a) direct and (b) indirect band-gap semiconductor materials

absolute temperature in Kelvin. The energy level where the probability of being occupied by charge carriers at any temperature is $\frac{1}{2}$ is referred to as the *Fermi energy level*.

To get a population inversion (see “Population Inversion and Pumping” below)—that is, when the number of electrons in the conduction band exceeds the number of electrons in the valence band—the electron occupation probability $f_c(E_2)$ at energy level E_2 in the conduction band must be larger than the electron occupation probability $f_v(E_1)$ at energy level E_1 in the valence band—that is, $f_c(E_2) > f_v(E_1)$.

This can be satisfied from Equation (7) and Equation (8) when

$$E_{fc} - E_{fv} > E_2 - E_1 > E_g \quad (9)$$

where $E_g = E_c - E_v$, while E_c is the minimum conduction band energy level and E_v is the maximum valence band energy.

In semiconductor lasers (lasers will be discussed in detail in “Fundamentals of Lasers” section below), the population inversion is achieved by injecting charge carriers by means of forward biasing the P-N junction.

Material, Band-Gap, and Wavelength

High-performance *hetero-junction* semiconductor crystals are made of epitaxial layers grown on a substrate. This requires the same crystal structure and the same lattice constant with band-gap energy as large as possible. The same lattice constant is required for different materials in epitaxial crystal growth to reduce the formation of defects and stress in the crystal.

Figure 4 presents the binary compounds with energy band gap plotted against the lattice constant. It shows that aluminum arsenide (AlAs) and GaAs have the same lattice constant and that replacing Ga with Al does not change the lattice constant. GaAs-based optical sources operate in the wavelength range of $0.81 \mu\text{m}$ to $0.87 \mu\text{m}$.

A ternary compound $\text{Al}_x\text{Ga}_{1-x}\text{As}$ can be grown on GaAs substrate because replacing Ga with Al does not change the lattice constant. Index x is called the *mole fraction*, and $0 < x < 0.45$. The band-gap energy can be approximated from the empirical formula (Agrawal 2002):

$$E_g(\text{eV}) = 1.424 + 1.247x \quad (10)$$

Figure 4: Band-gap energy versus lattice constant of binary compounds at room temperature (Singh 2003)

Table 1: Semiconductor Materials and Emission Wavelengths

Materials			
Active Layer	Confining Layer	Substrate	Emission Wavelength (μm)
InGa _N	AlGa _N	Al ₂ O ₃	0.2–0.6
AlGaAs	AlGaAs	GaAs	0.5–0.9
InGaAsP	InGaP	GaAs	0.5–0.9
InGaAsP	AlGaInP	GaAs	0.3–0.5
InGaAsP	AlGaAs	GaAs	0.4–0.8
InGaAsP	InP	InP	0.7–1.6

Source: Nakamura, Pearton, and Fasol (2000)

The quaternary compound InGaAsP can be grown on InP substrate. The In_{1-x}Ga_xAs_yP_{1-y} lattice matched to InP if the gallium and arsenic mole fractions x and y are chosen (Buus, Amann, and Blumenthal 2005) such that

$$x = \frac{0.452y}{1 - 0.031y} \quad (11)$$

The band-gap energy of In_{1-x}Ga_xAs_yP_{1-y} can be calculated (Nahory et al. 1978) from the approximate empirical equation

$$E_g(\text{eV}) = 1.35 + 0.668x - 1.17y + 0.758x^2 + 0.18y^2 - 0.069xy - 0.332x^2y + 0.03xy^2 \quad (12)$$

The emission wavelength range of In_{1-x}Ga_xAs_yP_{1-y} hetero-structure diodes is 920 nm to 1670 nm. Optical wavelength of a semiconductor LED or a laser diode can be calculated from the band-gap energy:

$$h\nu = E_g \quad (13)$$

Because $c = \nu\lambda$, $\lambda_g = \frac{hc}{E_g}$, and substituting the value of $c = 3 \times 10^8$ m/s and E_g in the eV unit, λ_g , in nanometer can be calculated as

$$\lambda_g(\text{nm}) \approx \frac{1240}{E_g(\text{eV})} \quad (14)$$

Semiconductor materials used for fabricating LEDs and laser diodes and their emission wavelength ranges are summarized in Table 1.

For more information on semiconductor materials and structures, readers can refer to Kapon (1999).

LIGHT-EMITTING DIODES

In a forward-biased P-N junction of a group III-V material such as GaAs, the recombination of electrons (in the conduction band) and holes (in the valence band) releases energy in the optical range as a stream of photons. A single-photon LED was first invented in 2002 using a InAs quantum dot layer between the P and N GaAs layers (Yuan et al. 2002; Smalley 2002). Single-photon sources have potential applications in quantum communication and quantum computation (Smalley 2002).

In *homo-junction* LEDs, the recombination takes place in the depletion region and the emitted light is incoherent—that is, photons are emitted in random phases and in all directions. The spectral width is relatively wide (30–60 nm) (Fukuda 1999). For these reasons, homo-junction LEDs are often used for data display purposes, whereas hetero-junction LEDs are more favorable for use in optical and data communications.

Light-emitting diodes are used for transmission with low bit rates (less than 200Mb/s) and for short distances of a few kilometers (Agrawal 2002). LEDs are cheaper than laser diodes and do not need temperature stabilization and optical frequency stabilization circuitry. The driving circuit for direct modulation is simple. However, LEDs have lower cutoff frequencies in the range of less than 100 MHz (Iizuka 2002).

LEDs are made of doped semiconductor materials based on group III-V semiconductors such as GaAs and InP. According to the structure, there are two types of LEDs: *edge-emitting* and *surface-emitting* (see Figures 5 and 6).

Fundamentally, the structures of edge- and surface-emitting LEDs are the same. However, in the surface-emitting type (known also as the *Burrus type*) LEDs, the light output is taken by etching a well through the substrate as shown in Figure 6. The light output is taken in the direction perpendicular to the junction planes.

Figure 5: Edge-emitting LED with stripe contact. Typical dimensions: length is 200–400 μm, width is 100–200 μm, height is approximately 50 μm. The active layer thickness is 0.1–0.2 μm, and the light-confining width is less than 10 μm

Figure 6: Schematic of double hetero-structure, high-radiance, surface-emitting LED. Optical fiber is bonded with resin to couple the light. Layer (a) N-type $\text{Al}_x\text{Ga}_{1-x}\text{As}$ = cladding layer; (b) P-type $\text{Al}_y\text{Ga}_{1-y}\text{As}$ = active layer; (c) P-type $\text{Al}_x\text{Ga}_{1-x}\text{As}$ = cladding layer; (d) P-type GaAs = capping layer for contact (Burrus and Miller 1971)

Both of the above types use a *double hetero-junction* (DH) to confine the injected carriers when the junctions are forward-biased. A double hetero-junction is made by growing an active region of narrow band-gap material in between the two wide band-gap materials.

LED Spectral Width

The *spectral linewidth* $\Delta\lambda$ of an optical source is defined as the *full width at half-maximum* (FWHM) intensity of the emission spectrum as shown in Figure 7. The linewidth is usually measured experimentally.

The typical spectral widths of LEDs are summarized in Table 2. The edge-emitting type of LED has a narrower spectral linewidth than that of the surface-emitting type. This is because shorter wavelength emissions are reabsorbed as the light travels relatively longer distances along the length of the active layer (Fukuda 1999).

Figure 7: Emission spectrum and FWHM spectral linewidth $\Delta\lambda$

Table 2: Spectral Linewidth of Typical LEDs

LED Material			
Active Layer	Substrate	Emission Wavelength Band (nm)	Spectral Linewidth (FWHM) (nm)
InGaN		465–520 (blue-green)	70
GaP		555 (yellowish green)	60
GaP:N		565 (yellow green)	60
InGaAlP		570–625 (greenish yellow–red)	30
GaAlAs		655 (red)	30
AlGaAs	GaAs	850	40
InGaAsP	InP	1300	110 (surface emitting)
InGaAsP	InP	1300	80 (edge emitting)
InGaASP	InP	1550	130

Source: Blue to red visible wavelength data are from Nakamura, Pearton, and Fasol (2000); infrared wavelength data are from Fukuda (1999).

The spectral linewidth of a LED diode also depends on temperature and can be approximated from the spontaneous emission rate (Agarwal 2002) as

$$\Delta\nu = \frac{1.8k_B T}{h} \quad (15)$$

where $k_B = 1.38 \times 10^{-23}$ J/K is the Boltzmann constant, $h = 6.63 \times 10^{-34}$ J-s is the Planck constant, and T is the temperature in Kelvin. The spectral linewidth is often expressed in wavelength width $\Delta\lambda$ in nanometers and can be converted as

$$\Delta\lambda = \frac{\lambda^2}{c} \Delta\nu \quad \text{and hence } \Delta\lambda = \frac{1.8k_B T \lambda^2}{hc} \quad (16)$$

For example, the spectral linewidth of a LED at room temperature ($T = 300$ K) and for an emission wavelength of 1300 nm can be estimated as

$$\Delta\lambda = \frac{1.8 \times 1.38 \times 10^{-23} \times 300 \times (1300 \times 10^{-9})^2}{6.63 \times 10^{-34} \times 3 \times 10^8} = 63 \text{ nm}$$

Modulation Response of LEDs

The output intensity of an LED can be modulated by a signal. It can be done by superimposing the signal current on the bias injection current. This type of modulation is known as *direct modulation*. The modulation response of a typical LED is shown in Figure 8. The output signal decreases as the modulation signal frequency increases because of the junction capacitance and the injected carrier lifetime τ_c .

The ratio of optical output power $P_o(\omega)$ at a modulation frequency ω to the power $P_o(0)$ at DC or without modulation can be written as (Fukuda 1999)

$$\frac{P_o(\omega)}{P_o(0)} = \frac{1}{\sqrt{1 + \omega^2 \tau_c^2}} \quad (17)$$

The optical modulation bandwidth or -3dB frequency $f_{3dB}(\text{optical})$ of an LED is the frequency at which the

Figure 8: Modulation response of a LED

output intensity decreases to one-half of the intensity at the DC bias point and depends on the carrier lifetime as

$$f_{3dB}(\text{optical}) = \frac{\sqrt{3}}{2\pi\tau_c} \quad (18)$$

Assuming that the diode threshold current is negligible, the optical output power is directly proportional to the injection current. Then the ratio of the optical output powers

$\frac{P_o(\omega)}{P_o(0)}$ in Equation (17) is equal to the ratio of injection current $[I(\omega)]$ with signal modulation to the bias current $[I(0)]$ without signal modulation (i.e., $\frac{P_o(\omega)}{P_o(0)} = \frac{I(\omega)}{I(0)}$).

Electrical input power P_e is proportional to the square of the injection current ($P_e \propto I^2$) and the electrical -3dB frequency where the input power ratio $P_e(\omega)/P_e(0) = 1/2$ occurs at $\frac{I(\omega)}{I(0)} = \frac{1}{\sqrt{2}}$ or at output optical power ratio

$\frac{P_o(\omega)}{P_o(0)} = \frac{1}{\sqrt{2}}$. Therefore, from Equation (17), electrical

-3dB frequency can be written as

$$f_{3dB}(\text{electrical}) = \frac{1}{2\pi\tau_c} \quad (19)$$

Therefore, at $f_{3dB}(\text{electrical})$, the output optical power is 70.7 percent of optical output power without modulation. For example, the typical value of a LED carrier lifetime is approximately 5 ns (Fukuda 1999), the value of $f_{3dB}(\text{optical})$ is approximately 55 MHz, and $f_{3dB}(\text{electrical})$ is approximately 32 MHz.

Conversion Efficiency of LEDs

The *internal efficiency* η_{int} is defined as the ratio of the number of generated photons to the number of electrons injected by the bias current I :

$$\eta_{int} = \frac{P_{int} / h\nu}{I / q} \quad (20)$$

where P_{int} is the optical power generated internally and $q = 1.6 \times 10^{-19}$ C is the electron charge.

The ratio of emitted optical output power P_{out} to the internally generated optical power P_{int} is known as the *external efficiency*:

$$\eta_{ext} = \frac{P_{out}}{P_{int}} \quad (21)$$

The *total power conversion efficiency* η_{tot} of a LED is defined as the ratio of the optical output power P_{out} to the electrical input power P_{in} :

$$\eta_{tot} = \frac{P_{out}}{P_{in}} = \frac{\eta_{ext}\eta_{int}}{V_0 I} = \frac{\eta_{ext}\eta_{int}(h\nu)(I/q)}{V_0 I} = \frac{\eta_{ext}\eta_{int}h\nu}{V_0 q} \quad (22)$$

where V_0 is the voltage drop across the diode.

If $qV_0 \approx h\nu$, then $\eta_{tot} \approx \eta_{ext}\eta_{int}$, where η_{tot} indicates the overall electrical-to-optical power conversion efficiency, which is also known as *wall-plug efficiency*.

FUNDAMENTALS OF LASERS

In optical networks and optical communications, laser diodes are used for their small size, relatively low price, and narrow spectral linewidth. The word *laser* is an acronym of *light amplification by stimulated emission of radiation*.

Laser Properties

Important laser properties that are different from those of ordinary optical sources such as incandescent lamp, fluorescent lamp, among others, are *monochromaticity*, *coherence*, *brightness*, *directivity*, and *beam divergence*, as described below.

Monochromaticity

Ideally, the laser light is characterized by a single wavelength and is referred to as *monochromatic* light. However, in reality the laser light contains a narrow spread $\Delta\nu$ of frequencies or wavelengths $\Delta\lambda$ called *spectral linewidth*. The spectral linewidth of the laser light depends on the type of laser diode (an element that converts an electrical current into light). A linewidth of a typical Fabry-Perot laser diode lasing at 1550 nm is approximately 1–5 nm (Fabry-Perot lasers will be discussed in detail in the section “Fabry-Perot Laser Resonator” below).

Coherence

In a laser light beam, the photons have the same phase or a constant phase relationship; that relationship of photons in a light beam is known as *coherence*. Because there is a frequency spread of $\Delta\nu$ in a laser light, photons with a small difference in frequencies with each other will get out of phase after a certain time called *coherence time*, which is a measure of temporal coherence. During this coherence time, photons in the laser light will travel coherently in space. The spatial coherence is determined by the distance traveled by the photons in the coherence time and is called *coherence length*. If the spectral linewidth is $\Delta\nu$, then coherence time τ_{coh} is conventionally defined (Milonni and Eberly 1988) as

$$\tau_{coh} = \frac{1}{2\pi\Delta\nu} \quad (23)$$

Coherent length l_c is defined as the distance traveled by laser light in the coherence time τ_{coh} :

$$l_c = v\tau_{coh} = \frac{c}{2\pi n \Delta\nu} \quad (24)$$

Laser beam spreads out as it is propagating

Figure 9: Gaussian intensity profile with peak intensity at the center of the beam. Beam divergence is defined as the full angle at I_0/e^2 points of the beam profile

where n is the refractive index of the medium. Because $\left|\frac{\Delta\nu}{\Delta\lambda}\right| = \left|\frac{c}{\lambda^2}\right|$, the coherent length l_c can be expressed as

$$l_c = \frac{\lambda^2}{2\pi n \Delta\lambda} \quad (25)$$

As an example, consider an 850-nm edge-emitting laser diode with a spectral width of 1 nm, a coherence length in space of 0.11 mm; in optical silica fiber ($n = 1.45$), it is 0.079 mm. For a 850-nm *distributed feedback* (DFB) laser diode with a spectral linewidth of 0.0001 nm, it has a coherent length of 790 mm in silica optical fiber.

Directivity and Beam Divergence

Multiple reflections of laser light inside a laser cavity results in the highly directional output beam of a laser. Directivity or beam divergence of a laser beam from an atomic (gas) laser source is described by full angle beam divergence 2θ at I_0/e^2 , where I_0 is the maximum intensity of the Gaussian intensity distribution as shown in Figure 9.

For a Gaussian beam, the half-divergence angle θ can be derived as (Milonni and Eberly 1988):

$$\theta = \frac{\lambda}{\pi \omega_0} \quad (26)$$

where λ is the *emission wavelength* and ω_0 is the *beam waist* (the smallest beam radius of I_0/e^2 point) at the center of the resonator.

Edge-emitting semiconductor hetero-junction lasers have elliptically shaped spots, and the beam divergence is usually defined by two angles measured in two perpendicular directions: θ_{\perp} perpendicular to the junction plane and θ_{\parallel} parallel to the junction plane as shown in Figure 10. Values of θ_{\perp} and θ_{\parallel} are measured as full angles at

Figure 10: Edge-emitting laser diode illustrating a beam spot at one-half the maximum intensity. The maximum intensity is at the center of the elliptical spot

half-maximum intensity. The value of θ_{\perp} is always larger than that of θ_{\parallel} because of stronger diffraction from narrower slit-like active layer thickness in the direction perpendicular to the junction plane.

Brightness

Because of their highly directional nature and small beam spots, the brightness or *intensity* (watt per unit area) of lasers is higher than that of incoherent light sources.

Atomic Energy Levels and Emission of Light

Light exhibits both wave nature and particle nature. This is known as the *wave-particle duality*. Quantum mechanics shows that a beam of light consists of light-wave packets (particles) called *photons*. A photon possesses a quantized energy ΔE given by Planck's equation

$$\Delta E = h\nu \quad (27)$$

where $h = 6.63 \times 10^{-34}$ J-s is the Planck constant and ν is the frequency of the light.

An atom has electrons orbiting in different *shells*. The shells are designated with principal quantum number n ($n = 1, 2, 3, \dots$). The innermost shell has the principal quantum number $n = 1$. Electrons in this shell are in the lowest energy level, which is called the *ground state*. The next shell with the principal quantum number $n = 2$ has higher energy level and so on. Each and every shell is characterized by its own respective energy level.

When an electron from a higher energy level E_2 goes down to a lower energy level E_1 , it emits a photon of energy

$$\Delta E = E_2 - E_1 = h\nu \quad (28)$$

where ν is the frequency of the emitted photon and ΔE is the difference of energies between a higher energy level E_2 and a lower energy level E_1 involved in the transition of the electron.

Absorption, Spontaneous Emission, and Stimulated Emission

When a photon of energy $h\nu$ is incident on an atom, the photon is absorbed and the atom is excited to a higher energy state. The photon is absorbed only when its energy $h\nu$ is exactly the same as the energy difference $E_2 - E_1$ of the higher and lower energy levels as shown in Figure 11. This process is called *stimulated absorption*.

The natural transition of an atom from the higher energy level E_2 to the lower energy level E_1 can occur at any time, and the emission of a photon occurs in a random direction with a random phase (Figure 11). This type of emission is known as a *spontaneous emission*.

If a photon with the same energy $h\nu = E_2 - E_1$ is passing nearby, it can trigger the atom to jump down from a higher energy level E_2 to a lower energy level E_1 , in which case the emitted photon is in the same direction and in the same phase with the passing photon as shown in Figure 11. This type of emission is known as a *stimulated emission*.

If the transition of the atom from a higher energy level E_2 to a lower energy level E_1 takes place without the emission of a photon, then the energy is transformed into the translational energy of the atom (or vibrational and rotational energy in the case of a molecule). This type of transition is called a *nonradiative de-excitation*.

Population Inversion and Pumping

For a medium at thermal equilibrium with its surroundings, the relative number of atoms at a high energy level E_2 and at a lower energy E_1 is given by the *Boltzmann distribution* as

$$\frac{N_2}{N_1} = e^{\frac{-(E_2 - E_1)}{k_B T}} \quad (29)$$

where N_2 and N_1 are the numbers of atoms at a higher energy level E_2 and at a lower energy level E_1 , respectively; $k_B = 1.380 \times 10^{-23}$ J/K is the Boltzmann constant; and T is the temperature in Kelvin (K). The Boltzmann distribution indicates that, at thermal equilibrium, the number of atoms at a higher energy level is lower than that at a lower energy level.

Through the collision of moving particles such as electrons or by absorbing radiations, the atoms of a medium can be excited to higher energy levels. In this situation, if the decay time τ_{21} from E_2 to E_1 is longer than the decay time τ_{10} from E_1 to ground state E_0 , then the number of atoms N_2 at an energy state E_2 will be higher than that N_1 of a lower energy state E_1 . This is known as *population inversion*.

As mentioned earlier, the atoms or molecules can be excited by colliding with other particles such as high-velocity electrons or molecules as well as by high-energy radiation of an appropriate frequency. In the case of semiconductor laser diodes, by forward biasing the P-N double hetero-junction, the charge carriers are injected to the higher energy band. The electrons in the valence band receive energy to go up into the conduction band. To get laser action, it is necessary to create a population inversion of electrons in the conduction band by continuously injecting the charge carriers into the active layer. This process of creating a larger population at the higher energy level (conduction band for electrons) than that of the lower energy level (valence band) is called *pumping*.

Figure 11: (a) Stimulated absorption, (b) spontaneous emission, and (c) stimulated emission

Figure 12: Boltzmann distribution and population inversion

For clarity and completeness, a four-level model of laser pumping in an atomic (gas) medium will be used for explanation. In Figure 12, atoms or molecules at the ground-state energy level E_0 are pumped to a higher energy level E_3 . The atoms or molecules decay rapidly to energy level E_2 as nonradiative transition. The transition from E_2 to E_1 is a radiative transition that emits photons. Then, again, the atoms or molecules at energy level E_1 jump down to the ground-state energy level E_0 without radiation. The transition time τ_{21} from E_2 to E_1 is much longer than the transition time τ_{32} from E_3 to E_2 and τ_{10} from E_1 to E_0 for the population inversion to achieve. $E_3 \rightarrow E_2$ and $E_1 \rightarrow E_0$ do not have to be nonradiative transitions, although because nonradiative processes are faster, it is better if they are nonradiative.

Figure 13 shows the energy band diagram of a semiconductor. In a semiconductor laser, forward biasing the P-N junction injects or pumps electrons into the energy level E_3 in the conduction band. Then the electron energy decays to the energy level E_2 with a decay time τ_{32} ($\sim 10^{-12}$ sec) (Pearsall 2003). This creates a population inversion of electrons between energy level E_2 and E_1 .

Figure 13: Four-level pumping in semiconductor lasers

because at thermal equilibrium there are more electrons in the valence band. An electron transition to E_1 is the recombination with a hole in the valence band, which emits the radiation with the transition time τ_{21} ($\sim 10^{-9}$ sec) (Pearsall 2003). Finally, the electron at the energy level E_1 relaxes to a lower energy level E_0 with a transition time $\tau_{10} < \tau_{21}$.

Fabry-Perot Laser Resonator

Normally, most of the atoms in the population inverted state undergo spontaneous emission and do not contribute to coherent stimulated emission. A resonator with positive feedback is necessary so that the majority of the atoms in the upper laser level will contribute in the coherent stimulated radiation. The resonator has two mirrors with high reflectivity facing each other at a distance L as shown in Figure 14. This arrangement is known as a *Fabry-Perot (FP) resonator* (Milonni and Eberly 1988). The photons traveling off-axis are absorbed by the wall of the resonator and eliminated. The photons traveling parallel to the axis of the resonator are reflected back and forth into the resonator by the end mirrors and interact with the atoms, and stimulated emission strongly takes place in the resonator. One of the mirrors has a reflective coating with partial transmission so that a small fraction of the laser light in the resonator is coupled out as a usable laser beam.

The resonance occurs when the resonator optical length nL is equal to an integer multiple of one-half of the free space wavelengths (Iizuka 2002), where n is the refractive index of the gain medium in the resonator:

$$nL = q \frac{\lambda}{2} \quad (30)$$

where q is the number of half-wavelengths in the standing wave in the cavity at resonant frequency as shown in Figure 14. Such a pattern is called the q th *longitudinal mode* of the resonator.

The resonant frequency ν is then

$$\nu = \frac{c}{\lambda} = q \frac{c}{2nL} \quad (31)$$

The frequency spacing between two adjacent resonance modes is

$$\Delta\nu = (q+1) \frac{c}{2nL} - q \frac{c}{2nL} = \frac{c}{2nL} \quad (32)$$

The spacing $\Delta\nu$ is larger for the shorter effective resonator length L .

Figure 14: Fabry-Perot laser resonator with gain medium of refractive index n

The number of modes leading to oscillation is determined by the gain linewidth divided by the mode spacing $\Delta\nu$.

Even if the cavity is very short, the number of possible longitudinal modes is still quite large. These modes are called *longitudinal modes* because they can be tuned by changing the cavity length longitudinally.

Laser Gain Curve and Lasing Modes

If the irradiance (sometimes called *intensity*) of the light at one mirror is equal to some value I_0 , then after one pass through the laser gain medium in the resonator the intensity grows to a value I as

$$I = I_0 e^{[g(\nu) - \alpha(\nu)]L} \quad (33)$$

where $g(\nu)$ is the (small signal) gain of the laser medium in the cavity and is a function of frequency ν ; $\alpha(\nu)$ is the distributed loss per unit length in the cavity resulting from losses such as scattering and absorption, which are frequency-dependent processes by nonactive molecules or atoms in the medium. If R_1 and R_2 are the reflectivity of the mirrors at each end of the cavity, then after one round trip the intensity becomes

$$I = I_0 R_1 R_2 e^{[g(\nu) - \alpha(\nu)]2L} \quad (34)$$

and the relative gain in intensity in one round trip is

$$G = \frac{I}{I_0} = R_1 R_2 e^{[g(\nu) - \alpha(\nu)]2L} \quad (35)$$

The round trip gain must be greater than unity for initial buildup of lasing and must be equal to 1 at steady state; that is,

$$g(\nu) \geq \alpha(\nu) + \frac{1}{2L} \ln \left(\frac{1}{R_1 R_2} \right) = g_{th} \quad (36)$$

where g_{th} is the threshold gain at steady state.

The conceptual small signal gain curve $g(\nu)$ of InGaAs (band-gap energy $E_g = 0.75$ eV) is shown in Figure 15 (Asada and Suematsu 1985). The gain is higher for higher carrier density N , which in turn depends on the injection (forward bias) current of a laser diode. This is indicated in Figure 15 by the arrow connecting the gain peaks and showing the trend of growth of the injection current with increasing injection carrier density Ni and the gain.

Normally, the gain curve is wider than the longitudinal mode spacing of the cavity. In long FP resonator-type lasers such as edge-emitting lasers, there would be a few longitudinal cavity modes lasing under the small signal laser gain curve as shown in Figure 16.

The longitudinal mode that coincides with the small signal gain peak will lase more strongly than the adjacent modes as shown in Figure 16. The adjacent modes on either side of the strongest one could have considerable intensity because the difference in gain $g(\nu)$ between these modes is exceptionally small ($\sim 0.1 \text{ cm}^{-1}$) (Agrawal 2002).

Lasers that are lasing with one or two adjacent longitudinal modes together with the main mode are

Figure 15: Conceptual gain spectra of a typical semiconductor laser

called *multilongitudinal mode (MLM) lasers*. Each mode propagates with different speed when traveling in fibers and contributes to a *group velocity dispersion*. In optical communications, dispersion limits the bit-rate distance product below 10 Gbps-km for systems operating near 1550nm (Agrawal 2002). By appropriately designing the structure and the cavity length, single-mode lasers oscillating at a *single longitudinal mode (SLM)* are

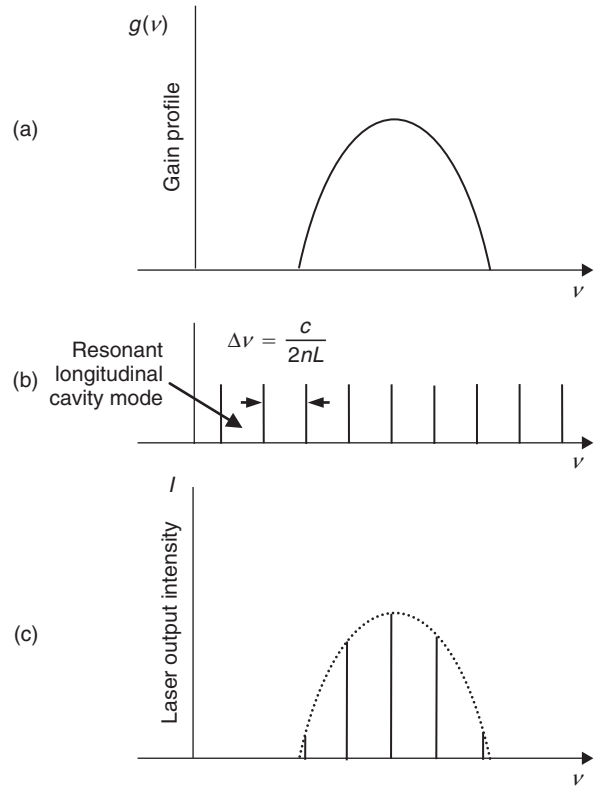

Figure 16: (a) Laser gain curve $g(\nu)$ at steady state lasing, (b) cavity resonant modes with frequency spacing $\Delta\nu = c/(2nL)$, and (c) lasing modes under the laser gain profile

fabricated. They are used in high bit-rate, long-haul optical communications.

The *side mode suppression ratio* (SMSR) is defined as the ratio of power of the main mode to the power of the adjacent dominant side mode and is expressed in dB (Agrawal 2002):

$$\text{SMSR} = 10 \log \left(\frac{P_{mm}}{P_{sm}} \right) \quad (37)$$

where P_{mm} is the main mode power and P_{sm} is the adjacent dominant side mode power. For a good SLM laser, the SMSR exceeds 30 dB (Agrawal 2002).

Spectral Lineshape and Linewidth

The spectrum of the atomic radiation has a *Lorentzian lineshape* because of transition lifetime broadening. The Lorentzian lineshape factor $g(\nu)$ (Iizuka 2002) is expressed as

$$g(\nu) = \frac{\frac{\gamma}{2}}{\left(\frac{\gamma}{2}\right)^2 + [2\pi(\nu - \nu_0)]^2} \quad (38)$$

where $\gamma = (\tau_{21})^{-1}$, τ_{21} is the transition or decay time of the transition from energy level E_2 to energy E_1 , and ν_0 is the lasing frequency at which the maximum intensity peak occurs ($\Delta E = E_2 - E_1 = h\nu_0$).

The *spectral linewidth* is defined as the full width at half-maximum of the intensity distribution curve. The spectral line has a width that results from the natural decay lifetime of photons in the cavity. This type of spectral line broadening is called *homogenous line broadening* because each and every atom contributes equally and in the same way in broadening a spectral line.

In semiconductor laser diodes, crystal imperfections, material inhomogeneity, and losses also contribute to spectral line broadening, which is known as *inhomogeneous line broadening*. The actual lineshape depends on the contributions of both homogeneous and inhomogeneous broadening. The spectral linewidth in semiconductor

lasers is also broadened by random spontaneously emitted photons adding into the lasing light. The linewidth $\Delta\nu$ of a semiconductor laser diode is derived (Buus, Amann, and Blumenthal 2005; Henry 1983) as

$$\Delta\nu = \frac{h\nu v_g^2 (\alpha_L + \alpha_m) \alpha_m n_{sp}}{8\pi P} (1 + \alpha_H^2) \quad (39)$$

where v_g is the group velocity, α_L is the cavity loss, α_m is the end loss including output as loss, n_{sp} is the spontaneous emission coefficient, P is the optical power per end, and α_H is the linewidth enhancement factor. Equation (39) is known as the *Schawlow-Townes-Henry linewidth equation*.

Lasers of distributed feedback type and *distributed Bragg reflector* (DBR) type lase in single-longitudinal mode and have extremely narrow laser linewidth (the above laser types will be discussed in detail in the section “Distributed Feedback and Distributed Bragg Reflector Lasers” below). Single-longitudinal mode narrow linewidth lasers are used for long-haul optical fiber systems. (Refer to Henry 1982, 1983 for detailed theory on laser linewidths and the noise of semiconductor lasers.)

LASER DIODES

The structures of laser diodes are similar to the structures of LEDs. The only difference is that laser diodes use the Fabry-Perot cavity for light amplification (Figure 17). Typical dimensions of a laser diode crystal are longitudinal direction length of 200–400 μm , lateral direction width of 100–200 μm , and transverse direction height of 50–60 μm . The active layer thickness is 0.1–0.2 μm , and the light-confining width in the active layer is less than 10 μm (the shaded area in the active layer with the slashed line in Figure 17). The active layer is surrounded by lower refractive index cladding and guiding layers on all sides; hence, this type of laser with index guiding is known as a *buried hetero-junction laser*.

In laser diodes, the active layer is grown between two wider band-gap materials, thus forming two hetero-junctions between the active layer and the wider band-gap materials. The injected currents, the injected

Figure 17: Edge-emitting laser with stripe contact for current confinement. The light-emitting ends are cleaved at a suitable crystal plane to form high-reflectivity facet mirrors required for the Fabry-Perot resonator

carriers, and the emitted light are confined in the thin active layer on the order of a few nanometers up to 0.2 μm thickness and less than 10 μm width so that the lasing threshold current is low and the electrical to light conversion efficiency is high.

Current and Carrier Confinement

The injected current is confined to the small active region by a narrow stripe contact to channel the injected current into the desired area along at the middle of the crystal. There are several other methods used in injection current confinement such as raised resistivity by proton bombardment, barricade by back-biased P-N junction layer, dopant diffused channel, and modulation of layer thickness (Iizuka 2002).

The carrier confinement is achieved by the double hetero-junction structure. The energy-band diagram for a DH structure is shown in Figure 18.

When the junctions are forward-biased, electrons in the cladding N-type material are injected into the undoped active layer. The injected electrons in the active layer cannot penetrate into the P-type cladding because the potential barrier at the P junction push them back into the active layer. Thus, the electrons are confined in the active layer. The injected holes are also confined in the active layer by the potential barrier at the N-junction cladding. The confined electrons and holes recombine in the active layer only, and the energy released from the recombination is emitted as the optical radiation in the active layer.

Light Confinement

The active layer also acts like a dielectric waveguide to guide the emitted light along its length (the longitudinal direction of the FP resonator) toward the end facets. The thickness of the active layer is 0.1–0.2 μm for most laser diodes emitting in the band of 850–1550 nm for use in optical communications. The refractive index of the

active layer is slightly higher than the adjacent P- and N-type cladding layers. The remaining two sides of the active layer are roughened to prevent reflections in the lateral direction. As a result, the emitted light in the active layer is confined by total internal reflections at the boundaries between the active layer and cladding layers. This type of confining and guiding the light along the longitudinal direction of the active layer is called *index guiding*.

The V parameter or *normalized frequency* (Kogelnik and Ramaswamy 1974) of a slab waveguide of thickness $2a$ is given by

$$V = kaNA \quad (40)$$

where $k = \frac{2\pi}{\lambda}$ and $NA = \sqrt{n_1^2 - n_2^2}$ is the numerical aperture of the slab waveguide, n_1 is the refractive index of the active layer, and n_2 is the refractive index of the P- and N-type cladding layers.

In general, if the value of V is $(m-1)\frac{\pi}{2} < V < m\frac{\pi}{2}$, then there are m number of modes propagating in the slab waveguide. The condition for single-mode propagation is $0 < V < \frac{\pi}{2}$. Thus, the number of modes in the active layer can be varied by changing the thickness $2a$ of the active layer.

The thickness of the active layer is so chosen that only the fundamental mode is propagating in the cavity. Thus, the thickness $2a$ of the active layer must fulfill the condition

$$2a \leq \frac{\lambda}{2\sqrt{n_1^2 - n_2^2}} \quad (41)$$

The propagating beam's intensity distribution is shown in Figure 19.

The diffraction from the thinner slit-like active layer at the facets will contribute to a larger output beam divergence. Consequently, in determining the thickness of the active layer, consideration must be taken to balance between the beam width divergence and optical confinement efficiency where the optical confinement factor Γ is defined (Buus, Amann, and Blumenthal 2005) as

$$\Gamma = \frac{\text{Mode power in the active layer}}{\text{Total mode power}} = \frac{\int_{-a}^a |E_y|^2 dy}{\int_{-\infty}^{\infty} |E_y|^2 dy} \quad (42)$$

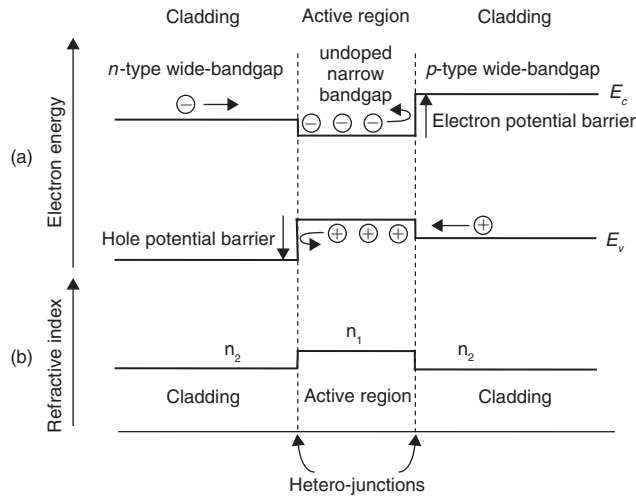

Figure 18: Energy bands and potential barriers for the injection carrier confinement in (a) forward bias condition and (b) refractive indexes of active and cladding layers for index waveguiding

Figure 19: Propagating beam intensity profile

Figure 20: Light is confined around the maximum gain at the center of the active layer width where the gain exceeds the lasing threshold gain g_{th}

where E_y is the electric field propagating along the longitudinal direction (z -direction) and is a function of transverse coordinate y .

Gain guiding occurs in the active layer because of injection current confinement. The injection current density is the highest at the center of the active layer in the lateral direction, and it approaches zero at both the sides of the active layers. Consequently, the injection charge carrier density N and hence the gain g is the highest in the center of the lateral width of the active layer. As a result, stimulated emission of photon is the highest at the center of the active layer. These phenomena are combined and lead to confining the lasing at the center of the active layer where the gain is the highest. Light confinement along the center of the active layers where the gain is the highest is known as *gain guiding* (Figure 20).

The tiny end surfaces of the active layer (facets) are constructed to have high reflectivity by cleaving the crystal at a crystal plane perpendicular to the junction planes, thus forming a Fabry-Perot type cavity along the length of the active layer. The power reflectivity or reflectance R of the cleaved surface is given by *Fresnel's equation* (Hecht 2002; Agrawal 2002):

$$R = \left(\frac{n-1}{n+1} \right)^2 \quad (43)$$

where n is the refractive index of the active region. For GaAs, $n = 3.5$ and hence the power reflectivity of the facet is 0.3.

Laser Diode Operating Characteristics and Conversion Efficiency

The typical operating characteristic of a laser diode is shown in Figure 21. When the forward bias current (known also as the *injection current*) is less than the threshold current I_{th} , the diode is operating in LED mode. The spontaneous emission is dominant because of insufficient carrier density in the conduction band to get a large enough population inversion and enough gain to overcome losses.

When the bias injection current is increased to the threshold current I_{th} , the population inversion starts to take place and stimulated emission occurs. Above the threshold current I_{th} , the optical output power P_{out} of the laser diode is directly proportional to $(I - I_{th})$. As the biasing current is increased, the peak power increases as well and

Figure 21: Operating characteristic of a laser diode

the spectral linewidth gets narrower [see Equation (39)]. The resonant wavelength of the cavity also increases because of the expansion of the cavity length and an increase in the refractive index by the rising temperature with increasing current (Iizuka 2002). The emission wavelength increases also because the band-gap energy of the gain medium is reduced when the temperature rises as (Iizuka 2002)

$$E_g(T) = E_0 - \frac{\alpha T^2}{\beta + T} \quad (44)$$

where E_0 is the band-gap energy at 0 K, T is the temperature in Kelvin, α is 4.5×10^{-4} eV/K, and β is 204 K for GaAs and 327 K for $\text{Ga}_x\text{In}_{1-x}\text{As}_y\text{P}_{1-y}$.

Change of cavity length can lead to sudden change in the emission frequency to a lower cavity resonant frequency mode (longer wavelength mode) that coincides with the gain peak. This is known as *mode hopping* (Iizuka 2002). Temperature stabilization circuits using *Peltier thermoelectric devices* (Kasap 2002; Godfrey 1996) are employed to prevent mode hopping and to avoid frequency shifting even inside the same mode.

The slope efficiency or responsivity η_s is defined as (Fukuda 1999):

$$\eta_s = \frac{dP_{out}}{dI} = \eta_d \frac{h\nu}{2q} \quad (45)$$

where η_d is the external differential quantum efficiency and dP_{out}/dI is the slope of the P - I characteristic at the operating point above the threshold current I_{th} . The factor $1/2$ arises because there are two facets in Fabry-Perot lasers that emit laser light. For Fabry-Perot lasers with coated rear facets or for DFB lasers, $1/2$ should be replaced by unity.

The spontaneously emitted power at threshold current I_{th} is often small compared to the laser power in operation so that dP_{out}/dI can be approximated as $P_{out}/(I - I_{th})$. The lasing output power (from one facet) can be calculated as

$$P_{out} = \frac{1}{2} \eta_d \frac{h\nu}{q} (I - I_{th}) \quad (46)$$

The external quantum efficiency η_{ext} is defined as the ratio of total photon emission rate to the electron injection rate (Agrawal 2002) and hence can be written as

$$\eta_{ext} = \frac{2P_{out}/h\nu}{I/q} = \eta_d \left(1 - \frac{I_{th}}{I} \right) \quad (47)$$

where $\eta_{ext} \approx \eta_d$ for $I \gg I_{th}$.

The total quantum efficiency (also known as wall-plug efficiency) is defined as the ratio of total optical output power to the electrical input power:

$$\eta_{tot} = \frac{2P_{out}}{V_0 I} = \frac{h\nu}{qV_0} \eta_{ext} \approx \eta_{ext} \quad (48)$$

because $h\nu \approx qV_0$. The external quantum efficiency η_{ext} is approximately 40 percent to 60 percent in a typical laser diode (Fukuda 1999).

Modulation Response of Laser Diodes

The signal can be modulated on the laser light by superimposing the signal current to the bias current of the optical source. This type of modulation is known as *direct modulation*. In a direct-modulated laser, the signal output power decreases with increasing modulation frequency. Figure 22 shows the small signal modulation response of a typical laser diode. There is a resonant frequency f_r where the small signal gain increases to a maximum. The value of f_r can be expressed as (Iizuka 2003)

$$f_r = \frac{1}{2\pi\tau_s\tau_n} (I - I_{th})^{1/2} \quad (49)$$

where τ_s is the photon lifetime in the cavity and τ_n is the electron (carrier) lifetime.

When the modulation frequency increases beyond f_r , the output power drops rapidly. The bandwidth is larger for a higher ratio of signal current to threshold current, but the output is lowered as seen in Figure 22. For a wider bandwidth or faster modulation, it is important that the threshold current of the laser diode would be as low as possible.

One undesirable effect in the direct modulation method is *frequency chirping*, or changing of laser light

Figure 22: Small signal modulation response of a laser diode

frequency (carrier frequency) by the modulating signal. The frequency of the laser light changes at the rising and falling edges of the signal pulses when direct modulation is used. For the positive chirping parameter, the frequency of the laser decreases at the rising edge of the signal and increases at its falling edge (Li and Yu 2003). The laser frequency changes are opposite for negative chirping parameter. The signal pulse spectrum is broader than that without chirping. Chirping limits the bit rates and hence the performance of the optical communication system. (Refer to Agrawal 2002 for further reading on frequency chirping.)

To avoid frequency chirping, turn-on delay time, and transient effects encountered in direct modulation, *external modulation* schemes are used in bit rates higher than 2.5 Gbps. In the external modulation method, the laser source operates in the *continuous wave mode*—that is, the intensity of the source laser is kept constant by biasing at a constant current. The laser light is passed through an electro-absorption modulator or a LiNbO₃ electro-optic modulator (known as the *Mach-Zehnder modulator*) (Li and Yu 2003) placed next to the laser. When the electrical signal pulses are applied to the modulator, the applied electric field changes the refractive index of the modulator; hence, the intensity of the laser varies in accordance with the signal.

Distributed Feedback and Distributed Bragg Reflector Lasers

To get a single longitudinal mode laser diode, the distributed feedback method (Figure 23) is used for positive feedback instead of the FP resonator. As discussed earlier, the mode spacing $\Delta\nu$ is small for a long cavity length L . Fabry-Perot laser diodes usually have longer than 100- μ m cavity length, which leads to MLM lasing as the small signal gain curve is wider than the intermode spacing.

In a distributed feedback laser diode, a sinusoidal periodically varying refractive index grating known as a *Bragg grating* (Agrawal 2002) is grown in the guiding layer between the active layer and one of the cladding layers (Figure 24). The refractive index of the guiding layer

Figure 23: Cross-section of distributed feedback laser diode

Figure 24: Active, cladding, and guiding layers and the index grating structure of a distributed feedback laser. A single-mode field propagating along the longitudinal direction and the reflected field are shown (Fukuda 1999)

is slightly lower than that of the active layer and higher than that of the cladding layer so that optical confinement is achieved by the slab waveguide structure. The grating next to the active layer reflects light back into the active layer. Each grating tooth acts as a reflection center. The intensity of the reflected light depends on the grating height and shape as well as on the distance between the grating and the active layer (Fukuda 1999).

The spatial periodicity (or *pitch*) Λ of the grating and the equivalent refractive index n_{eq} are the important parameters that are adjusted when fabricating the multilayer crystal to set the lasing wavelength λ of a DFB

laser. The Bragg mode wavelength λ_{Bm} is given as (Fukuda 1999)

$$2\bar{n}\Lambda = m\lambda_{Bm} \quad (50)$$

where $m = 0, 1, 2, \dots$ is the order of reflection from the grating and \bar{n} is the average equivalent refractive index of the multilayer medium in which the optical wave is propagating (Kogelnik and Shank 1972).

The coupled wave theory of distributed feedback lasers indicates that their lasing frequency ν of cavity length L is detuned from the Bragg frequency $\nu_{Bm} = c/\lambda_{Bm}$ and is derived as (Kogelnik and Shank 1972):

$$\nu = \nu_{Bm} \pm \Delta\nu \quad (51)$$

$$\Delta\nu = \frac{c}{2\bar{n}L} \left[\frac{1}{2} + \frac{1}{\pi} (\text{Phase}(\kappa)) \right] \quad (52)$$

where κ is the coupling constant, which is a measure of the amount of feedback per unit length imparted by the Bragg grating. The phase of κ is zero for index coupling and $\pi/2$ for gain coupling (Kogelnik and Shank 1972). Therefore, there are two lasing frequencies detuned on each side of ν_{Bm} as shown in Figure 25. The range between lasing detuned frequencies is known as the *stop band*. For gain coupling $\Delta\nu = c/2\bar{n}L$, which is the same as cavity frequency mode spacing. Hence, there is a cavity resonance frequency at the Bragg frequency ν_{Bm} , and there is no stop band.

Figure 25: Spectra of (a) uniform grating DFB laser and (b) $\lambda/4$ shifted grating DFB laser (Fukuda 1999)

Figure 26: Distributed Bragg Reflectors replacing end facets to form the FP resonator

For a uniform grating, there are always two detuned cavity resonance frequencies, one on each side of the Bragg frequency as shown in Figure 25. This is undesirable, and to get a single frequency or a SLM laser, the reflected wave needs an additional phase shift of $\pi/2$ (equivalent to a $\lambda/4$ phase shift in wavelength).

There are several methods to obtain a $\lambda/4$ phase shift to tune the emission at Bragg frequency ν_{Bm} . One method is to remove one-half of the pitch ($\Lambda/2$) of the grating tooth at the center of the grating as shown in Figure 25b. This is equivalent to $\lambda/4$ shift in wavelength. Such $\lambda/4$ phase-shifted DFB lasers operate in single longitudinal mode at Bragg frequency. Some of the methods employed for $\lambda/4$ shift include etching and adjusting height of the grating tooth at the center of the cavity, using $\lambda/4$ coating at one end of the cavity, and using multi-electrode phase control to select only one of the detuned frequency modes mentioned above (Iizuka 2002).

Gratings can also be grown in one or both the ends of the active layer, replacing the facet mirrors in forming the Fabry-Perot resonator as shown in Figure 26. In this configuration, the gratings are called *distributed reflectors* and the lasers with this configuration are called *distributed Bragg reflector* lasers.

Vertical-Cavity Surface-Emitting Laser

A *vertical-cavity surface-emitting laser* (VCSEL) is one solution for obtaining a single-mode laser with narrow linewidth. Surface-emitting lasers have several advanced properties compared to the edge-emitting type:

1. ease of fabrication with a large-scale integration method;
2. ability to be tested at the wafer level, thus reducing the manufacturing cost;
3. narrow far-field beam divergence with circular beam spot;
4. ability to be used at high bit-rate modulation (>10 Gbps);
5. high coupling efficiency to low numerical aperture fibers;
6. narrower spectral linewidth compared with edge-emitting laser diodes; and
7. low threshold current.

There are several types of surface-emitting lasers, some of which are vertical-cavity surface-emitting types, grating surface-emitting types, deflecting-mirror surface-emitting types, and two-dimension stack-array types. (Refer to Yang and Liang 2003 for further details on these types.)

The schematic diagram of an early type GaAlAs and GaAs VCSEL (Iga et al. 1984) is shown in Figure 27. The laser light is coupled out in the direction perpendicular to the junction plane instead of coupling out from one of

Figure 27: Vertical-cavity surface-emitting laser (VCSEL) (Iga et al. 1984)

the end facets. A mesa well is etched perpendicular to the active layer to couple out the laser light. The length of the vertical cavity is short ($\sim 7 \mu\text{m}$), hence the mode spacing between two adjacent modes is larger than the gain bandwidth of the laser. Consequently, there exists only a single longitudinal mode in this type of vertical-cavity laser. The output beam has a circular distribution of light, and FWHM beam divergence angle is small ($\sim 10^\circ$). The lasing wavelength depends on the temperature of the laser diode, and the mode hopping occurs when the change in temperature is extremely high ($\Delta T \approx 800 \text{ K}$) (Iga et al. 1984).

Later versions of VCSELs use two stacks of multilayer DBRs having from twenty to forty layers per stack, depending on required reflectivity and electrical resistance. Multilayer DBRs are grown on both sides of a thin active layer as shown in Figure 28. Each layer has an optical thickness nd (product of refractive index n and physical thickness d) equal to $\lambda/4$ and has alternating high and low refractive indexes. The reflectivity of this type of DBR is normally higher than 99.5 percent.

There are three types of DBRs used in VCSELs: dielectric, semiconductor, and hybrid. Dielectric DBRs are made of a stack of multilayer dielectrics such as SiO_2 and TiO_2 . Semiconductor DBRs are built with a stack of multilayer semiconductors such as GaAs and AlAs. Hybrid type DBRs are constructed with a metal reflector as the outermost layer combined with semiconductor DBR or dielectric DBR. Hybrid type DBRs are not suitable for coupling out the laser because the metal layer has a zero transmission coefficient (Yang and Liang 2003). The two main functions of stacked DBRs are to form a vertical FP optical resonator and to provide a conduction path for the injection current to the active layer.

As noted earlier, electrons have a wave-particle dual nature in quantum mechanics. A moving electron (a particle) has a momentum p and associated wavelength of $\lambda = h/p$ that is known as the *de Broglie wavelength* (Milonni and Eberly 1988). The thickness of the active

Figure 28: Bottom-emitting VCSEL with etched well in the GaAs substrate for coupling out the light from the bottom

layer in a VCSEL is less than the de Broglie wavelength of the electron. In VCSEL DBR lasers, the thin active layer becomes a *multi-quantum well* (MQW) active layer, and the electrons are confined in quantum wells that are each less than the de Broglie wavelength of electrons. The optical gain of a MQW active layer is extremely high and the loss is extremely low (Yang and Liang 2003). Consequently, the threshold current is especially low and the spectral linewidth is especially narrow for a VCSEL. This low threshold current contributes to higher modulation bandwidth. Narrow linewidth, single longitudinal mode lasers are widely used in dispersion-limited, long-haul fiber links.

VCSELs are available for different wavelengths from 650 nm to 1550 nm. The 850 nm VCSELs are the most widely used sources in local area networks and data transfers because of their low cost.

Readers can refer to Suhara (2004) for more information on quantum well structures and stimulated emission in them.

TUNABLE LASER DIODES

In dense wavelength-division multiplexed optical communication systems, sixteen or thirty-two multiplexed channels are normally used. In such applications, tunable lasers are a good alternative to reduce cost. Furthermore, tunable lasers are useful in optical sensing and optical measurements such as reflectometry and optical spectrometry where the tunability of laser wavelengths is an important factor for the applications.

Referring to the Bragg grating equation

$$2\bar{n}\Lambda = \lambda$$

the laser wavelength depends on the average refractive index of the semiconductor material. The basic principle applied for wavelength tuning in laser diodes is to change the refractive index of the active layer and the Bragg grating by varying the carrier injection current.

There are two ways to change the refractive index of the laser diode: (1) change the injection current to vary

the refractive index of the DBR or DFB laser diodes and (2) control the temperature of the laser diodes to change the temperature-dependent band-gap energy and the refractive index.

The temperature-control method for tuning can be done by a simple external thermoelectric controller, and it is suitable for sensing and measurements. Injection current tuning is more suitable for applications in communication systems in the wavelength band of 1300–1550 nm.

There are three tuning modes, depending on the structure of the laser diode: (1) discontinuous tuning, (2) continuous tuning, and (3) quasi-continuous tuning. Spectral linewidth and single longitudinal mode lasing need to be sustained throughout the tuning process.

Discontinuous Tuning

In discontinuous tuning, after a narrow tuning range, the wavelength hops suddenly from one longitudinal mode to an adjacent shorter wavelength mode as the tuning current is increased (see Figure 29). At the same time, the overall tuning range achievable is approximately 100 nm.

Figure 29: Discontinuous tuning characteristic in a two-section DBR or DFB laser

Figure 30: Longitudinally integrated two-section tunable (a) DBR laser and (b) DFB laser

Longitudinally integrated two-section DBR or DFB lasers, shown schematically in Figure 30, are the simplest structures used for discontinuous tuning.

Here I_{pw} is the power control injection current, and I_t is the wavelength tuning control current. Wavelength tuning is carried out by applying different tuning bias current I_t that changes the refractive index of the DBR or DFB section so that it tunes from one mode to another. The wavelength also depends on the output power control current I_{pw} because the varying output power can induce temperature deviations and hence changes of cavity length. Consequently, there is no single independent control for tuning wavelength in laser diodes.

Continuous Wavelength Tuning

In continuous tuning, the wavelength is adjusted in extremely small steps within the spectral width of the lasing main longitudinal mode under the gain curve $g(\nu)$ without

Figure 31: Continuous tuning characteristic of a laser diode

Figure 32: Longitudinally integrated three-section tunable DBR laser (Buus et al. 2005)

changing the mode (see Figure 31). All of the parameters apart from the tuning control current or voltage must be kept constant to ensure the stability of the single longitudinal mode as well as to ensure that the side-mode suppression ratio is above an acceptable value (>30 dB). The tuning range is narrowest (≤ 15 nm) among the three tuning modes (Buus, Amann, and Blumental 2005).

One of the methods for achieving continuous tuning is to use longitudinally integrated three-section DBR as shown in Figure 32. A phase shifter electrode I_{ph} that controls the phase shift of the propagating wave in the active layer is added. Simultaneous adjustment of I_{ph} and I_t enables the user to tune the wavelength continuously within a longitudinal mode. However, the wavelength also depends on the power. Changing the injection current I_{pw} for power adjustment would also change the wavelength. Thus, I_{pw} is usually kept constant when adjusting the phase control current I_{ph} and tuning control current I_t for the desired wavelength in one of the lasing modes as shown in Figure 33.

Figure 33: I_{ph} versus I_t plot for operation of selected longitudinal modes. Continuous tuning is achieved by adjusting I_{ph} and I_t so that these currents stay inside a pair of mode boundaries (solid lines) at which the mode hopping occurs. Dashed line indicates one possible trace of I_{ph} and I_t that fall in single mode N (Yang and Liang 2003)

Figure 34: Quasi-continuous tuning characteristics by each of I_{pw} , I_{ph} , and I_t of three-section tunable DBR lasers (Yang and Liang 2003)

Quasi-Continuous Wavelength Tuning

The longitudinal, integrated three-section lasers shown in Figure 32 can also be used in a quasi-continuous tuning mode. The laser output power control current I_{pw} induces temperature change in the laser diode, which leads to the change of emission wavelength. As a result, all three control currents I_{pw} , I_{ph} , and I_t affect the emission wavelength of the laser diode as shown in Figure 34.

Highly precise and sophisticated devices are used to control the tuning so that mode jumping and instabilities are prevented. (Refer to Buus, Amann, and Blumenthal 2005 for details on tunable laser diodes.)

External Cavity Tunable Laser Diodes

Tunable external cavity laser diodes can be employed as an alternative to tunable monolithic laser diodes. However, their tuning speed is slow because of the mechanical movements of gratings and mirrors that are involved in the tuning arrangement.

Figure 35: Two-sided external cavity tunable diode laser. Both facets of the laser diode are AR-coated

Figure 36: Single-sided external cavity tunable laser. Only one facet facing the external cavity is AR-coated

In an external cavity laser diode, the resonant cavity consists of the diode, which is the gain medium as well as a part of the cavity, and an external cavity for tuning. An extended external cavity is incorporated using a movable grating and a mirror. Gratings and mirrors of extremely small dimensions, the *micro-electromechanical system*, are also used in external cavity tuning. Two examples of the arrangement of tunable external cavity laser diodes are shown in Figures 35 and 36.

In the two-sided external cavity design as shown in Figure 35, the extended cavity, on each side of the *antireflection* (AR) coated laser diode, provides positive feedback. Wavelength selection is achieved by rotating the grating.

Figure 36 shows the single-sided external cavity design that is most commonly used because it has the following advantages: (1) It needs only one AR-coated facet; (2) the arrangement is simple, and it is easy to align the system; and (3) it has excellent performance (Ye 2004).

A continuous, single-mode wavelength tuning without mode hopping over a wide frequency range was obtained by rotating the grating at the pivot point at the intersection of the mirror and grating planes (Levin 2002; Schremer and Tang 1990). The linewidth of external cavity tunable laser sources are narrow (~ 15 kHz) (Ip et al. 2005).

In addition to the laser diodes discussed above, there are other types of lasers implemented in quite different ways such as quantum cascaded lasers and photonic band-gap lasers. Readers can refer to Lucent Technologies (2000) for more information on quantum cascaded lasers and Nikbin (2006) for photonic band-gap lasers.

OPTICAL DISPERSION AND OPTICAL RESOLUTION IN DATA COMMUNICATION AND STORAGE SYSTEMS

Bit-Rate Distance Product in Optical Communications

In optical communication terms, *dispersion* is the spreading of pulses as they propagate through the optical fiber. A rectangular pulse train consists of a fundamental frequency and higher harmonic frequencies. Different frequency groups propagate with different speeds as well as with different paths in the fiber. A pulse with an initial width of T will have a broadened width of $T + \Delta T$ after propagating through a length of L in the fiber. The dispersion or the spreading of pulse ΔT is proportional to the propagating length L and the modulated source linewidth (in root mean squared value) $\Delta\lambda_s$, and it is given as (Agrawal 2002)

$$\Delta T = |D|L \Delta\lambda_s \quad (53)$$

where D is the chromatic dispersion constant, which is the sum of waveguide and material dispersion constants. D is expressed in practical unit of ps/(km-nm), L in km, and $\Delta\lambda_s$ in nm.

The often-used criterion (Agrawal 2002) is that the dispersion ΔT should be less than or equal to one-quarter of the bit period $T_B = \frac{1}{B}$, that is

$$|D|L \Delta\lambda_s \leq \frac{1}{4B} \quad (54)$$

where B is the bit rate.

In designing a fiber link while taking into account the dispersion and bit rate, this criterion is often stated as the bit-rate distance product:

$$BL \leq \frac{1}{4|D|\Delta\lambda_s} \quad (55)$$

The bit-rate limitation depends especially on source linewidth. For optical sources with extremely narrow laser linewidths, the bit-rate distance product is derived as (Agrawal 2002)

$$B\sqrt{L} = \frac{1}{4\sqrt{\beta_2}} \quad (56)$$

where $\beta_2 = \frac{\partial^2 \beta}{\partial \omega^2}$ is called the *group velocity dispersion* parameter, and β is the *propagation factor*, which depends on the angular frequency ω of the laser light propagating in the fiber.

Usually, Equation (55) is applied to estimate the probable distance if the bit rate is known. Other factors such as power budget, rise time budget, and so on must be taken into account in determining a fiber link distance at a specified bit rate. For a long-haul fiber link

at high bit rates, laser sources with smaller linewidth $\Delta\lambda_s$ (single-mode lasers) such as DFB and DBR lasers have better performance and have been widely used.

Optical Resolution and Blue Laser Diodes for Data Storage Systems

Beside their use in data communication systems, laser diodes have found wide application in data storage devices such as various optical disks and relevant systems.

The image of a focused uniform beam consists of concentric circular rings known as *Airy's disk* (Hecht 2002) as shown in Figure 37.

The circular spot at the center is brightest, and the intensity of the rings increasingly fades while progressing outward.

The images of two closely spaced spots can be resolved only when the centers of the spots are separated by at least the radius of the central spot. This is known as the *Rayleigh criterion*. The radius of the center spot is given as (Hecht 2002):

$$r = \frac{0.61\lambda}{NA} \quad (57)$$

Here $NA = n \sin\theta$ is the numerical aperture of the lens used for focusing the spot as shown in Figure 38.

The spacing between two adjacent tracks on an optical data storage disk should be larger than or at least equal to r so that the *pickup head* reads the data without an error. The total data storage capacity on the disk depends on the resolution distance r , which in turn is a function of source wavelength λ and NA . The NA used in a compact disk lens is 0.45 (Pohlmann 1992; Rilum 2000). Currently, laser diodes in infrared region of wavelength 700–780 nm are used in an optical compact disk ROM.

Figure 37: Focused spot of light forming Airy's disks because of the diffraction of light from (a) a circular aperture and (b) two closely placed spots at resolution limit r

Figure 38: Numerical aperture (at the focusing side) = $n \sin\theta$

As an example, consider a laser diode with a 780-nm emission wavelength used in CD players for recording. The NA of the lens is 0.45 and hence, using the Rayleigh criterion, the resolvable distance of writing with a 780-nm laser is 1.06 μm ; and for an 830-nm laser, the resolvable distance is 1.13 μm . The standard distance between the adjacent tracks on a CD is 1.6 μm , which is larger than the minimum resolvable distance of 780 nm and 830 nm between the tracks.

To increase data storage capacity, shorter wavelength laser diodes emitting wavelengths in the blue region around 400 nm or shorter are required. Blue laser diodes are made of GaN-based materials such as InGaN, which emits in the wavelength range of 200 nm to 600 nm (Table 1). The blue laser diodes have great potential application for increasing the capacity of optical data storage. By using 405-nm blue laser diodes, the storage capacity can be increased by a factor of 2.6 times that of a *digital video discs* (Rilum 2000). Currently, 405-nm VCSEL diodes are available, but their price is still high for use in optical data reading and writing.

CONCLUSION

This chapter presents optical sources that are widely used in various devices and systems related to the field of computer communications, networking, and data storage. The main attention is given to the “workhorses” in the field: light-emitting diodes and laser diodes (fixed wavelength and tunable types). The chapter provides substantial overview of the theoretical foundations of the optical sources technology as well as discusses the technical implementations, benefits, disadvantages, and applications of the sources.

The current fast pace of the technological development in computer engineering and communications implies that new and more efficient optical sources will appear on the stage in the near future. This will lead to significant improvements in characteristics and functionality of existing devices and the systems employed in computer networking as well as to the development, practical implementation, and applications of devices and systems belonging to new generations of computer and data communications technology. For example, the notion of optical computing for many years has been deeply rooted in the scientific and engineering community. There are signs that practical optical computer systems may finally be realized in the near future. Optical computers would use sources with high direct-modulation rates to eliminate the requirement of external modulators, thus leading to the reduction of the optical source components.

Another good example where the progress in optical sources leads to serious advancement in a wide range of areas is the emergence of the commercial GaN blue laser diodes. As a result, the development and implementation of a new generation of high-density digital data storage systems, high-resolution laser printers, medical equipment, and so on is becoming a reality.

Intensive theoretical and applied research in the field of optical sources is currently under way in different countries carried out by a large number of scientists and

engineers. For example, substantial efforts by a number of research teams are currently focused on improving such characteristics of tunable laser diodes as output power, repeatability of the tuning range and wavelength, temperature stability, and easiness of tuning, among others.

GLOSSARY

Active layer: The area between two hetero-junctions where the electron-hole recombination and radiation (light) emission takes place inside a laser diode or a light-emitting diode.

Bragg grating: The perturbation of the effective refractive index inside a fiber or inside a laser diode where the reflection of optical wave takes place. The Bragg condition for the reflection grating is $d(\sin\theta_m - \sin\theta_i) = m\lambda$, where d is the spatial period or pitch of the grating, θ_m is the m th order ($m = 0, 1, 2, \dots$) reflection angle, θ_i is the incident angle, and λ is the wavelength. θ_m and θ_i are measured from the normal to the plane of the grating. In most cases for waves propagating inside *distributed Bragg reflector* (DBR) or *distributed feedback* (DFB) laser diodes, $\theta_i \approx 90^\circ$ and the Bragg condition becomes $d\sin\theta_m = m\lambda$.

Carrier lifetime: The time taken for the electrons in the conduction band to reduce to $\frac{1}{e}$ of the initial electron number because of the recombination process.

Digital video disc (DVD): Optical data storage disk on which high-density data such as movies with high-quality video and sound data can be recorded.

Fresnel equation: The mathematical expression describing the power reflectivity or reflectance R of an interface between two optical media with refractive indices n_1 and n_2 , respectively, for a perpendicular incident ray as $R = \left[\frac{n_1 - n_2}{n_1 + n_2} \right]^2$.

Group velocity dispersion: Pulse scattering while propagating in the fiber. The group velocity (i.e., velocity with which the intensity maximum propagates in a medium) of a pulse in a fiber depends on frequency. Thus, different spectral components of the pulse travel at different velocities and the pulse is dispersed as it is propagating in the fiber.

Hetero-junction: Junction between two different types of semiconductor materials—for example, the junction between InGaAsP and InP.

Homo-junction: Junction between two semiconductor materials of the same type but differently doped, such as the junction between P-type silicon and N-type silicon.

Junction capacitance: Resultant capacitance from the accumulation of minority carriers (electrons) in the P-type and (holes) in the N-type in the depletion region of a P-N junction.

Peltier effect: The phenomenon of heat transfer between two different metal junctions or two dissimilar semiconductor junctions when a current passes through them. The heat in one junction is carried away by the current and transferred to the other junction. This results in cooling of one junction and heating of the other.

Photon lifetime: The period of time (τ_p) during which the number of photons in a laser cavity decays to $\frac{1}{e}$ or 36.8 percent of the initial photon number after the pumping is stopped. If the initial number of photons in a laser cavity is $N_p(0)$, then the number of photons at time t after the pumping is stopped can be expressed as $N_p(t) = N_p(0)\exp(-\frac{t}{\tau_p})$, where τ_p is the photon lifetime in the cavity.

INTRODUCTION

Optical switching in the form of whole optical channel or *lambda* (λ) *switching*—that is, a network node switching to one specific output all of the data units of coming in on an optical channel—is well understood. However, the problem of switching fractions of the optical channel (also known as *sub-lambda switching*)—that is, a network node selectively switching to different outputs all of the subsets of the data units of an incoming optical channel—is more challenging and much less understood. Having the capability for sub-lambda switching would result in two basic advantages: (1) efficient use of switching and transmission capacities and (2) extension of the optical network all the way to the edges. Consequently, the two advantages have the potential to provide a major reduction in the overall optical network cost. However, technological challenges remain in realizing sub-lambda switching. This chapter presents and analyzes some of the possible solutions while assessing complexity, scalability, and cost.

To set the context and scope of this chapter, the following assumptions are made regarding sub-lambda switching.

1. No segmentation: Data packets of variable size are switched as a whole.
2. No “stopping” of the serial bit stream: Signals carrying data packets are switched at least once without being digitized—that is, without explicitly decoding and buffering the data packet in the electronic domain. In other words, bits flow continuously in either the optical or electrical domains.

The discussion on sub-lambda switching involves two basic topologies.

1. Linear topology networks: rings or buses in which data packets are possibly removed by their destinations—that is, spatial bandwidth reuse is deployed.
2. Mesh (arbitrary) topology networks.

It is assumed that both topologies form an undirected graph, which implies that data packet transmission is possible in both directions. Because data networks are interconnected to one another, the linear topology network has diminishing importance; therefore, the main emphasis of this chapter is on mesh topology networks.

The main benefit and therefore the motivation for sub-lambda switching are to save on the “expensive” operation of converting: (1) from electronic-to-optical and (2) from optical-to-electronic. However, several challenges must be considered and analyzed in depth to fully appreciate sub- λ switching. The main focus of this chapter is to examine various solutions to those challenges. The following are some of the challenges for sub-lambda switching in the optical domain:

1. Header decoding and processing.
2. Buffering or memory for storing data packets.
3. Speedup of memory access and switch fabric. Assuming that the speed of light is constant, in the optical domain (sub-lambda switching) speedup is always 1—that is, no speedup is possible.
4. Switch control and arbitration—that is, deciding which of multiple packets to forward through the switch to the same output port (also termed a many-to-one problem: from many input ports to one output port).

The main motivation for optical technology has been to solve bottleneck problems: transmission and switching.

Although transmission bottleneck was solved with *wavelength-division multiplexing* (WDM), solutions to the switching bottleneck are still undergoing research and development. Note that relying on overprovisioning to solve other networking problems such as delay and loss will inevitably worsen the switching bottleneck problem.

Definition 1: Sub-lambda switching. Each data unit is transmitted through optical fibers and switches—without any “stopping” of the serial bit stream—such that each data unit on a given optical channel may be treated differently by network switches.

Regarding *synchronous optical network* (SONET) in the optical domain, the following should be noted. SONET uses only frequency (or clock) synchronization with known bounds on clock and frequency drifts. To overcome possible data loss resulting from clock drifts, SONET uses complex overhead information to accommodate: (1) the accumulation of various delay uncertainties or jitter and (2) the continuous clock drifts from a nominal value. The SONET solution is a sophisticated forwarding of one-byte data units that are transported in time slots (TS). The TS duration in 10 Gb/s is less than one nanosecond. Consequently, it is not possible to realize the sophisticated SONET operation in the optical domain. Therefore, SONET is outside the scope of this chapter.

In the past decade, there has been significant progress in optical switching but further major improvements are still required as discussed in the next major section. As discussed later in “Whole Lambda Switching,” mapping the current model of asynchronous packet switching to sub-lambda switching is significantly more complicated than whole lambda switching. Asynchronous packet switching is based on four components: (1) transmission, (2) memory, (3) processing, and (4) switching. To achieve optical networking, all four components should be implemented in the optical domain. As summarized in Table 1, optical transmission is widely deployed, optical switching is commercially viable, optical processing is still difficult, and optical memory using optical fibers is feasible and well understood. However, as discussed later, optical memory is a major implementation obstacle that hinders the realization of optical asynchronous packet switching.

Given the scalability limitations of whole lambda switching soon to be discussed and the technical challenges of asynchronous sub-lambda switching as discussed in later sections, a novel synchronous sub-lambda switching is presented in “Synchronous Sub-Lambda Switching.” Finally, the conclusion summarizes this chapter and indicates future directions.

OPTICAL SWITCHING TECHNOLOGIES

The problem of switching, whatever the switched data unit is, can be broadly split into two parts: (1) the actions performed on data units in order to actually move them, which take place in the data plane; and (2) the logic behind it—that is, when and where data units should be moved through the switch, which is the responsibility of the control plane. Although the latter will be the focus of the next sections, below we survey existing solutions for the former in the optical domain—that is, where optical signals are moved from inputs to outputs.

Various technologies are currently available for switching optical signals, and they differ significantly according to various criteria. The main optical switching performance indexes are listed below in order to set a comparison framework before we survey the most popular switching technologies and evaluate them on the basis of the features that are most significant in the context set for this chapter. A more general but high-level and schematic comparison of switching technologies can be found in Ma and Kuo (2003), which also includes summary comparison tables.

Optical Switching Performance Indexes

The following indexes are used to assess optical switching performance.

- **Switching speed:** The time required to change input-output interconnections through a switch. This performance index is particularly critical when implementing sub-lambda switching because, as Definition 1 shows, the switch configuration needs to be changed between data units traveling on the same input optical channel and being switched onto different output optical channels. The lower the switching speed (i.e., the longer the time required to change the switch configuration), the longer the time distance between two subsequent data units and the lower the network throughput.
- **Bit-rate transparency:** Solutions that are transparent to the encoding of information transmitted on an optical channel provide more flexibility and breadth of use.
- **Insertion loss:** The power lost by an optical signal traversing a switch. Low insertion loss is key when signal regeneration should be avoided, which is important, for example, in limiting costs and safeguarding bit-rate transparency.
- **Power equalization:** Deals with the insertion loss changing along different routes (paths) inside the optical switch. This difference should be minimized when the switching pattern (i.e., input ports to output ports interconnection) is changing dynamically.

Table 1: Comparison of Whole λ versus Sub- λ Switching

	Optical Transmission	Optical Memory	Optical Switching	Optical Processing
Whole λ switching	WDM	Not needed	Solutions exist	Not needed
Sub- λ switching	WDM	Solutions exist (sophisticated)	Solutions exist (fewer)	Practical solution needed

- *Cross talk*: The signal interference between channels measured as the ratio of the power leaked to wrong outputs and the power conveyed to the correct output.
- *Polarization sensitivity*: A measure of polarization dependence.
- *Wavelength dependency*: Provides a measurement of how switch properties depend on the wavelength of optical channels being switched. Low wavelength dependency enlarges the deployment potential of a switch.
- *Multicast*: The capability of replicating an input optical signal to various outputs is desirable when multicasting services are to be implemented in the network.
- *Equipment dimensions*: As telecom equipment is usually installed in controlled environments of limited dimensions where space is a valuable resource and real estate is rented out on the basis of the footprint of equipment, their physical dimensions is a major concern as larger equipment imply higher operation cost.
- *Scalability*: As stated above, the main motivation for optical switching is the realization of large-scale, broadband communication infrastructures. The availability of switching elements with a large number of ports to be used as building blocks reduces the complexity of realizing large scale switches featuring (tens of) thousands of inputs and outputs.
- *Nonblocking operation*: Deals with the flexibility to interconnect any input to any idle output. Given that, as discussed later, optical memory is a delicate issue, optical switches need to be strictly nonblocking.
- *Power consumption*: Extremely important because it is connected to several types of costs, including
 - a proper power supply system,
 - the complex design of heat dissipation in the switching system,
 - the large amount of electrical power needed by the switching system,
 - the complex design of heat dissipation in the environment in which many units may be operating, and
 - the large amount of electrical power used by the air conditioning system for the environment in which possibly multiple units are operating.

Optical Switching Technology Overview

Among the various existing optical switching technologies, the ones based on the deployment of *micro electromechanical systems* (MEMS) (De Dobbelaere et al. 2002) are probably among the most mature, best understood, and most sensible from the economical and industrial viewpoints. In general, this solution is based on miniature devices with optical properties (e.g., mirrors, membranes, and waveguides) that perform mechanical actions in response to an electrical stimulus. A popular example is given by switches consisting of two- or three-dimensional arrays of micro mirrors that can be tilted by an electrical field to insert them or exclude them from the path of a light signal. The selection of the specific mirror within an array to reflect the signal determines the output port for the signal.

Common properties of MEMS switches are low cost, sensitivity to vibrations (because of the presence of moving

parts), high driving voltages, and high power consumption. Other performance indexes depend significantly on the specific technological solution. For example, switches based on mirrors or other electrostatic actuators have especially low insertion loss and cross talk, but the switching speed is on the order of milliseconds, thus making them unsuitable for sub-lambda switching. On the other hand, planar waveguide switches based on *silicon on insulator* (SOI) (Ollier 2002) are characterized by switching speeds on the order of tens of nanoseconds. However, only small SOI switching elements (1×2 , 2×2 , or $1 \times N$) are currently manufactured and can be used for realizing small scale switches, such as optical add-drop multiplexers. Instead, large size mirror-based switching elements are available (e.g., 512×512) whose scalability is limited by their own structure: the number of tilting mirrors required to build two- and three-dimensional arrays grows with the square and cube, respectively, of the number of inlets.

Thermo-optic switches are based on thermal phenomena of materials that can be exploited in various ways. Planar light-wave circuit technology leverages on the waveguide thermo-optic effect (Kasahara et al. 2002) and is being used in both digital optical switches and interferometric switches. Other kinds of thermo-optic switches are based on thermocapillarity (Sakata et al. 2001), thermally generated bubbles, and coated microsphere resonators (Tapalian, Laine, and Lane 2002). The size of commercially available switching elements varies significantly, depending on the specific technology. For example, 1×2 switches are built using coated microsphere resonators, whereas switching elements based on thermocapillarity can have a large number of inlets and outlets. In general, thermo-optic switches are characterized by low switching speed as the switch reconfiguration time ranges from a millisecond to tens of milliseconds.

Faster switching speeds, ranging from fractions of nanoseconds to tens of nanoseconds, are offered by *electro-optical switches*. The oldest optical switching solutions belong to this category and are based on the electro-optic properties of lithium niobate (LiNbO_3) and on *semiconductor optical amplifiers* (SOA). The former can lead to the implementation of either optical couplers based on interference or digital optical switches whose steplike response depends on the applied voltage (Krähenbühl et al. 2002). A more recent version of digital optical switch is based on lead lanthanum zirconium titanate, which leads to devices with especially good overall performance because of a higher electro-optic coefficient than LiNbO_3 (Nashimoto et al. 2001).

Although the first realizations of SOA-based switches (Gallego and Conforti 2002) used optical amplifiers as gates controlled by their bias current, more recent ones are based on Mach-Zehnder interferometers or multimode interference couplers (Earnshaw and Allsopp 2002).

Liquid crystal switches deploy an electro-optic effect to control the polarization of light (Riza and Yuan 1998). Having an electro-optic coefficient much higher than LiNbO_3 , liquid crystal is one of the most efficient electro-optic materials. However, this kind of switch is characterized by switching speeds on the order of milliseconds. Electroholographic optical switches (Pesach et al. 2000),

which are based on controlling the reconstruction of holograms by applying an electric field, feature nanosecond level switching speeds, but require extremely high voltages, which are impractical and expensive. Finally, electronically switchable waveguide Bragg gratings switches (Domash et al. 1997) are a combination of liquid crystal and electroholographic switches.

Acousto-optic switches exploit the properties of crystals such as tellurium dioxide (TeO_2) to enable ultrasonic waves to deflect light that traverses them (Enguang, Deming, and Ansh 2000). This technology is currently deployed to manufacture small size switches (e.g., 1×2) with submicrosecond switching speed.

Opto-optical switches exploit nonlinear optic effects in optical waveguides such as two-photon absorption, light-wave self-action, and the Kerr effect to obtain switching functions. Opto-optical switching technologies are still fairly immature and consequently not especially attractive for the near future.

WHOLE LAMBDA SWITCHING

Before we delve into sub-lambda switching, we discuss the advantages and shortcomings of *whole lambda switching* (W λ S), another type of optical switching. This can be used as a baseline in the evaluation of benefits and limitations of the various flavors of sub-lambda switching presented in the remainder of this chapter

Definition 2: Whole lambda switching. All data packets are transmitted through optical fibers and switches such that all data units on a given optical channel are treated the same way by network switches that may not digitize the optical signal carrying them.

Clearly, whole lambda switching represents a more significant paradigm change from current packet and circuit switching than sub-lambda switching does. However, because of its coarse switching granularity, no major technological challenge hampers the implementation and large-scale deployment of whole lambda switching; this is not the case for sub-lambda switching, as summarized by Table 1.

Whole lambda switching aims to create an optical channel between ingress point and egress point to the network such that data units transmitted at the ingress point reach the egress point through a number of optical switches. As switch input-output interconnections are modified only as a result of a provisioning or fault recovery action, a switch controller deployed in whole lambda switching is basically static. Consequently, switch reconfiguration occurs on a long time scale, and any of the various optical switch technologies and architectures presented in the previous section is suitable to whole lambda switching.

Similarly, a data source or a data destination changes optical channel only for provisioning or for fault recovery purposes. Consequently, optical transmitters and receivers with tuning time on the order of milliseconds can be deployed.

The main shortcoming of whole lambda switching stems from its coarse switching granularity. In particular,

whole lambda switching suffers a major *scalability* problem because it requires a dedicated optical channel between each pair of access points and egress points. Consequently, when a whole lambda switching backbone has n bidirectional access points, $n^2 - n$ optical channels (lambdas) are potentially required globally through the network. Whenever a new optical channel is set up, a wavelength is chosen for data transmission. A *wavelength routing and assignment* (WRA) problem must be solved in order to choose a wavelength and a path through the network such that the given wavelength is not being used on any of the links constituting the path (see, for example, the discussion in Ramaswami and Sivarajan 1995, 2002). In order for the optical channel to be feasible in the worst case (i.e., all the optical channels traverse the same link), $n^2 - n$ wavelengths are potentially required on each link between network nodes. A large body of literature is available on solving the WRA problem and minimizing the overall number of wavelengths required on each network link.

Given the number of wavelengths that commercially available WDM equipment accommodates on a single fiber, W λ S potentially requires parallel fibers to be deployed between nodes. This results in both an increase in the number of physical interfaces of optical switches and the deployment of large quantity of fiber, thus limiting the scalability of the solution and, in turn, undermining the very motivations (discussed at the beginning of this chapter) for resorting to optical switching. For the sake of a numerical example, let's consider an optical backbone with $n = 10,000$ access points, an average optical channel length of 1000 km, and WDM equipment that supports 100 wavelengths per fiber. To get an idea of the extent of W λ S scalability issues, consider the worst case requirement of wavelengths per link, which is on the order of n^2 or 10^8 wavelengths. The total amount of fiber required on such a backbone is 10^9 km (i.e., $[10^8/100] \times 1000$ km), which is equal to circling the Earth 25,000 times. Assuming that 10 km of fiber is 1 kg, the total amount of fiber required is approximately 100,000 tons!

Although the example just given obviously aims only to provide a general appreciation about the extent of the problem, with a smaller number of wavelengths per link there is a non-null probability that the network will be unable to accommodate an optical channel between an ingress point and egress point, although wavelengths are still available on a possible path. This so-called blocking probability depends on the capability of finding an optimal solution to the WRA problem.

Wavelength conversion reduces both the blocking probability and the complexity of the WRA problem—that is, the required number of wavelengths per link that ensures an optical channel between any ingress-egress pair. However, wavelength conversion performed in the optical domain is still an immature technology, and optoelectro-optical transformation is expensive (both in terms of space and power consumption), which works against the main motivations for deploying optical switching.

On the other hand, the WRA problem is made harder by constraints on the set of wavelengths available to ingress and egress points that stem from the tunability characteristics of transmitters and receivers. In fact,

transmitters and receivers that are capable of working on a wide range of wavelengths might be impractical from the point of view of cost.

In summary, W λ S scalability and efficiency issues lead to various trade-offs in the design and deployment of the technology and are a compelling reason for resorting to sub-lambda switching.

PHYSICAL DIMENSIONS OF OPTICAL MEMORY AND BUFFER

This section analyzes the implications in the optical domain of buffer dimensions traditionally associated with asynchronous packet switching. Although many important challenges exist in the optical domain with other issues such as processing, switching technologies, and switching devices, the discussion of optical memory is particularly significant because it clearly illustrates the need for departing from the current asynchronous packet-switching paradigm when considering the implementation of sub-lambda switching. Various techniques for reducing the memory/buffer requirements are discussed later in “Memory Reduction Techniques for Sub-Lambda Switching.”

The following assumptions are derived from what is known about optical devices today.

Assumption 1: Optical memory is implemented with optical fiber, made from silicon, with a diameter of 125 μm .

Thus, optical memory is a delay line or a pipeline with continuously “streaming” photons representing bits of information.

Assumption 2: The speed of light in optical fiber is 200,000 kilometers per second.

In the context of this work, the following two definitions are applied.

Definition 3: *Bulk optical memory* (BOM). An optical fiber that is capable of storing a predefined amount of bits encoded within an optical signal. The access to such bulk optical memory is strictly sequential—that is, first in, first out.

For example, a 1-km fiber is a bulk optical memory that can store 50,000 bits at 10 Gb/s.

Definition 4: *Optical random access memory* (O-RAM). An optical memory wherein each of the stored data units can be accessed at any predefined time (in general, RAM can be accessed at any time), independently of the order in which they entered the O-RAM.

For example, 1 km of fiber at 10 Gb/s tapped (e.g., with 1×2 optical switches) at regular 10-m intervals is an O-RAM that is capable of storing as many as 50,000 bits encoded in data units of 500 bits each. The data units can be accessed in any order through the taps. However,

because the data units are traveling at the speed of light, the access to a data unit at a different time will be done through a different tap. In other words, a common knowledge of time is required in order to use O-RAM.

Device-Level Analysis of Bulk Optical Memory

The physical dimension of optical memory is compared with that of electronic memory—that is, a *dynamic RAM* (DRAM) with equivalent capacity.

Raw Material

A synchronous DRAM chip that is capable of storing 256 Mbits is manufactured with state-of-the-art technology on a $10 \times 10^{-3} \times 10 \times 10^{-3} \times 0.5 \times 10^{-3} = 50 \times 10^{-9} \text{m}^3$ (or 50×10^{-6} liter) silicon chip.

A 256-Mbit optical memory for an optical signal encoded at 10 Gb/s (thus, each bit is stored in 2×10^{-2} meters of fiber) is realized with a $256 \times 10^6 \times 2 \times 10^{-2} = 5,120,000$ meter fiber. Because the fiber diameter, core, and cladding is 125×10^{-6} meter, the total volume is $\pi(125 \times 10^{-6}/2)^2 \times 5,120,000 = 62.8 \times 10^{-3} \text{m}^3$ or 62.8 liters.

Hence, the step from DRAM to optical memory corresponds to a more than 1 million fold decrease in information density. Consequently, if we assume shrinking of the silicon circuitry by a factor of two every eighteen months (as stated by Moore’s law), the transition to optical memory translates into a step back of thirty years (as far as device size is concerned)!

Packaging

The above-mentioned 256-Mbit synchronous DRAM chip is contained in a 66-pin package with a volume of $10 \times 10^{-3} \times 23 \times 10^{-3} \times 1 \times 10^{-3} = 230 \times 10^{-9} \text{m}^3$ or 230×10^{-6} liter.

The fiber needed to realize an equivalent optical memory can, for example, be rolled on a number of spools. For the sake of comparison, the packaging of Corning fiber is considered here. The longest spools that Corning sells are 25.2 km. Hence, building a 256-Mbit optical memory requires $5,120/25.2 \times 204$ spools occupying a volume of 767 liters (vs. 230×10^{-6} liter of DRAM) and weighing 461 kg. Hence, the step from packaging DRAM to packaging optical memory corresponds to a more than 3 million fold decrease in information density.

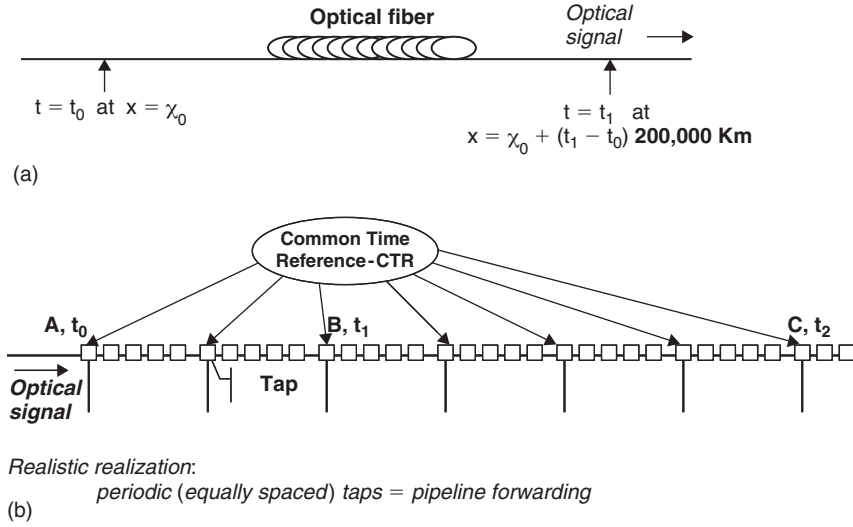

Subsystem Analysis of Bulk Optical Memory

Table 2 shows the physical dimensions of BOM required to implement buffers of typical sizes on state-of-the-art IP packet switches for one 10-Gb/s dense WDM channel. The volume and weight of the optical fiber rolled on 25.2-km spools are provided in the last two columns of Table 2. For example, the memory for an all-optical switch with 256 MB of optical memory per channel will weigh 3686 kg.

Obviously, weight is not the only realization constraint. Fiber length is another. *Amplification* is required to compensate the attenuation introduced by transmission over long fibers. Moreover, the signal degenerates because of the distortion introduced along the fibers and by the amplifiers; hence, after traveling a given distance, the

Table 2: Physical Dimensions of BOM for a Single 10-Gb/s Optical Channel

Buffer Size (MBytes)	Fiber Length (km)	Fiber Volume (lt)	Spool Volume (lt)	Spool Weight (kg)
128	20,480	251	3068	1843
256	40,960	503	6136	3686
1000	160,000	1963	23,969	14,400

**Figure 1:** The O-RAM (b) is time-dependent (a).

signal must be regenerated. *Regeneration* is an electrical, not an optical, process and encompasses the reamplification, retiming, and reshaping performed by repeaters. As shown in Table 2, the fiber length for a 256-MB buffer is 40,960 km (the same as the Earth's circumference).

Subsystem Analysis of Optical Random Access Memory

Random access implies that at any given time any part of the memory can be accessed. Because the stored optical bits travel along the optical fiber at the speed of light (see Figure 1a), at any given time the bits are in another position along the optical fiber. Consequently, to access such optical memory, there are two requirements (see Figure 1b).

1. *Infinite number of taps:* A tap realized by a 1×2 switch enables the light that is stored in the fiber to either continue along the fiber or be switched out of the fiber.
2. *Common time reference (CTR):* A precise knowledge of time is required in order to access a given sequence of bits at a given spot along the optical fiber. This knowledge of time should be based on the same time reference along the optical fiber (including the ingress edge), which is why it is called a *common* time reference.

Because an infinite number of taps is not feasible, access is possible at predefined times as stated in Definition 4. Two types of O-RAM, which are also referred to as (optical) *programmable delay lines* (PDLs), can be found in the literature: (1) linear delay line or *linear O-RAM* and

(2) parallel delay line or *parallel O-RAM*, shown in Figures 2a and 2b, respectively.

Discussion

The current high-speed, asynchronous packet-switching paradigm is well established with realistic implementation criteria based on optical transmission and electronic switching. The all-optical realization of this paradigm presents multiple challenges. This section has analyzed the optical memory challenge and shown that even though optical memory is well understood and feasible in principle, it hinders the implementation of the current high-speed, asynchronous packet-switching paradigm because of the huge physical size.

We further showed that O-RAM is time dependent and requires a common time reference. As we will show later in “Synchronous Sub-Lambda Switching,” CTR is not only required for realizing O-RAM but also essential for minimizing the amount of memory required per optical channel. Furthermore, by using CTR, it is possible to eliminate the need for optical header processing, which, as shown in Table 1, is one of the main challenges in realizing asynchronous sub-lambda switching (e.g., optical burst and packet switching), as discussed in the next sections.

ASYNCHRONOUS SUB-LAMBDA SWITCHING

The discussion on asynchronous sub-lambda switching is divided into mesh (arbitrary) topology and linear topology.

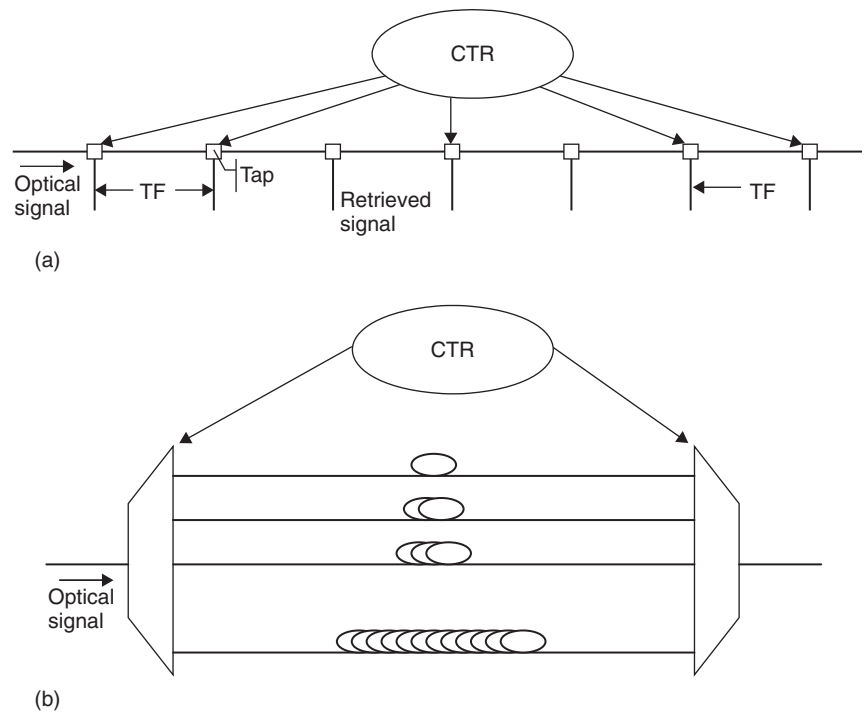

Figure 2: CTR with (a) linear O-RAM and (b) parallel O-RAM

Mesh Topology Networks

In the context of mesh topology, the main implication of asynchronous transmission of packets is that the traffic over the network is not coordinated. Therefore, data packets are subject to congestion and loss just as they are over any other asynchronous packet-switching network. Asynchronous packet switching is an obvious solution for sub-lambda switching because it provides a flexible division of the optical channel into fractions with two major advantages: (1) fine granularity and (2) statistical multiplexing. However, this approach suffers from high complexity because of the following:

- Packet headers are to be optically processed in real time.
- Packet level optical switching—that is, extremely short switching fabric reconfiguration time, is required.
- Without speedup and with limited processing, it is difficult to implement sophisticated scheduling algorithms such as weighted fair queuing, so the service can be unpredictable.
- The relative and well understood optical memory has prohibitive scalability limitation in the optical domain as discussed earlier.

In essence, even if there will be effective solutions for packet header processing and packet-level optical switching, the optical memory and buffer physical dimensions constitute an obstacle that may not be overcome in the foreseeable future.

Current activities on (asynchronous) optical burst switching (see, for example, the discussions in Turner 1999, Rosberg et al. 2003, and Vu et al. 2005) are focusing primarily on optical implementation issues, which are complex and challenging (e.g., header processing). Although burst-level (rather than packet-level) operation somewhat

simplifies some of the optical implementation issues (e.g., header processing and switching speed requirements), it does not affect the unresolved O-RAM issue. Because the relationship between *random access memory* (RAM) requirements and utilization in optical burst switching is not expected to be different from current IP switching, low utilization with reservation can be exploited to reduce RAM requirements. See “Optical Switching Techniques in WDM Optical Networks” for a complete discussion of optical burst and packet switching.

Sub-Lambda Switching over Linear Topology Networks

Linear topology networks have three primary variants: bus, ring, and star. Since the 1980s (see, for example, Ofek 1987) there has been a lot of research work on packet over optical bus and ring networks (see Kazovsky et al. 2000 and Marsan et al. 1997), effectively realizing sub-lambda switching. The main reason for the attractiveness of linear topologies for optical implementations is derived directly from their linearity: There is no congestion (because traffic inside the network has priority over external traffic) and buffering requirements are thus minimal. Conversely, as discussed later in “Memory Reduction Techniques for Sub-Lambda Switching,” in asynchronous sub-lambda switching over mesh networks there is congestion, and therefore buffering requirements can be prohibitively large.

The main types of linear topology applicable to sub-lambda switching are: (1) optical buffer insertion ring or bus (see Figure 3), (2) optical slotted ring or bus (see Figure 4), and (3) *passive optical* (star) *network* (PON) (see Figure 5). In the next subsections, these architectures are discussed. Note that there are many ways to describe and realize these ring, bus, and star architectures, and what is described in the following is only one possibility.

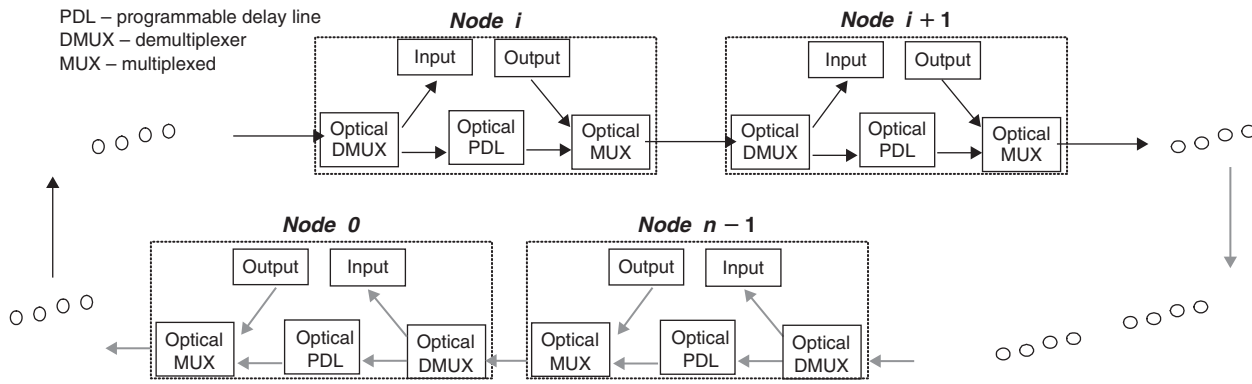

Figure 3: Optical buffer insertion ring or bus

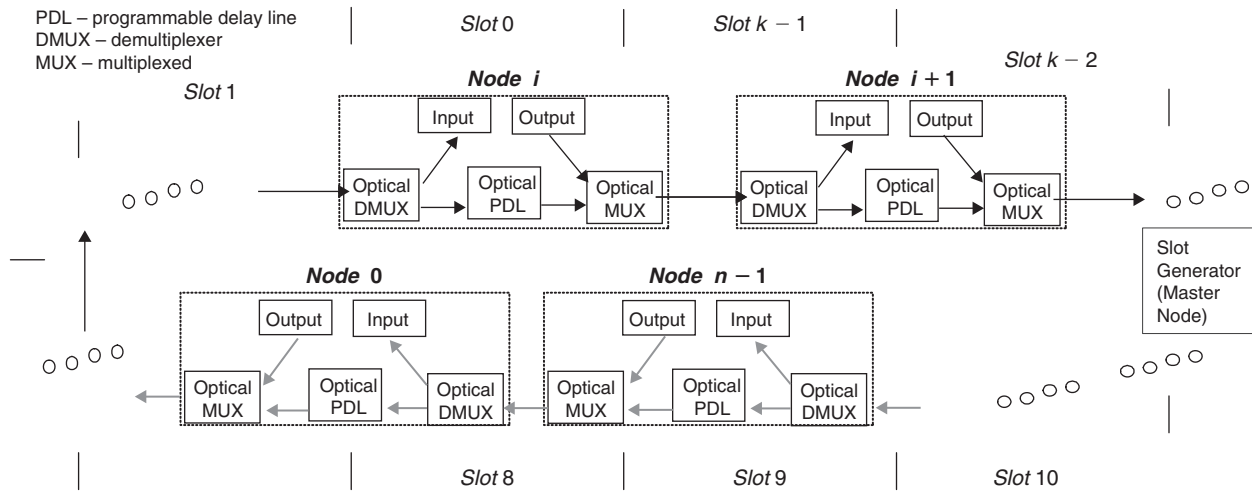

Figure 4: Optical slotted ring or bus

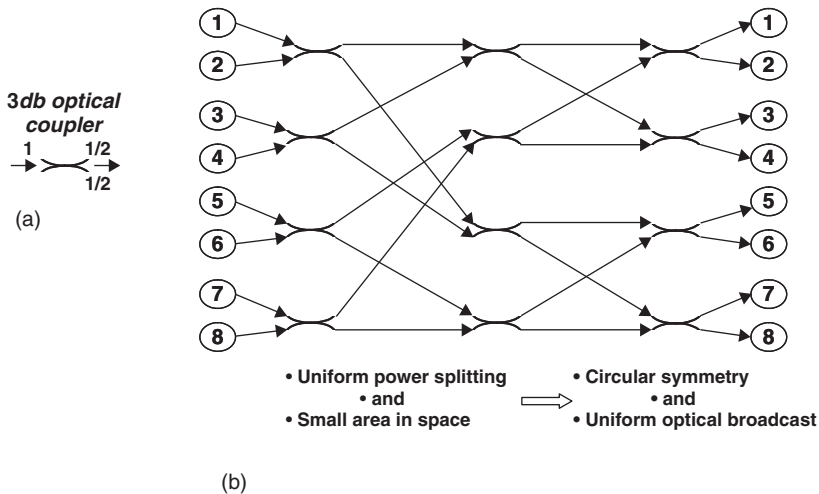

Figure 5: Passive optical network

Optical Buffer Insertion Ring or Bus

An optical buffer insertion ring or bus can be constructed in a way similar to how it is realized in the electronic domain (see, for example, Cidon and Ofek 1993). Figure 3 shows a ring with n nodes (0 to $n - 1$) that is designed

to transport variably sized data packets. Each node schematically consists of three parts:

1. An optical *demultiplexer* (DMUX) is a simple 1×2 optical switch that determines whether an incoming

packet should be switched to the node's input or to the optical PDL. This determination is based on decoding the packet header before switching. The header decoding can be done in the electronic domain by converting some of the incoming optical signal to electronics and then using the decoding results for controlling the optical DMUX.

2. An optical *multiplexer* (MUX) is a simple 2×1 optical switch that determines when data packets can be transmitted from the output of the node into the ring. This determination depends on the state of the optical PDL. If the optical PDL is empty, then the node can transmit a packet from its output. The optical MUX control can be done electronically after optically sensing the state of the PDL.
3. An optical programmable delay line can be implemented as shown in Figure 2. Multiple taps are needed to control how long a data packet is delayed by the optical PDL as explained below.

The principle of operation of an optical buffer insertion ring or bus is simple. An incoming packet has priority to be forwarded to the next node over an outgoing packet from the output of the current node. However, an incoming packet will be delayed by the optical PDL if, before its arrival, the node already started to transmit a packet. The maximum delay of an incoming data packet in the optical PDL is one maximum sized packet. This can happen when the node has started to transmit a packet just before the arrival of an incoming packet.

Optical Slotted Ring or Bus

An optical slotted ring or bus can be constructed in a way that is similar to how it is realized in the electronic domain (see, for example, Cidon and Ofek 1993). Figure 4 shows a ring with n nodes (0 to $n - 1$) that is designed to transport data packets with variable sizes. The main difference is that time is divided into time slots of fixed duration. The slots are numbered from 0 to $k - 1$ and are generated by a "slot generator" master node, as shown in Figure 4. Note that an optical slotted ring or bus is sometimes also called a *synchronous* ring or bus. As is apparent from Figure 4, the architecture of optical slotted ring nodes is similar to that of buffer insertion ring nodes.

The principle of operation of an optical slotted ring or bus is simple. Each slot can be either empty or full. Without loss of generality, it is possible to assume that a full slot contains exactly one fixed-size packet. An incoming packet—that is, full slot—has priority to be forwarded to the next node over an outgoing packet from the output of the current node. An incoming packet will be delayed by the optical PDL if, before its arrival, the node already started to transmit a packet. However, the maximum delay in an optical slotted ring can be (much) shorter than an optical buffer insertion ring. In principle, if a node decides to transmit or not transmit at the beginning of each time slot and if the transmission clocks on all links are identical and there is no accumulation of jitter, then the optical PDL can be eliminated. In reality, a small optical PDL is needed.

The node that generates the slots ("Slot Generator" in Figure 4) requires an optical PDL with maximum programmable delay of one time slot. This is necessary to ensure that there is an integer number of time slots (from 0 to $k - 1$) around the ring. Now, for fault tolerance and robustness, it may be reasonable to incorporate the slot generator functionality to all n nodes; consequently, the delay of the optical PDL on all nodes will be capable of introducing a one-time-slot maximum delay.

Passive Optical Network Sub-Lambda Switching

Passive optical networks are an attractive last-mile solution. The basic component typically used in implementing this architecture is the *optical coupler* or *star coupler*. The optical coupler (typically) splits the signal coming in to one of its two inputs evenly to the two outputs as shown in Figure 5a. A large shared (broadcast) medium can be constructed with an array of optical couplers as shown in Figure 5b.

Over the past twenty years, there have been many proposals on how to use optical couplers and PONs. Some of the proposals are synchronous (similar to slotted rings) (see, for example, Ofek 1987), and recent proposals are asynchronous with a medium access control protocol that is a derivation of Ethernet's and hence is called an *Ethernet PON* (EPON) (see, for example, Kramer, Mukherjee, and Pesavento 2001, and Kramer and Pesavento 2002).

The array of optical couplers as shown in Figure 5b can be constructed in a small area in space, so it is possible and simple to synchronize and coordinate the access of all nodes; see, for example, the method presented in Ofek (1988). Transmission in multiple lambdas can also be used on PONs (e.g., arrays of optical couplers); see, for example, the hybrid access protocol proposed in Ofek and Sidi (1993).

MEMORY REDUCTION TECHNIQUES FOR SUB-LAMBDA SWITCHING

Previously, we demonstrated that optical memory might be a major obstacle to realizing sub-lambda switching while assuming the current asynchronous packet-switching paradigm. Specifically, one of the previous sections calculated the physical dimension of optical memory based on optical delay line (i.e., optical fiber), showing that there is at least a factor of 1 million between fiber-based optical memory and solid-state memory. Then in the next section, we showed that sub-lambda switching based on linear topologies and asynchronous packet switching (optical packet or burst switching) on mesh topology provides only a partial solution. Specifically, linear topologies provide limited throughput, whereas optical packet or burst switching largely ignore the actual optical buffering requirement as it arises in equivalent asynchronous packet switching when implemented in electronics. Note that, in electronics, it is simple to implement highly flexible RAM, and therefore the buffering requirement should be lower than in an equivalent optical packet switching that is based on using programmable optical delay lines.

Low utilization is another assumption that is often associated with optical packet switching and optical

burst switching over a mesh network. Although optical transmission has high potential capacity, it is not free of charge (as more or less explicitly assumed by many proposed solutions). Furthermore, low utilization already characterizes electronic packet-switching deployment. Nevertheless, today's packet switches are using extremely large buffers that are known to significantly increase the cost of those switches. This dichotomy is extremely interesting, and only time will tell how best to realize asynchronous packet switching in the optical domain. However, it is important to evaluate in depth the relationship between network architecture and the corresponding memory and buffer requirements.

Although there are still unknowns regarding optical processing, amplification, regeneration, and so on, it is clear that the optical memory size should be reduced significantly. In this section, various memory reduction alternatives for mesh networks are analyzed. The analysis is based on the following engineering assumption.

Assumption 3: Optical fibers, optical channels, transmission bandwidth, network interfaces, memory size, memory access bandwidth, switching fabric capacity, protocol processing, and so on are not free of charge.

High-Level Analysis for Mesh Networks with Arbitrary Topology

First, some switching trade-offs are presented with two main parameters: *time* and *space*. The semantic of *time* in this context refers to whether there is a schedule for sending data units over the network or if there is no schedule. The semantic of *space* in this context refers to whether there is a predefined route for sending data units across the network or a nondeterministic route (i.e., the route was not defined before the data-packet transmission). Four cases shown in Table 3 can be defined by the time and space parameters.

Case 2 in the table is defined by having scheduled times for forwarding data units over nondeterministic routes, which results in a scheme that is not sensible. In other words, it is not practical to schedule the transmission of a data unit over a link when the data unit was actually routed elsewhere.

Case 3 corresponds to the current asynchronous packet-switching paradigm with large random access memory requirements. As discussed before, the current implementation of asynchronous packet switching is not practical for sub-lambda switching. Furthermore, in case 3, large RAM ensures low loss at the expense of long delays (i.e., possibly longer than the propagation delay between source and destination), and the throughput of streaming media applications can be defined only statistically. Note that case 3 also includes various load-balancing methods such as sending data units of the same flow over multiple routes and sending data units to intermediate destinations and to their final destinations.

However, although the relationship between utilization and RAM has been the subject of extensive research in the past three decades, there is still no definitive answer other than to keep utilization (extremely) low or to use (extremely) large RAM. Cases 1 and 4 have small buffer requirements (with no need for optical RAM), and therefore can be used for sub-lambda switching. As it will be shown later using (1) reservation, (2) scheduling, and (3) common time reference (e.g., coordinated universal time), it is possible to maintain full utilization without using any optical RAM (only programmable optical delay lines are required).

In case 4, various well-studied schemes can be used such as hot-potato routing (Baran 1964; Acampora and Shah 1992) or deflection routing (Maxemchuk 1987) as well as convergence routing (Ofek and Yung 1995). In these schemes, data units are stored for only a short period of time (thus requiring only small buffers that can be realized with programmable optical delay lines) and then are forwarded to the next switch even if it is not on the

Table 3: Time and Space Trade-Offs

Space Time	Predefined Routes	Nondeterministic Routes
Schedule	Case 1: Small buffers (RAM not needed)	Case 2:
Loss	None	Not sensible
Delay	Short	
Jitter	Constant	
Throughput	Deterministic	
No schedule	Case 3: Large RAM	Case 4: Small buffers (RAM not needed)
Loss	Low	None
Delay	Long	Long
Jitter	Large	Large
Throughput	Statistical	Unpredictable

best route to their destinations. Consequently, the number of switches traversed can be large, which implies long delays (i.e., much longer than the propagation delay on the shortest path between source and destination). Because data units can be forwarded over a large number of links and a source can transmit only when an outgoing link is idle, the transmission throughput between source and destination is unpredictable. Consequently, their unpredictable delay and throughput make the schemes of case 4 unsuitable for streaming media applications. However, these schemes can perform distributed-computing and parallel-processing applications exceptionally well.

Case 1 has no loss, short delay (i.e., close to the propagation delay between source and destination), and deterministic throughput. Therefore, case 1 is suitable for streaming media applications. Case 1 is traditionally associated with *circuit switching* (CS)—for example, SONET. CS is based on byte-by-byte multiplexing, which is not possible in sub-lambda optical networking. A special case of case 1 is static or whole lambda switching, as discussed earlier. Whole lambda switching is simple to implement; however, as mentioned, its scalability is limited by the n square problem (i.e., the potential need of n^2 optical channels) and low utilization (i.e., provisioning of a full wavelength when only a fraction is needed).

The problems that arise with whole lambda switching are fully solved by sub-lambda switching under the conditions of case 1 by a solution called *fractional lambda switching*, which dynamically allocates fractions of an optical channel (i.e., lambda) over predefined routes in the network. This solves the n square problem while ensuring full utilization. Each lambda fraction or *fractional lambda pipe* (FLP) is equivalent to a leased line in CS.

SYNCHRONOUS SUB-LAMBDA SWITCHING

This section describes *fractional lambda switching* (FLS), the novel synchronous sub-lambda switching solution (see, for example, Baldi and Ofek 2003, 2004; Grieco, Pattavina, and Ofek 2005; Nguyen et al. 2005; Ofek 2005), and gives the rationale for its importance and suitability. FLS is based on using a CTR in which time is divided into time frames of duration T_f . Time frames can be viewed as “virtual containers” of IP packets. The time duration of a time frame is a parameter that may change according to the optical link rate. For example, for 10 Gb/s with $T_f = 20 \mu\text{s}$, the virtual container may store as many as 200 Kbits or 25 Kbytes of variably sized IP packets. For this and various other reasons, time frames are quite different from SONET frames and slots. As an example, time frames begin with an explicit delimiter symbol (like the framing flag in PPP), and the contents of two neighboring time frames are separated by a safety margin, which simplifies the implementation of this synchronous sub-lambda switching method.

Another difference between SONET and FLS is that the latter eliminates clock drifts by using a CTR as discussed in the next section. One common time reference established today is the time-of-day international standard called *coordinated universal time* (UTC; also known as

Greenwich mean time, or GMT). Specifically, time is measured by counting the oscillations of the cesium atom in multiple locations. In fact, 9,192,631,770 oscillations of the cesium atom define one UTC second. UTC is available everywhere around the globe from several distribution systems, including U.S. global positioning system (GPS) satellites, the Russian Federation satellite system (GLO-NASS), and, in the near future, Galileo (the European Union and Japanese satellite system). There are other means for distribution of UTC such as the CDMA cellular telephone system and the two-way satellite time and frequency transfer (TWFT) technique based on communications satellites. UTC receivers from GPS are available from many vendors with an accuracy of 10–20 nanoseconds. By combining UTC from GPS with local rubidium or cesium clocks, it is possible to have a correct UTC ($\pm 1 \mu\text{second}$) without an external time reference from GPS for days (with a rubidium clock) and months (with a cesium clock).

FLS Principles of Operation

The operation of FLS is based on the following principles, which are necessary to realize UTC-based *pipeline forwarding* (PF) of time frames— T_f —as shown in Figure 6.

1. Switching of time frames: (a) Each time frame has a predefined duration and contains a payload (plurality of IP packets) with a maximum predefined size (i.e., number of bytes); (b) between two successive payloads there is a safety margin or idle time of a predefined duration; and (c) the payload of a time frame (plurality of IP packets) is switched as a whole from input to output.
2. The idle time or safety margin between two successive payloads is used to change the switching matrix (or permutation) of the optical switch so that the payload of each time frame of a given optical channel can be switched to a different output. This idle pattern can also be used as an explicit delimiter between time frames.
3. Common time reference is UTC and coupled to all switches. The UTC second is divided into a predefined number of equal duration time frames as shown in Figure 7. Time frames are grouped into *time cycles*, and time cycles are grouped into *super cycles*, with the super cycle equal to one UTC second as shown in Figure 7.
4. All received time frames are aligned to UTC such that the delay between inputs of adjacent optical switching fabrics and, consequently, between the inputs of any two optical switching fabrics after alignment is an integer number of time frames. The alignment operation is performed before the optical switching so that time frames coming in to all of the inputs begin at the same time (i.e., are aligned) as shown in Figure 8.
5. A periodic switching pattern through the optical switching fabric repeats every time cycle or super cycle. In other words, during every time frame within a time cycle (or super cycle) the optical switching fabric has a predefined input-output configuration, and the sequence of the input-output configurations repeats every time cycle (or super cycle). This implies that for

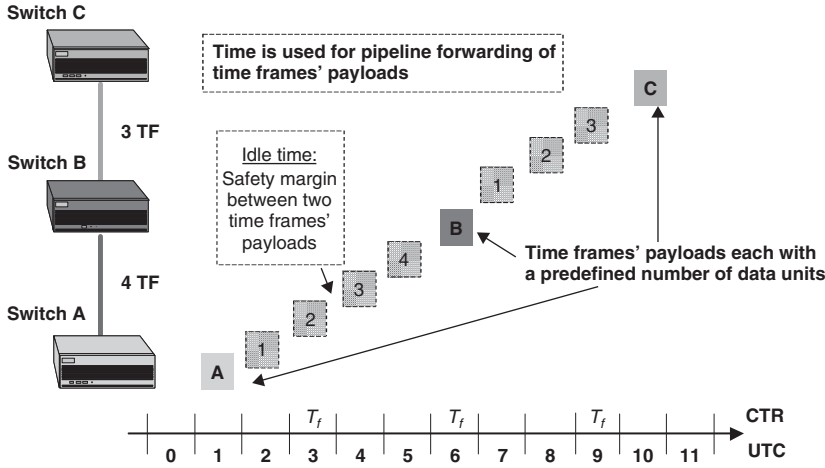

Figure 6: UTC-based pipeline forwarding of time frames

Figure 7: UTC with $T_f = 12.5 \mu s$

every time frame within a time cycle (or super cycle), (a) the time frame payload is switched to a predefined output and (b) the switching fabric configuration during one time frame is known before its beginning—that is, switch control has low complexity.

UTC-Based Pipeline Forwarding over a Fractional λ Pipe

A fractional lambda pipe, p , is defined along a path of successive F λ S switches: $S_p(1), S_p(2), \dots, S_p(k)$ such that

the forwarding of a time frame along p has a predefined schedule. More specifically, let:

1. the delay in time frames between inputs of successive optical switching fabrics along p be $d_{1,2}, d_{2,3}, \dots, d_{k-1,k}$;
2. the time cycle and super cycle duration be c and s time frames, respectively; and
3. the scheduling per F λ P repeat itself every $c(s)$ time frames.

Then a time frame forwarded along path p from $S_p(1)$ at t_0 will be forwarded by $S_p(2)$ at $(t_0 + d_{1,2}) \bmod c$ by $S_p(3)$ at $t_0 + d_{1,2} + d_{2,3} \bmod c(s)$, and so on; and it will reach the last switch of p , $S_p(k)$, at $t_0 + d_{1,2} + d_{2,3} + \dots + d_{k-1,k} \bmod c(s)$.

The capacity allocated to an F λ P is determined by the number of allocated time frames in every time cycle (or super cycle). For example, if $c = 100$ and one time frame per time cycle is allocated for an F λ P, then the capacity of the F λ P is 1/100 of the optical channel capacity.

Thanks to PF, if all F λ Ps are unchanged, the switching and forwarding operations along all F λ Ps at all time frames are known in advance in a reoccurring order every time cycle or super cycle. Consequently, all switches

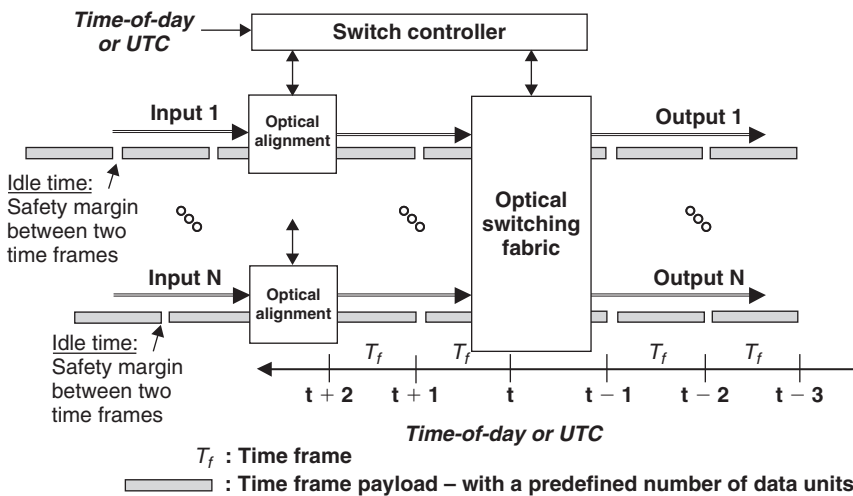

Figure 8: Incoming time frames are aligned with UTC before reaching the optical switching fabric

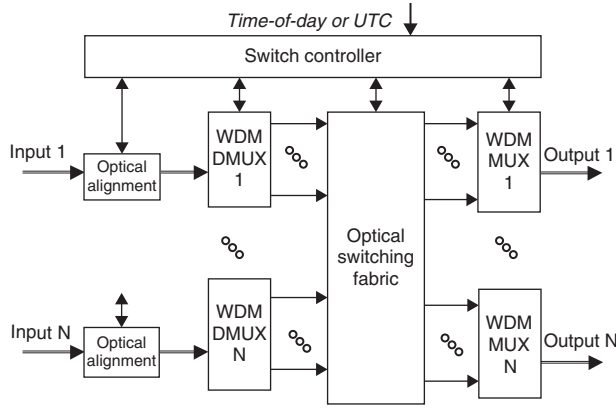

Figure 9: Optical switch with per-optical-fiber alignment

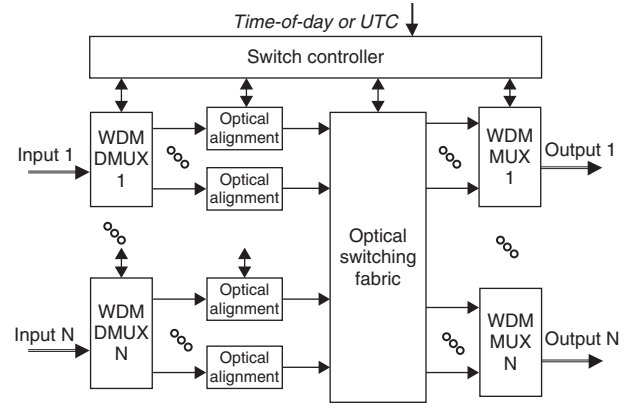

Figure 10: Optical switch with per-optical-channel alignment

know in advance the switching and forwarding operations that are to be performed during every time frame, which greatly simplifies the implementation of the switch controller. The deterministic operation of PF makes F λ S suitable for interactive and noninteractive multimedia applications (Baldi and Ofek 2000) and group communications (Baldi, Ofek, and Yener 2000) on a global scale.

CTR and UTC Accuracy

The required CTR accuracy, and hence UTC accuracy, directly affects stability, implementation complexity, and (consequently) cost. With a time frame delimiter, either explicitly transmitted or realized by the idle time between the payloads of two successive time frames, the required UTC accuracy is $\frac{1}{2} \times T_f$ [i.e., $\text{UTC} \pm \frac{1}{2} (20 \mu\text{s to } 100 \mu\text{s})$]. The reason for such a relaxed requirement is that the UTC is not used to detect the time frame boundaries (because they are detected by the idle times or the explicitly transmitted delimiters) but only to enable the correct mapping of the incoming time frames to the CTR time frames. It is easy to show that as much as $\frac{1}{2} \times T_f$ timing error can be tolerated while maintaining the correct mapping of time frames and without requiring extra buffering.*

F λ S Switch Architecture

Two F λ S switch architectures are shown in Figures 9 and 10. The main difference between them is where the alignment operation is performed: before the WDM DMUX as in Figure 9 or after the WDM DMUX as in Figure 10. Placing the alignment function before the WDM DMUX is more efficient because it can be done simultaneously on multiple optical channels. However, in some cases, because time frames of different optical channels may be skewed in time over a long fiber, the alignment should be performed on each optical channel separately.

Alignment implies that the beginning of all time frames are aligned with respect to UTC before switching. Implementation of the alignment subsystem in the electronic domain has low complexity because it requires only three queues without memory access speedup with

respect to the input link bandwidth. An optical implementation of the alignment subsystem can be based on a simple optical, programmable delay line. The advantage of optical alignment is it can be performed on multiple optical channels at the same time, provided that the different speed of light did not shift the optical channels too much from one another.

A *switch controller* changes the configuration of the switching fabric before the beginning of each time frame. For each time frame, a switching matrix contains the input-output connections the switching should realize during that time frame. The switch controller can take as much as a whole time frame to download the next switching matrix. Because the switch reconfiguration is so simple and slow (comparable with the control of a T1 add-drop multiplexer), the switch controller can be implemented by means of a microprocessor or a field programmable gate array without requiring the development of complex and costly application-specific integrated circuits.

Each time an F λ P is set up or torn down, the switch controller updates the switching matrices corresponding to the time frames allocated to the F λ P. Switch controllers of adjacent switches exchange signaling messages to handle F λ P creation and release. For example, the resource reservation protocol deployed in the generalized multiprotocol label-switching framework can be adopted as signaling protocols in F λ S networks. Notice that, for scalability purposes, the switch controller can include two processors that can easily coordinate the parallel execution of their tasks: one handling switching fabric reconfiguration, the other dealing with signaling and updates of switching matrices.

The properties of F λ S can be leveraged also in the design of the switching fabric. Nonblocking switching fabrics and speedup (i.e., transfer rate through the switching fabric higher than the transmission rate on input and output interfaces) are commonly used to maximize the throughput while simplifying the scheduling of the data unit transfer. Deployment of blocking switching fabrics is not practical solution in either circuit switches or packet switches, but it is appealing because of the minimum complexity and hence high scalability and low cost. For example, an $N \times N$ crossbar switch (which is, in the strict sense, nonblocking) contains N^2 crosspoints. However,

*An arbitrary timing error can be tolerated on UTC by adding a corresponding buffering capability in the alignment system.

an $N \times N$ Banyan switching fabric implemented, for example, by interconnecting $\log_2 N$ stages of $N/2 \times 2$ crossbar switches (four crosspoints each) contains $2N \times \log_2 N$ crosspoints. For example, a tenfold increase in the required input-output capacity results in a thousand-fold increase in the complexity and cost for a crossbar but only a thirty-fold increase for a Banyan switching fabric.

In F λ S, the scope of contention on internal switching resources is limited to a single time frame, and scheduling can be performed—and optimized—off-line (i.e., at F λ P setup time). Consequently, blocking can be avoided during switching pattern computation by avoiding conflicting input-output connections during the same TF. Results in Baldi and Ofek (2004) show that (especially if multiple WMD channels are deployed on optical links between fractional λ switches) high link utilization can be achieved with negligible blocking, even when the switching fabric is a Banyan network without speedup.

CONCLUSION

Sub-lambda switching is quite challenging. It has the potential to save on the costly conversions from electronic to optical and from optical to electronic while achieving efficient resource utilization. However, unlike optical transmission and whole lambda switching, sub-lambda switching presents a multitude of challenges that result from the need to perform certain operations in the optical domain. Such operations include (1) buffering, (2) sub-microsecond switching time, (3) decoding control information, and (4) changing transmission bit rate. Although such operations are well understood and easily performed in the electronic domain, there is a clear need for further major advancements in high-speed optical switching and processing.

Fractional lambda switching was proposed as a novel optical switching paradigm with the following properties (Baldi and Ofek 2004; Grieco, Pattavina, and Ofek 2005; Nguyen et al. 2005; Ofek 2005): (1) eliminating the need for random access memory, (2) minimizing the need for optical buffers (only used for alignment with UTC), (3) reducing the switching complexity from both the control and switching (optical fabric with speedup of 1 and Banyan topology) point of view, and (4) eliminating the need for header processing, which remains a major challenge in the optical domain.

F λ S uses a global common time reference that is realized with UTC to implement pipeline forwarding of time frames, which are virtual containers of 5–20 Kbytes each. Pipeline forwarding over a meshed F λ S network requires that the delay between any two switching fabric inputs be an integer number of time frames, which is realized with an alignment to UTC operation before each switching fabric input. Because the time frame boundaries are explicitly identified, a relaxed UTC accuracy of less than one-half of a time frame suffices.

The efficient and deterministic bandwidth provisioning of F λ S enables the optical core to be extended toward the edges of the network in the metro and enterprise, thus confining costly header processing to the low-capacity periphery. The fractional lambda pipes realized in F λ S networks have the same deterministic characteristics as

leased lines in SONET and circuit emulation in ATM. Consequently, F λ S eliminates the need for SONET or other service protocols, thus enabling a network “nirvana” in which IP and MPLS packets travel from source to destination without format conversion.

Although F λ S is suitable for all-optical implementation, given the state of the art of commercial technology, the most sensible, cost-effective, and scalable solution for sub-lambda switching today is a best-of-breed switch featuring optically interconnected, integrated electronic switching elements.

GLOSSARY

Alignment: The delay between inputs of adjacent switching fabrics and, consequently, between the inputs of any two switching fabrics after alignment, is an integer number of time frames.

Bulk Optical Memory (BOM): An optical fiber capable of storing a predefined amount of bits encoded within an optical signal. The access to such bulk optical memory is strictly sequential or first in, first out.

Common Time Reference (CTR): A common reference established today is the time-of-day international standard called *coordinated universal time* (UTC) or *Greenwich mean time* (GMT). In the context of F λ S, the CTR is realized by dividing the UTC second into a predefined number of equal duration (T_f) time frames that are grouped into *time cycles*; time cycles are grouped into *super cycles*, wherein the super cycle is equal to one UTC second.

Fractional Lambda Pipe (F λ P): Defined along a path of successive F λ S switches: $S_p(1), S_p(2), \dots, S_p(k)$ such that the forwarding of a time frame along the F λ P has a predefined schedule. Consequently, the switching and forwarding operations along all F λ Ps at all time frames are known in advance in a reoccurring order every time cycle or super cycle.

Fractional Lambda Switching (F λ S): A novel synchronous sub-lambda switching solution based on using a common time reference.

Optical Random Access Memory (O-RAM): An optical memory wherein each of the stored data units can be accessed at any predefined time (in general, RAM can be accessed at any time), independently of the order in which they had entered the O-RAM.

Optical Switching: The actions performed on data units in the optical domain in order to actually move them from the inputs to the outputs of network nodes.

Pipeline Forwarding (PF): A periodic switching pattern through switching fabrics and forwarding pattern through links that repeats every time cycle or super cycle, ensuring that for every time frame within a time cycle (or super cycle) the time frame payload is switched to a predefined output and forwarded to the next hop on its path to the destination.

Sub-Lambda Switching: Network nodes selectively switch to different outputs subsets of the data units incoming on an optical channel—that is, data units are transmitted through optical fibers and switches such that each data unit on a given optical channel may be treated differently by network switches.

Time Frame: Virtual container of 5–20 Kbytes.

Whole Lambda Switching (W λ S): Network nodes switch to a specific output all of the data units coming in on an optical channel—that is, data packets are transmitted through optical fibers and switches such that all of the data units on a given optical channel are treated the same way by network switches.

INTRODUCTION

Optical cross connects (OXCs) are the fundamental building blocks in a seamless, intelligent, and high-capacity optical transport network. An OXC is an optical switching system that can incorporate several compelling features, including wavelength conversion (making use of all available wavelengths to improve wavelength utilization), improvement of signal quality through reamplifying, reshaping, and retiming of the optical signal (known as *3R regeneration*), and implementation of network protection and restoration to provide the desired optical circuit (lightpath) availability in accordance with the service-level agreement signed with customers. OXCs are essential for provisioning lightpaths in a large optical mesh network automatically without having to perform manual patch panel connections (Iannone and Sabella 1996). This capability is of particular importance in dealing with a large number of wavelengths and nodes in any future large optical transport network. It is also important when the lightpaths in the network need to be reconfigured rapidly to match dynamically changing traffic demands and traffic patterns. The OXCs also play important roles in network management functions, such as performance monitoring and alarm handling. OXCs can detect failures in the network and rapidly reroute lightpaths around the failure.

To establish a lightpath between a pair of source and destination nodes, it is generally required that the same wavelength be assigned to all of the fiber links along the path. This requirement is known as the *wavelength continuity constraint*. Optical networks with such a constraint are generally referred to as *wavelength path* (WP) networks (Sato, Okamoto, and Hadama 1994). A simple example of such a network is shown in Figure 1a; five OXC nodes are interconnected by seven bidirectional fiber links. Assume that each bidirectional fiber link has two fibers transmitting in opposite directions and each fiber has two wavelengths available. As shown in Figure 1a, there are three bidirectional lightpaths in progress in the network, each of which is assigned with a single wavelength. For instance, the first lightpath between nodes 1 and 3 uses wavelength λ_1 , the second lightpath between nodes 2 and 4 uses λ_2 , and the third lightpath between nodes 1 and 4 uses λ_1 . Wavelength λ_1 is used in two lightpaths

simultaneously, while the second lightpath uses λ_2 . Now if a new lightpath is requested to be set up between nodes 3 and 5, this lightpath cannot be fulfilled because of wavelength continuity constraint, even though along the path, the links (3, 4) and (4, 5) each have a free wavelength, λ_1 and λ_2 , respectively. The wavelength continuity constraint distinguishes a WP network from a circuit-switched network where call blocking occurs only if there is no capacity on any of the links along the path assigned to the call. Therefore, effective routing and wavelength assignment algorithms are essential to ensure the network resources are efficiently utilized in WP networks (Ramaswami and Sivarajan 1995).

Wavelength continuity constraint can be eliminated if a wavelength can be converted to another wavelength at any OXC node in the network. Optical networks that are capable of wavelength conversion are generally referred to as *virtual wavelength path* (VWP) networks (Sato, Okamoto, and Hadama 1994), where a lightpath may have different wavelengths over different links along the route. Under the same situation as that in Figure 1a, Figure 1b shows that a new lightpath request can then be set up between nodes 3 and 5, using wavelength λ_2 on link (4, 5) and wavelength λ_1 on link (3, 4). Studies

Figure 1: A simple example showing lightpaths between nodes for (a) a WP network and (b) a VWP network

in Sato, Okamoto, and Hadama (1994) have shown that a VWP network can improve network blocking performance with relaxed network control and management at the expense of increasing implementation costs because of the requirement of wavelength converters.

This chapter describes and examines various configurations and architectures of OXC that are reported in the literature. The rest of the chapter is organized as follows. The next section discusses two generic OXC architectures, of which one is for WP networks and the other for VWP networks. The section following after describes and discusses several typical wavelength-selective OXCs. “Wavelength Interchangeable OXCs” describes and investigates OXCs that use either space switching or wavelength switching. The last section before the conclusion presents and discusses OXCs that are capable of multicasting.

GENERIC OXC ARCHITECTURES

Depending on their wavelength conversion capability, OXCs are generally classified as being either *wavelength-selective OXCs* (WS-OXCs) or *wavelength-interchangeable OXCs* (WI-OXCs). A WS-OXC can switch a wavelength channel from any input fiber to any output fiber, but it cannot change its wavelength. Hence, WS-OXCs are used in WP networks. A WI-OXC not only can switch a wavelength channel from any input fiber to any output fiber but also can change an input wavelength to a different output wavelength. WI-OXCs are essential for VWP networks. In practice, WI-OXCs may only have limited wavelength conversion capability. In a limited wavelength convertible OXC, only a subset of the input wavelength channels have a chance to use the wavelength converters (e.g., on a first come, first serve basis), and hence only a subset of the input channels can be converted to different output wavelengths (Chai et al. 2002). In this chapter, we only consider WI-OXCs with full wavelength conversion capability. In both WS-OXC and WI-OXC, wavelength routing (cross connection) is achieved by wavelength-selective elements (such as wavelength multiplexers and demultiplexers and optical

filters) or optical space switches. For example, a fixed wavelength routing OXC will probably use *wavelength-division multiplexers* (WDMs) in a back-to-back configuration to allow the interchange of wavelengths between the input and output fibers in a predetermined pattern. A more advanced and intelligent OXC is usually made with optical space switches or other tunable components so that wavelength channels can be reconfigured arbitrarily. Using such reconfigurable wavelength routing OXCs, each wavelength on any input fiber can be routed to any output fiber provided that the output fiber is not using that wavelength. The capability of reconfiguring wavelength channels is a critical feature in optical networks because the traffic demand and its pattern are unlikely to be static but will change dynamically.

Figure 2a and 2b show the generic architectures for WS-OXCs and WI-OXCs, respectively. Both architectures are based on wavelength multiplexers and space switch matrices. Unless otherwise specified, throughout this chapter we assume that the number of input-output fibers connected to an OXC is N and the number of wavelengths carried in each fiber is M . Hence the total switching capacity is proportional to NMB , where B is the bit rate per wavelength channel. The basic operation for both the WS-OXC and WI-OXC is that they select wavelengths and rearrange them in the spatial domain. Throughout this chapter, an OXC with N inputs and N outputs is generally denoted as an $N \times N$ OXC. Similarly, an optical device with i inputs and j outputs is denoted as an $i \times j$ device.

As shown in Figure 2a and 2b, the incoming WDM signals entering at each input port (fiber) are first demultiplexed using wavelength *demultiplexers* (DMUXs) and then fed into the space switch where individual incoming wavelength channels are routed toward different output channels. Wavelength channels that are routed to a particular output fiber are combined by a wavelength *multiplexer* (MUX) or an optical coupler. The difference between WS-OXCs and WI-OXCs is the wavelength conversion function that is incorporated within WI-OXCs. In Figure 2b,

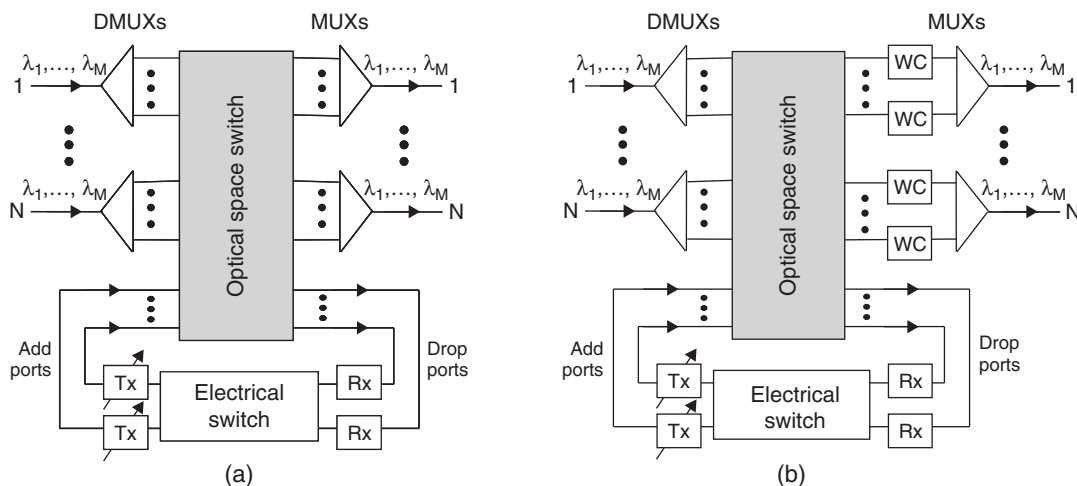

Figure 2: Generic OXC architecture—(a) wavelength-selective OXC and (b) wavelength-interchangeable OXC

the *wavelength converters* (WCs) are placed at the output side of the switch matrix. It is also possible to locate the WCs at the input side of the space-switch matrix. The former case can use fixed wavelength converters, whereas the latter case requires tunable WCs, which are more expensive and complicated than fixed WCs. As illustrated in Figure 2, apart from wavelength channels being cross connected from a particular input fiber to a particular output fiber, some wavelength channels may be terminated (dropped) at the OXC node and new channels may be added to the network from the local node. The dropped wavelengths are converted into electrical signals and then fed into an electrical (packet) switch or router that not only can provide low-speed electronic traffic grooming (aggregation) but also perform packet switching or routing. Traffic grooming is important in high-capacity optical networks, through which many low-speed traffic flows (streams) are packed (multiplexed) into a high-capacity lightpath so as to efficiently utilize optical wavelengths and optimize network throughput. A detailed study on OXCs incorporating traffic grooming can be found in Zhu, Zang, and Mukherjee (2003). As illustrated in Figure 2, the channels that are added from the electrical switch to the optical switch may have tunable wavelengths.

An OXC is usually referred to as an *optical add-drop multiplexer* (OADM) if the number of input-output fibers is one (Giles 1999). An OADM can be made to be fixed or reconfigurable. A fixed OADM can drop and then add one or more fixed wavelength channels, whereas a reconfigurable OADM can arbitrarily drop any one or more wavelength channels among the incoming wavelength channels and then add the same number of wavelength channels as the dropped ones (Tran et al. 2001). This chapter focuses on OXCs with multiple input and output fibers. For simplicity of description, we will omit add-drop ports and the electronic switch in the description of the various OXCs in the rest of this chapter.

From the point of view of blocking performance, OXCs may be classified as nonblocking and blocking (Clos 1953). A *blocking OXC* may not be able to connect an idle (free) input wavelength channel λ_i on any input fiber to any output fiber, even if λ_i is not being used on that output fiber. *Nonblocking OXCs* are further divided into strictly nonblocking and rearrangeably nonblocking OXCs (Clos 1953). If a WS-OXC is *strictly nonblocking*, then any idle input wavelength channel λ_i on any input fiber can always be connected to any output fiber without disturbing any existing connections, provided that λ_i is not being used on that output fiber. If it is *rearrangeably nonblocking*, then any idle input wavelength channel λ_i on any input fiber can be connected to any output fiber by rerouting some of the existing connections, provided that λ_i is not being used on that output fiber. A strictly nonblocking WI-OXC is capable of connecting any idle input wavelength channel on any input fiber to any output fiber without disturbing any existing connections, provided that that output fiber has at least one free (unused) wavelength. A rearrangeably nonblocking WI-OXC is capable of connecting any idle input wavelength channel on any input fiber to any output fiber by rerouting some of the existing connections, provided that that output fiber has at least one free (unused) wavelength. The blocking performance of the two generic OXCs

in Figure 2a and 2b depend on the blocking properties of the optical space switch matrices used.

Optical space switches are the basic components for OXCs. Various types of optical space switches based on a variety of technologies have been developed. These include electro-optic switches that use lithium niobate (LiNbO_3) material in the form of a Mach-Zehnder interferometer; thermo-optic switches that make use of thermo-optic effects to achieve switching; acousto-optic switches, *semiconductor optical amplifier* (SOA) switches, bubble-based optical waveguide switches, and *micro-electromechanical system* (MEMS) switches. Large switch matrices can be constructed by smaller switch modules using multistage interconnection networks such as a Clos network (Clos 1953), a Benes network (Benes 1962), or a Spanke network (Spanke 1987).

Apart from space switches, wavelength converters are essential in the implementation of WI-OXCs. There are mainly two different ways to build wavelength converters: an opto-electronic approach and an all-optical approach. An *opto-electronic WC* first converts the input optical signal into an electrical signal, and the electrical signal is then modulated onto another optical light that may be at a different wavelength. Opto-electronic WCs can incorporate 3R regeneration function (reamplifying, reshaping, and retiming) to improve the quality of signals. *All-optical WCs* may use a variety of techniques such as cross-gain modulation, cross-phase modulation, and four-wave mixing in nonlinear optical devices such as SOAs. Details on the operating principles and implementation issues of various wavelength converters can be found in Durhuus et al. (1996) and Yoo (1996).

WAVELENGTH-SELECTIVE OXCs

This section describes and discusses several WS-OXCs that are of different configurations and use different technologies.

WS-OXCs Using Space Switching

Figure 3a and 3b illustrates two different configurations of WS-OXCs in which four input-output fibers each carry four wavelengths—that is, $N = M = 4$. Both configurations use optical space switches to perform switching. In configuration 1, WDM signals entering at each of the input ports are first demultiplexed by wavelength demultiplexers, and channels of the same wavelength are then fed to a specific space switch where they are routed to different output ports; that is, each space switch routes channels of the same wavelength. In contrast, channels of the same wavelength are fed to different space switches in configuration 2—that is, each space switch routes channels of different wavelengths. In general, configuration 1 uses $N \times N$ space switches, whereas configuration 2 employs $M \times N$ space switches where M may not equal to N . In Figure 3, both M and N are equal to 4. Compared to configuration 1, configuration 2 has a better cross-talk performance as reported in Zhou et al. (1996). This is because each space switch in configuration 2 routes channels of different wavelengths and the dominant cross talk arising in the space switches is out-of-band

Figure 3: Wavelength selective OXCs—(a) configuration 1 and (b) configuration 2

Figure 4: Wavelength-selective OXC using DC switches—(a) configuration and (b) $i \times j$ DC switch

cross talk, whereas the main cross talk in configuration 1 is inband cross talk. The inband cross talk is more detrimental to the main signal than the out-of-band cross talk, because the out-of-band cross talk can always be removed by optical filters. As a result, the cross-talk requirement for the space switches in configuration 1 is more stringent. However, configuration 2 suffers higher power loss because it has to use optical couplers to combine the signals that are switched to the same output fiber, whereas configuration 1 can use optical multiplexers (whose power loss is much smaller than optical couplers, particularly when the number of signals to be combined is large) to combine channels that are directed toward the same output fiber. It may be noted that if the space switches are nonblocking, then both of the above WS-OXCs are also nonblocking.

Figure 4a shows a different WS-OXC using optical *delivery-and-coupling* (DC) switches reported in Okamoto, Watanabe, and Sato (1996). With this WS-OXC, the incoming WDM signal entering at each input fiber is demultiplexed into M wavelength channels, which are then fed to a DC switch. A DC switch is a specific space switch that allows more than one of the incoming optical signals to be connected with any one of the outputs so long as those incoming signals are of different wavelengths. With reference to Figure 4a, it may be seen that the signals that are fed to the same DC switch are of different wavelengths. Following the DC switches, optical couplers are used to combine signals coming from different DC switches that are being directed to the same output fiber. A general $i \times j$ DC switch is reproduced in Figure 4b. This consists of an array of 1×2 switches and a set of couplers, one at each output. A gate

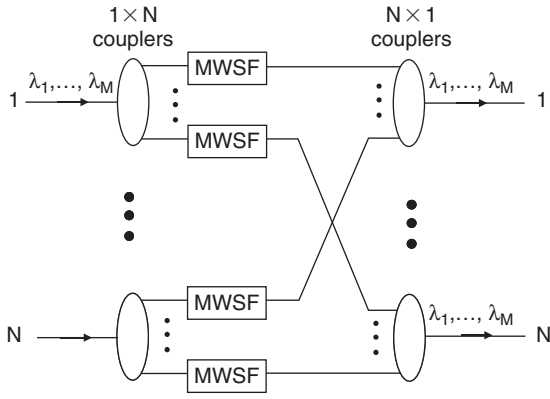

Figure 5: Broadcast-and-select-based OXC using MWSFs

switch is inserted at each input of the couplers, which would significantly suppress the cross talk but at the expense of higher implementation costs. The gate switches may not be necessary if the 1×2 switches induce a cross-talk level less than -30 dB. Each of the i incoming signals can be switched to any one of the j outputs through the array of 1×2 switches. A 1×2 switch can be fabricated in the form of a Mach-Zehnder interferometer with a thermo-phase shifter. A coupler is used to combine the signals coming from the i different inputs. As reported in Watanabe et al. (1996), the DC switch with a large number of inputs and outputs can be fabricated on a silicon board using planer silica waveguide technologies.

Broadcast-and-Select-Based WS-OXCs

Figure 5 illustrates a broadcast-and-select-based WS-OXC (Okamoto, Watanabe, and Sato 1996). It consists of a set of *multiwavelength-selective filters* (MWSFs) and optical couplers. For such an $N \times N$ WS-OXC, one requires $2N$ $1 \times N$ couplers (N of which are used as splitters, and the rest as combiners) and N^2 MWSFs. An MWSF is a specific optical filter that can pass or block any combination of M incoming wavelength channels on each input fiber. Different types of MWSFs have been reported. These include the integrated *acousto-optic tunable filters* (AOTFs) (Simith et al. 1991) and *arrayed-waveguide-grating-based filters* (Doerr 1998). With this OXC, an input channel can appear at multiple output fibers if it is selected by multiple MWSFs. Hence, this WS-OXC not only can provide a point-to-point connection but also offer point-to-multipoint connections, which is known as *multicasting*. Multicasting is critically important for supporting various multimedia services such as videoconferencing, multiplayer online gaming, and distance learning. More OXC architectures that are capable of multicasting will be discussed later in this chapter.

WS-OXCs Using Fiber Bragg Gratings and Circulators

Apart from the architectures discussed above, WS-OXCs based on optical *fiber Bragg grating* (FBG) are highly attractive and promising, particularly in applications such

Figure 6: WS-OXC using (a) fixed FBGs and space switches and (b) tunable FBGs

as interconnecting WDM rings. In such applications, the number of ports required is small. As such, it is cost-effective to use FBGs to build OXCs that are of small size. Figure 6a shows a FBG-based 2×2 WS-OXC in which a series of FBGs with fixed Bragg wavelengths and 2×2 optical space switches are used, with each FBG inserted between two 2×2 space switches (Liaw, Ho, and Chi 1998). Each 2×2 space switch has one of the “cross” and “bar” states at one time. Switching two 2×2 space switches, one before and one after the FBG, to the “cross” state, a channel whose wavelength matches with the center wavelength (also called the *Bragg wavelength*) of the FBG will be re-lected back by the FBG, then exit from port 3 of *optical circulator* (OC) 1. Meanwhile, other channels can pass through the FBG chain and appear at port 3 of OC 2. When two or more 2×2 space switches are properly cascaded, multiple-wavelength switching can be realized. Each group of an FBG and a 2×2 optical space switch can be replaced by a tunable FBG, as shown in Figure 6b. Large FBG-based WS-OXCs can be configured using the Benes structure as reported in Wu et al. (2000). Using tunable FBGs and OCs, we can also build bidirectional WS-OXCs that are highly useful for interconnecting bidirectional WDM rings, as reported in Yuan, Zhong, and Hu (2004).

WAVELENGTH-INTERCHANGEABLE OXCs

Wavelength conversion is necessary for VWP optical networks. In this section, we describe and examine several different WI-OXC architectures. Studies have shown that, under many circumstances, WI-OXCs can enhance the efficiency of transmission resources (Sato, Okamoto, and Hadama 1994). This is because the use of WI-OXCs eliminates the requirement for the wavelength continuity constraint in the establishment of lightpaths, so they can considerably reduce the lightpath blocking probability (refer to Figure 1 for an example). More importantly, WI-OXCs allow optical lightpath topologies to be

configured and reconfigured more rapidly than WS-OXC, hence they facilitate optical network management. This is because WI-OXCs allow a lightpath traveling a number of nodes to have a different wavelength over each fiber link along the route and hence simplify establishment of new optical lightpaths and restoration of optical lightpath failures. In other words, using WI-OXCs, wavelengths allocated to optical lightpaths only have local importance, resulting in significant simplification of wavelength assignment in large optical networks; conversely, with the use of WS-OXCs, wavelength assignment has to be done globally, resulting in increased complexity of network management.

In general, there are two approaches to realizing WI-OXCs. The first approach is to employ space switching in conjunction with wavelength conversion, which is generally referred to as the *space-switching* approach. In this case, connecting a wavelength channel from a particular input fiber to a desired output fiber is carried out by optical space switches; wavelength conversion is performed either before or after the space switching, depending on the system architecture. The second approach is to use wavelength routing in conjunction with wavelength conversion (Zhong, Lacey, and Tucker 1996), which is referred to as the *wavelength routing* approach. As we will see subsequently, although some of the WS-OXC architectures described in the previous section may be modified to become WI-OXCs by simply incorporating WCs, others cannot be modified in this fashion.

WI-OXCs Based on Space Switching

Figure 7 illustrates a WI-OXC using the space-switching approach. It is modified from the WS-OXC in Figure 4a. As shown in the figure, after it is demultiplexed, an incoming wavelength channel is converted to a desired output wavelength channel by a *fixed-input, tunable-output wavelength converter* (FTWC). An FTWC can convert an optical signal with a fixed wavelength to any other output wavelength. Following wavelength conversion, individual wavelength channels are then switched by the

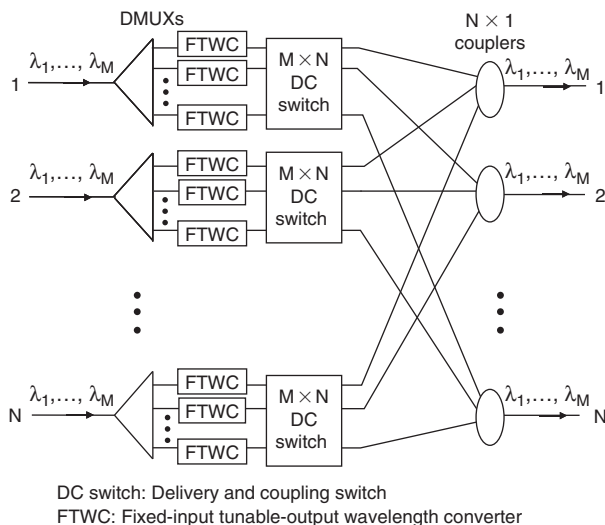

Figure 7: WI-OXC using DC switches and FTWCs

DC switches toward their desired output ports. It may be noted that here wavelength conversion is performed before space switching (i.e., before a wavelength channel is routed to a specific output fiber). It is not possible to reverse the order of the wavelength conversion and the space switching, because this WI-OXC uses DC switches, and each output of a DC switch may have more than one wavelength channel. Because a DC switch is strictly non-blocking, this WI-OXC is also strictly nonblocking in both the space and wavelength domains.

Figure 8 shows another WI-OXC structure based on space switching (Hill et al. 1993). In this WI-OXC, each incoming WDM signal is first split into N equal parts and fed to a *tunable input and tunable output wavelength converter* (TTWC). After being selected and wavelength converted by TTWCs, wavelength channels are then individually switched by space switches toward their desired output ports. Figure 9 shows the schematic of a TTWC. The TTWC in the figure uses cross-gain modulation in SOA to perform wavelength conversion, but in general other wavelength conversion techniques can also be used. Details on different wavelength techniques can be found in Durhuus et al. (1996) and Yoo (1996). Because the input signal is a WDM signal, a tunable filter is necessary to select a specific wavelength channel out of M possible input wavelength channels. The selected input wavelength is then converted to a particular output wavelength by tuning the tunable laser. The selected input signal and the continuous light at wavelength λ_{out} generated from the tunable laser are injected into an SOA in opposite directions.

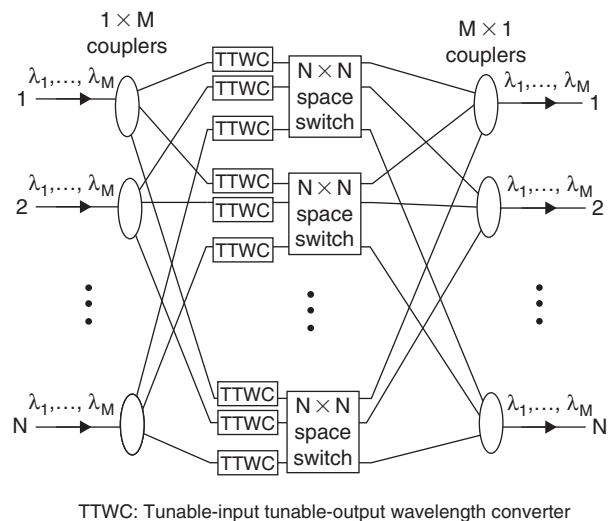

Figure 8: WI-OXC using space switches and TTWCs

Figure 9: TTWC based on cross-gain modulation in SOA

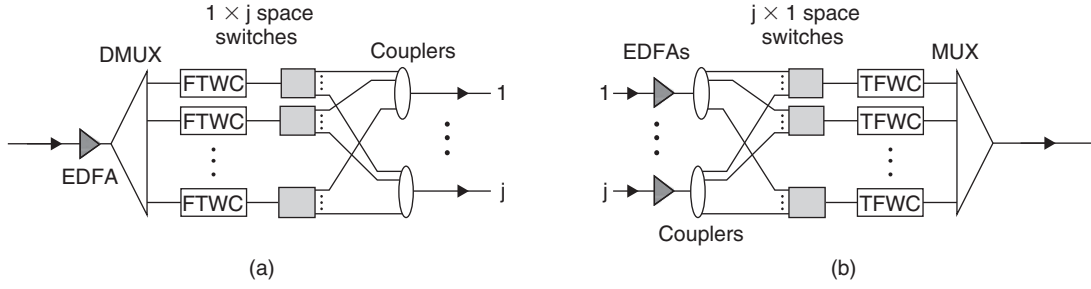

Figure 10: Wavelength interchange device with (a) single input and multiple output and (b) multiple input and single output

This facilitates the separation of the desired output wavelength from the input wavelength. Note that if the incoming signal is of single wavelength, the tunable filter in Figure 9 is not necessary. Such a wavelength converter without a tunable filter at the input is an FTWC. If the tunable laser is replaced with a fixed laser, then the WC in Figure 8 becomes a *tunable-input fixed-output WC* (TFWC). A WC with fixed output wavelength is simpler than a WC with tunable output wavelength because a tunable laser is more complicated and expensive than a fixed wavelength laser. In both of the WI-OXCs in Figures 7 and 8, the WCs are placed before space switching and of tunable output wavelengths. Recently, a new type of WI-OXCs based on space switching is reported in Panda et al. (2004) in which the WCs are located after space switching and are of fixed output wavelengths.

WI-OXCs Based on Wavelength Routing

We next describe a class of WI-OXCs using the wavelength routing approach reported in Zhong, Lacey, Tucker (1996) and Zhong, Lacey, Tucker (1997). These WI-OXCs employ *wavelength interchange devices* (WIDs) and *arrayed waveguide grating multiplexers* (AWGMs) to perform wavelength cross connection. A WID is generally denoted as $i \times j$ WID(u, v, w). This device has i input fibers that between them carry a total of w WDM data channels on u possible wavelengths on each input fiber, and j output fibers that between them carry the same number w of WDM data channels on v possible output wavelengths on each output fiber, where $w \leq \min\{iu, jv\}$. The basic WIDs that are of particular interest are 1×1 WID(u, v, w), $1 \times j$ WID(u, v, w), and $i \times 1$ WID(u, v, w) because they can be built in a relatively simple way and used as building blocks for various WI-OXCs (refer to Zhong, Lacey, and Tucker 1996, and Zhong et al. 1997 for more details).

Figure 10a shows the schematic configuration of a $1 \times j$ WID(u, v, w) (Zhong et al. 1997). The input WDM signal is amplified by an erbium-doped fiber amplifier (EDFA). After being demultiplexed, each individual wavelength signal is fed to an FTWC where it can be converted to any wavelength out of v possible output wavelengths. The individual signals from the FTWCs are then switched by the optical space switches toward one of j output fibers.

Figure 10b shows the schematic configuration of a $j \times 1$ WID(u, v, w). Each input WDM signal is amplified and then split into v equal parts. Each $j \times 1$ space switch

selects one of the input WDM signals. The selected WDM signal is fed to a TFWC where a specific wavelength out of u possible input wavelengths is selected by a tunable filter and then converted to a preassigned output wavelength. Because the individual wavelengths emerging from the TFWCs are fixed, they can be combined by a multiplexer. The $1 \times j$ WID and the $j \times 1$ WID both become 1×1 WID when all of the space switches and unused input and output fibers and corresponding components are removed.

Figure 11 shows an $N \times N$ WI-OXC using WIDs and AWGMs (Zhong et al. 1996). Each column of WIDs is denoted as a stage. Two adjacent stages are interconnected by an $N \times N$ AWGM that performs wavelength routing. An important property of an $N \times N$ AWGM is that it has a *free spectral range* (FSR) or a frequency period (Dragone 1991; Takahashi et al. 1990). By making use of this property, multiple wavelength connections, each separated by an FSR, can be simultaneously set up through the AWGM between any two WIDs in two adjacent stages.

Figure 12 illustrates an equivalent circuit of a 4×4 AWGM in which a connection between a DMUX and an MUX represents a set of frequencies, each separated by an FSR. Let f_0, f_1, \dots, f_{N-1} be the N consecutive operating frequencies within an FSR of an $N \times N$ AWGM. The set of frequencies $f_{p,q}$ that connect the i th input to the j th output of an $N \times N$ AWGM can be expressed in terms of f_q and FSR as $f_{p,q} = p \times \text{FSR} + f_q$ where q is determined by $q = (i + j) \text{ modulo } N$, and p is an integer indicating the number of FSR periods. The operating frequencies f_0, f_1, \dots, f_{N-1} can be made to be either equally spaced or unequally spaced for AWGMs. If a wavelength-division channel or connection is looked on as a space-division channel or connection, then each 1×1 WID(u, v, w) is equivalent to a $u \times v$ nonblocking space switch that switches w data channels. Because each 1×1 WID(u, v, w) is equivalent to

Figure 11: WI-OXC using 1×1 WIDs and AWGMs

Figure 12: Equivalent circuit of a 4×4 AWGM

a $u \times v$ nonblocking space switch and an AWGM can provide multiple wavelength connections (each separated by an FSR) between any two WIDs in adjacent stages, the WI-OXC in Figure 11 can be translated into an equivalent three-stage space-division switching network, which is similar to the Clos network (Clos 1953). It has been shown in Zhong et al. (1996) that the WI-OXC in Figure 11 can be either (1) a strictly nonblocking network if at least two wavelength connections (each separated by an FSR of the AWGMs) are provided between any two WIDs in adjacent stages or (2) a rearrangeably nonblocking network if at least one wavelength connection is provided between any two WIDs in adjacent stages.

Figure 13 illustrates another WI-OXC using WIDs and AWGMs. Unlike the structure in Figure 11, which uses three stages of 1×1 WIDs, the WI-OXC in Figure 13 consists of two stages of WIDs, resulting in reduction in the implementation cost. The first stage uses $1 \times j$ WIDs, and the second stage uses $j \times 1$ WIDs. The WIDs in the first stage and the WIDs in the second stage are interconnected by $jN \times N$ AWGMs. In addition to wavelength switching, this WI-OXC also uses space switching to route a wavelength channel from any input fiber to any output fiber. The space switching is carried out within the $1 \times j$ WIDs

Figure 13: WI-OXC using $1 \times j$ WIDs, $j \times 1$ WIDs, and AWGMs

and the $j \times 1$ WIDs. This WI-OXC is generally a blocking network, but the blocking probability can be made smaller than 10^{-3} for $j \geq 5$ with a relatively high traffic load of 75 percent (Zhong et al. 1997). Several other WI-OXCs using WIDs and AWGMs can be found in Zhong et al. (1996) and Zhong et al. (1997).

MULTICASTING-CAPABLE OXCS

The increasing popularity of multicast services such as videoconferencing, distance learning, and multiplayer online gaming is anticipated to become a major contributor to the growth in Internet traffic demand. These services and applications are quite demanding in their required bandwidth and service quality (i.e., the assurance of bandwidth availability during the life of a particular service session). Their operation inherently requires the simultaneous transmission of information from one source to multiple destinations. Multicasting would be efficient in these applications because it would eliminate the necessity for the source to send an individual copy of the information to each destination. Even though this may be implemented in electrical Internet protocol routers at the Internet layer alone, that would not be an efficient approach in a future Internet over optical network because it would not use the additional flexibility provided by the optical network. In view of this, there has been strong interest in implementing multicasting in the optical layer using multicasting-capable OXCs. This section presents several multicasting-capable OXCs.

Multicasting-Capable WS-OXCs

Figure 14a illustrates a multicasting-capable WS-OXC using *splitting-and-delivery* (SD) switches as reported in Hu and Zeng (1998). This multicasting-capable WS-OXC is modified from the WS-OXC in Figure 4a. In fact, the WS-OXC in Figure 4a becomes the multicasting-capable WS-OXC in Figure 14a if the inputs and outputs are swapped. As shown in Figure 14b, an SD switch is the reverse version of a DC switch (refer to Figure 4b).

More specifically, a DC switch becomes an SD switch if the inputs and the outputs of the DC switch are swapped—that is, the inputs of the DC switch are used as the outputs of the SD switch, and vice versa. In an $i \times j$ SD switch, any input signal is split equally into j branches via a $1 \times j$ optical coupler, and each branch is then selected by a 1×2 switch. Therefore, the SD switch is able to connect any input signal to any combination of the outputs or all the outputs and hence is strictly nonblocking. It can be shown that the WS-OXC in Figure 14a not only can switch any input wavelength channel to any combination of the N output fibers but also can connect multiple or all wavelength channels entering at the same input fiber to any single output fiber and hence is strictly nonblocking.

Figure 15 shows another multicasting-capable WS-OXC that was reported in Hu and Zeng (1998). This has a configuration similar to that of the WS-OXC in Figure 3a in which the space switches are replaced by SD switches. It consists of a set of N demultiplexers and multiplexers, each associated with an input-output

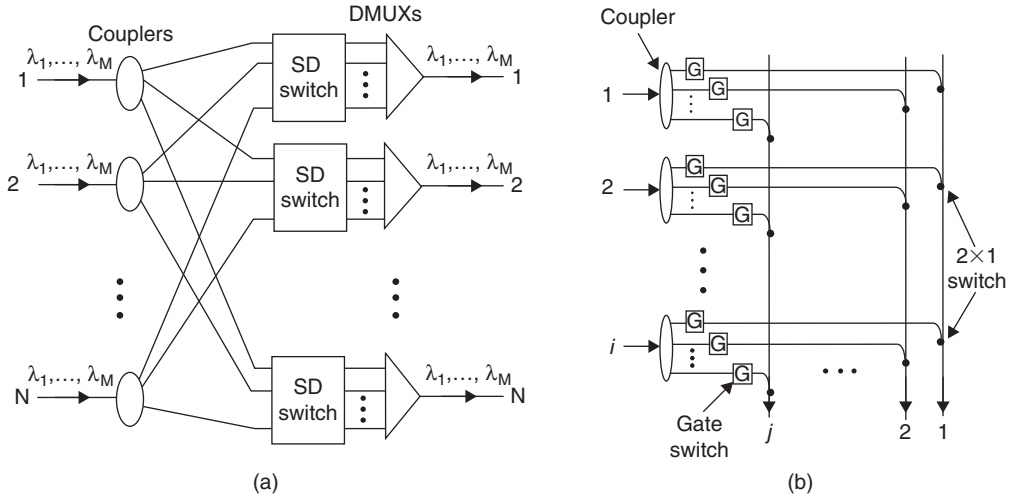

Figure 14: Multicasting-capable WS-OXC using SD switches—(a) OXC configuration and (b) SD switch structure

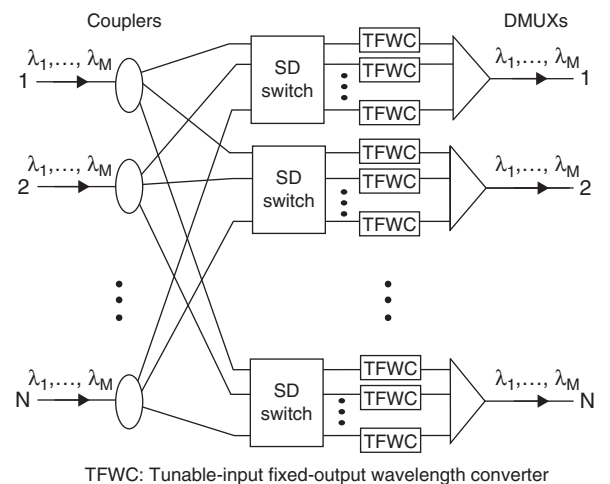

Figure 15: Multicasting-capable WS-OXC reported in Hu and Zeng (1998)

fiber, and a set of $M \times N$ SD switches, each of which handles a single wavelength. After being demultiplexed, all incoming signals with the same wavelength are fed to the same SD switch whereby any signal can be switched to one or more than one output fiber. Signals that are switched to the same output fiber are multiplexed by a multiplexer.

Multicasting-Capable WI-OXCs

By incorporating wavelength conversion, the multicasting-capable WS-OXC in Figure 14a can be modified to be a multicasting-capable WI-OXC as shown in Figure 16 (Hu and Zeng 1998). Here TFWCs are inserted at the outputs of the SD switches. Each incoming WDM signal entering a SD switch can be arbitrarily switched to any combination of M outputs within the SD switch. In each TFWC, a tunable filter is used to select a specific wavelength channel that is subsequently converted to a predetermined output wavelength. Note that the TFWCs cannot be placed at the input side of the SD switches because an optical input channel may

TFWC: Tunable-input fixed-output wavelength converter

Figure 16: Multicasting-capable WI-OXC using SD switches and TFWCs

have to be switched to multiple outputs, each of which may be converted to a different wavelength.

CONCLUSION

Optical cross connects play an imperatively important role in future high-capacity and multifunctional optical transport networks. They can be built with different technologies in various configurations. This chapter discussed various OXC architectures and their implementation details. Depending on wavelength conversion capability, OXCs can be classified as wavelength-selective OXCs and wavelength-interchangeable OXCs. Wavelength-selective OXCs can be implemented with optical space-switching technologies, optical multiplexers, or filters. Wavelength-interchangeable OXCs require wavelength converters in addition to optical space switches and multiplexers and filters. Multicasting can also be realized in the optical domain, which may significantly reduce the cost for large-capacity multicast networks. Several multicasting-capable OXCs were described and discussed.

Table 1: List of Acronyms

AOTF	Acousto-optic tunable filter
AWGM	Arrayed waveguide grating multiplexer
DC	Delivery-and-coupling
EDFA	Erbium-doped fiber amplifier
FBG	Fiber Bragg grating
FSR	Free spectrum range
FTWC	Fixed-input tunable-output wavelength converter
MEMS	Micro-electromechanical system
OADM	Optical add-drop multiplexer
OC	Optical circulator
OXC	Optical cross connect
SD	Splitting-and-delivery
SOA	Semiconductor optical amplifier
TFWC	Tunable-input, fixed-output wavelength converter
TTWC	Tunable-input, tunable-output wavelength converter
VWP	Virtual wavelength path
WC	Wavelength converter
WDM	Wavelength-division multiplexing
WID	Wavelength interchange device
WI-OXC	Wavelength-interchangeable optical cross connect
WP	Wavelength path
WS-OXC	Wavelength-selective optical cross connect

GLOSSARY

Blocking Network: A switching network in which a free (idle) input may not be able to be connected to a free output.

Delivery-and-Coupling Switch: A specific optical space switch in which multiple input signals can be connected to the same output as long as these input signals have different wavelengths.

Lightpath: An optical wavelength connection from a source node to a destination node. A lightpath is assigned with a unique wavelength over each intermediate link along the route if the wavelength is not convertible in the network. A lightpath may be assigned with a different wavelength over different links along the route if intermediate nodes are capable of wavelength conversion.

Lightpath Topology: A graph that consists of network nodes with an edge between two nodes if there is a lightpath between them. The lightpath topology refers to the topology seen by the higher network layers using the optical layer.

Multicasting-Capable Optical Cross Connect: An optical cross connect in which an input optical channel

can be copied from one input fiber to multiple output fibers.

Optical Space Switching: A switching technique in which an optical wavelength channel is routed from any input port to any output port by optical space switches.

Optical Wavelength Switching: A switching technique in which an optical channel is routed from any input port to any output port by means of wavelength conversion.

Rearrangeably Nonblocking Network: A switching network in which a free input can be connected to a free output by rearranging some of the existing connections.

Split-and-Delivery Switch: A specific optical space switch in which an optical signal can be connected to more than one or all of the outputs of the switch.

Strictly Nonblocking Network: A switching network in which a free input can always be connected to a free output without disturbing any existing connections.

Virtual Wavelength Path (VWP) Network: An optical network capable of wavelength conversion. In such

a network, a lightpath from a source node to a destination node may be assigned with a different wavelength over different links along the route. Such a lightpath is usually referred to as a *virtual wavelength path* (or *virtual lightpath*) and hence the network as a *virtual wavelength path* (VWP) network.

Wavelength Converter: An optical device that changes the wavelength of an input signal to a different wavelength.

Wavelength Interchangeable Optical Cross Connect (WI-OXC): An optical cross connect in which an input optical channel can be connected from any input fiber to any output fiber, and the wavelength of the input channel can be changed to a different wavelength.

Wavelength Path (WP) Network: An optical network in which wavelength conversion is not possible. In such a network, a lightpath from a source node to a destination node has to be assigned with a unique wavelength over all of the links along the route. Such a lightpath is referred to as *wavelength path*, and hence the network is a *wavelength path* (WP) network.

Wavelength-Selective Optical Cross Connect (WS-OXC): An optical cross connect in which an input optical channel can be connected from any input fiber to any output fiber, but the wavelength of the input channel cannot be changed.

INTRODUCTION

In today's information society, the demand for high digital data storage capabilities, at increased data rates, has fueled the development of new storage technologies. The dominant data storage technology is magnetic storage—that is, *hard disc drives* (HDD) that offer data storage capacities far in excess of any other storage technology now commercially available. However, although magnetic HDDs offer vast storage capabilities (as much as 1 Terabyte in a single drive), they are limited by the fact that they are fixed, unlike optical memories, which offer relatively large storage capacities (as much as 50 GB on a single 12-cm disc) and the ability to record and erase data using a universal, removable, and reliable disc-based storage medium. The now ubiquitous *compact disc* (CD) and *digital versatile disc* (DVD) have revolutionized the way we archive our data, listen to music and watch movies, and produce our own multimedia content. The next generation of optical memories, such as the *high-definition DVD* (HD-DVD) and the Blu-ray disc, promise superior data storage capabilities with the increased data rates necessary for the recording and viewing of high-definition video content.

This chapter discusses the technology of optical memories and presents an overview of the readout and recording mechanisms in the most popular consumer read-only, write-once, and rewritable disc formats. In addition, the evolution of optical disc memories, from the humble CD to the next generation of ultrahigh-density formats, will be discussed. Finally, new storage technologies being developed for use in future optical memories will be presented, such as near-field recording, magnetic super-resolution techniques for advanced magneto-optical storage, and holographic memories.

OPTICAL DISC STORAGE

Figure 1 illustrates the key components of an optical disc memory, which includes the disc, containing the storage layer where the digital data is stored,

and the optical head that is used to retrieve the stored digital data from the disc as well as record the digital data to the disc in recordable formats. The digital data are stored along a spiral track across the storage layer of the disc that originates from the disc center; in the case of the CD, the track is more than 5 km in length. The data are encoded in the form of pits or recorded marks along the track, which are modulated in length according to the data being recorded. The data are recorded to the disc and recovered using a diffraction-limited focused spot, or optical stylus, which scans along the data track as the disc spins beneath the optical head. The optical stylus is produced by focusing the monochromatic laser light produced by a laser diode through the disc substrate onto the surface of the storage layer beneath, as illustrated in the inset of Figure 1. Focusing through the disc substrate is performed to limit the effect that any surface contaminants or dust has on the quality of the optical stylus on the underlying storage layer (Bouwhuis et al. 1985; Marchant 1990; Pohlmann 1989). The design of the objective lens takes into account the spherical aberrations introduced by focusing the laser beam through the disc substrate such that an optimally focused spot is observed at the storage layer.

The storage mechanism depends on the disc format and whether the disc is recordable or not. In the case of read-only formats, such as the CD-ROM, the digital data are embossed into the disc substrate during manufacture as a sequence of phase pits along the data track. In recordable formats, such as the *compact disc-recordable* (CD-R), a focused laser beam, or write beam, which is of a higher intensity compared to that used for readout, is used to record the digital data to the storage layer. A recorded mark is formed by the write beam heating the storage layer to change some physical property of the recording medium, such as its reflectance in phase-change storage media or out-of-plane magnetization in *magneto-optic* (MO) media.

Readout of the digital data from the disc is performed using a low-power focused laser beam, or *read beam*, that

Figure 1: The optical head is used for reading and writing data in optical disc memories. The laser illumination produced by the laser diode is focused by the objective lens to a diffraction limited spot, or optical stylus, on the surface of the storage layer in the disc. The light reflected from the disc is directed to the detection arm of the optical head where it is converted to an electrical form by a detector. Additional detector optics (not illustrated) are used to provide a focus error signal, as well as other optical detection techniques. The inset illustrates the focusing of the laser beam through the disc substrate onto the storage layer beneath

in recordable formats has insufficient power to affect the physical properties of the disc. As the disc spins, the optical stylus scans along the data track and the phase, intensity, or polarization state of the reflected light, depending on the storage mechanism employed, is modulated according to the digital data stored along the data track. The reflected light is then directed to the detection arm of the optical head by a beam splitter and is converted to an electrical form by a detector to produce a high-frequency analog replay waveform. The replay waveform is then processed to recover the digital data—that is, the digital 0's and 1's stored on the disc.

In most consumer optical disc formats, such as the CD and the DVD, a 12-cm diameter disc is typically used. Exceptions are the MiniDisc, which uses a 64-mm disc, and professional optical storage formats, which often use large diameter discs to boost the attainable storage capacity for data archiving.

The Optical Stylus

The data storage capacity of the disc is determined by the size of the features along the storage layer that represent the stored digital data—that is, the pits or marks, along with the track separation, or track pitch. Increased data

storage capacity can be achieved by reducing the size of the recorded features or reducing the track pitch or both. However, ultimately the storage capacity is limited by the size of the optical stylus used for the recording and readout of data. If the pits or recorded marks are too small in comparison with the diameter of the optical stylus, then they will not be “seen” or resolved by the scanning optical stylus and will not contribute to the replay waveform. If the track pitch is too small, then the optical stylus will sense data from tracks adjacent to the main data track, which will introduce cross talk that will degrade the replay waveform, making the recovery of data more prone to error.

The practical size and shape of the optical stylus depends on several factors, including the intensity profile of the laser illumination incident on the objective lens and the presence of any aberrations, such as defocus, in the optical system. The theoretical minimum spot diameter, d_s , expressed in terms of the *full width at half maximum* (FWHM) of the total light intensity, is given by

$$d_s \approx \frac{\lambda}{2 \cdot \text{NA}}$$

where λ is the wavelength of the laser illumination and NA is the *numerical aperture* of the objective lens (Bouwhuis et al. 1985). Optical disc memories (CD, DVD, HD-DVD, etc.) have evolved to offer increased storage density by employing an optical stylus of reduced diameter, primarily by a reduction of the wavelength of the incident illumination and an increase in the NA of the objective lens.

Problems such as defocus, in which the disc surface does not lie at the focal point of the objective lens, will affect the quality of the focused spot at the surface of the disc storage layer and act to increase its size, resulting in a loss of resolution and an inability to resolve the pits or recorded marks. An additional problem is the need to hold the optical stylus on the center of the data track as the disc spins because any movement of the optical stylus off-track will result in a loss of signal from the main data track and an increase in the amount of cross talk introduced by the neighboring tracks. The effects of defocus and tracking error require careful consideration; to address these problems, optical disc memories incorporate systems to maintain focus and tracking during the recording and readout of data.

Focusing

The minimum spot size is only maintained over a limited range about the focal point of the objective lens called the *depth of focus*, Δz , which is given by (Bouwhuis et al. 1985)

$$\Delta z \approx \pm \frac{\lambda}{2 \cdot \text{NA}^2}.$$

To enable the reliable recording and recovery of data, the storage layer has to be held within the depth of focus of the objective lens as the disc spins beneath, otherwise the storage layer will become out of focus. However, optical discs are not perfectly flat; as a result, the position of the storage layer can vary by as much as $\pm 100 \mu\text{m}$ as the disc rotates (Mansuripur and Sincerebox 1997) and the disc is invariably out of focus. Vertical

Figure 2: An optical disc player contains a spindle (A), which holds and spins the disc; and an optical head assembly (B), which contains the objective lens (C). The objective lens is mounted in an actuator assembly (D) that allows the positioning of the objective lens vertically for focusing and horizontally for tracking

movement of the disc is particularly prevalent near the outer edge of the disc, which is why the data track starts from the center of the disc. As optical memories have evolved, the amount of defocus that can be tolerated has been reduced as a consequence of the reduction in the wavelength of laser illumination and the increase in the NA of the objective lens. As an example, the depth of focus for the CD is $\approx \pm 1.9 \mu\text{m}$, whereas it is $\approx \pm 0.9 \mu\text{m}$ for the DVD. To combat the effect of defocus, an automatic focusing system is required in which the vertical position of the objective lens is adjusted to shift the position of the focused spot about the optical axis to correct for any defocus present. Active positioning of the objective lens is achieved by mounting it in an actuator assembly (see Figure 2) that allows positioning in both the axial (vertical) and radial (horizontal) directions for focusing and tracking, respectively. By applying servo-controlled feedback signals to the actuators, the position of the objective lens in both directions can be precisely controlled (Marchant 1990).

In the case of focusing, the amount and sense of defocus can be measured optically by monitoring the light reflected back from the disc using several optical techniques, including the pupil obscuration method (Bouwhuis et al. 1985) and the commonly used astigmatic method (Braat, Dirkson, and Janssen 2003). The derived focus error signal is fed to the actuator assembly, and any measured defocus is corrected for by moving the objective lens in the appropriate axial direction.

The Pupil Obscuration Method

The pupil obscuration method is based on the principle of the Foucault knife edge (Marchant 1990) whereby the light reflected back from the disc is focused past an obscuration onto a split detector as illustrated in Figure 3 (Bouwhuis et al. 1985; Mansuripur 1995). The obscuration is positioned so that half of the area of the converging light beam is masked so that as the beam moves in and out of focus, the light distribution across the split detector varies.

When the storage layer in the disc is in focus, then the beam is incident on the center of the split detector and the two halves are equally illuminated. However, as the storage layer moves out of focus, the light reflected back from the disc is no longer collimated and is either

Figure 3: In the pupil obscuration focusing method, the light reflected from the disc is focused onto a split detector. Half of the beam is obscured so that when the disc moves in or out of focus, the light distribution across the split detector varies. The focus error signal is calculated by taking the difference between the signals generated by the two detectors, which is zero when in focus

converging or diverging, depending on the direction of defocus; this is translated into a horizontal shift in the position of the focused light spot on the split detector. The focus error signal is derived by measuring the difference between the signals generated by the two halves of the detector; the magnitude and sign of this signal give the amount and direction of defocus, respectively. An alternative technique, which eases the tolerances on the detector position, involves the replacement of the obscuration and split detector with a pair of prisms and a row of four detectors (see Figure 4), which is also more efficient because of the use of all of the light reflected from the disc (Marchant 1990).

Figure 4: A modified pupil obscuration method involves replacing the obscuration with a pair of prisms and an additional two detectors. The resulting focusing method eases the tolerances on the detector position and is more efficient.

Figure 5: In the astigmatic focusing method, the light reflected from the disc is focused through a cylindrical lens onto a quadrant detector. When in focus, each quadrant receives equal light and the focus error signal is zero. However, as the disc moves out of focus, an astigmatic beam is observed on the quadrant detector and the error signal is given by the sum $(A+D) - (B+C)$ from the outputs from the four detectors

The Astigmatic Method

In the astigmatic method, the light reflected back from the disc is focused through a cylindrical lens onto a four-quadrant detector as illustrated in Figure 5 (Bouwhuis et al. 1985; Bricot et al. 1976).

When the storage layer on the disc is in focus, a circular spot is observed on the detector and each quadrant is equally illuminated. However, as the storage layer moves out of focus, an astigmatic beam is observed on the detector and diagonal pairs of quadrants—that is, A and D, or B and C, receive more light, depending on the direction of defocus. The focus error signal is given by the signal combination $(A + D) - (B + C)$ generated from the output signals from the four quadrants of the detector; the replay waveform is generated by summing the four signals: $(A + B + C + D)$. The sign and magnitude of the focus error signal give the direction and amount of defocus, respectively.

Tracking

In addition to the problem of maintaining focus, the optical stylus must be positioned over the center of the data track, to submicron precision, as the disc spins. Coarse tracking of the optical stylus is achieved by moving the complete optical head assembly across the radius of the disc using a linear actuator. Fine tracking is achieved using servo control of the radial position of the objective lens. Several optical techniques may be used to derive a tracking error signal, and these have been used successfully in commercial optical disc memories. In the same

way as focusing techniques, these methods monitor the light reflected back from the disc.

The Three-Spot Method

In the *three-spot* (or *twin-spot*) *method*, two additional focused spots are generated on the surface of the storage medium using a diffraction grating placed after the laser diode. The two satellite spots are projected before and after the main focused spot and are displaced by a quarter of the track pitch off the track center as illustrated in Figure 6 (Bouwhuis and Burgstede 1973). The reflected light resulting from each satellite spot is directed to its own detector, A and B, from which the output signal is low-pass filtered to produce a DC-content signal. The tracking error signal is derived by calculating the difference between these two signals, which is zero when the main spot is on-track and nonzero when it moves off-track. The sign and magnitude of the derived tracking error signal gives the direction and amount of tracking error, respectively. The three-spot method is especially popular in read-only formats (Mansuripur and Sincerbox 1997), although it does suffer from a number of disadvantages: in particular, the need for a precisely aligned diffraction grating, and a loss of optical power resulting from the generation of the satellite beams, which may be a problem for recording.

The Radial Wobble Method

In the *radial wobble method* the optical stylus is forced to oscillate about the track center as the disc spins as illustrated in Figure 7 (Marchant 1990). The resulting tracking error signal is derived from any intensity and phase variations in the light reflected back from the disc. The radial wobble method suffers from several disadvantages such as the introduction of increased cross talk (Braat, Dirkson, and Janssen 2003), the need for the presence of data along the track to enable tracking, and the reduction in the replay waveform resulting from the spot moving off-track (Marchant 1990). A similar technique, which can alleviate some of these problems, involves the use of a wobbled groove on the disc.

The Radial Push-Pull Method

The *radial push-pull method* is well suited for use in storage formats employing a prefabricated phase structure such as read-only disc formats (Mansuripur and Sincerbox 1997). The pit phase structure on the disc acts like a diffraction grating, such that any movement of the main spot off-track introduces a change in the phase difference between the light reflected from the pits and the land (the flat disc surface surrounding the pit), which results in the displacement of the spot across the detector. If the detector is replaced with a split detector, as illustrated in Figure 8, then the tracking error signal can be measured as a difference in the signals from the two halves of the detector as the focused spot moves off-track; the replay waveform is derived by summing the two signals. Again, the sign and magnitude of the tracking error signal give the direction and amount of tracking error, respectively.

One problem with the push-pull method is the need for phase pits on the disc; this makes tracking difficult in the case of recordable formats, such as CD-R, because of

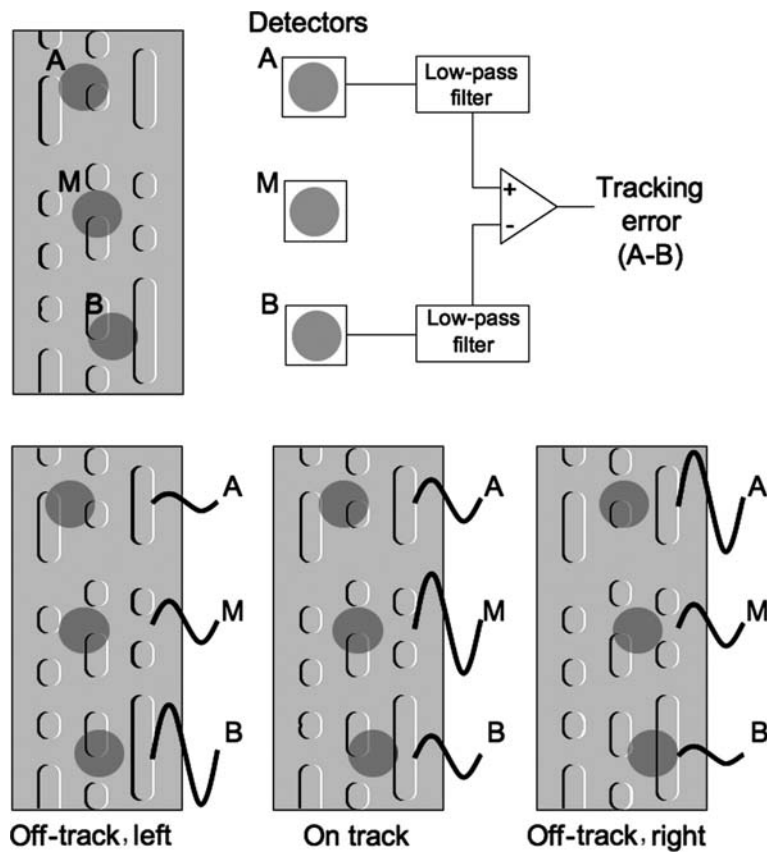

Figure 6: In the three-spot tracking method, tracking is performed using two satellite spots projected in front of and behind the main spot, which are both displaced by a quarter of a track pitch off-track. Each additional spot has its own detector (A and B). The difference between the low-pass signals from the two detectors gives the tracking error signal

Figure 7: In the radial wobble tracking method, the focused spot is made to oscillate about the track center as it scans along the track. The tracking error signal is calculated from light intensity and phase variations on the main detector

Figure 8: In the radial push-pull tracking method, the main detector is replaced with a split detector. As the scanning spot moves off-track, the phase difference between the pit and land displaces the beam across the split detector. The tracking error signal is found by calculating the difference between the signals from the two halves of the detector

the lack of pits. To remedy this, a prefabricated continuous groove is embossed into the disc substrate during manufacture to form a track for recording and a phase structure for tracking (Mansuripur and Sincerebox 1997). The push-pull method is sensitive to the pit and track depth, and these quantities should be chosen carefully such that they are far enough away from $\lambda/4$ because, in this case, the push-pull signal is zero (Bouwhuis et al. 1985).

Differential Time Detection

An alternative tracking technique commonly used in DVD systems is *differential phase detection* or *differential time detection* (Braat 1998; Braat and Bouwhuis 1978; ECMA International 2001). Here phase changes in the reflected beam introduced as the optical stylus moves off-track give rise to differences in the signals from diagonal pairs of quadrants in a four-quadrant detector; the tracking error signal is then derived from these signal differences.

Data Encoding and the Recovery of Data

The recording and readout process in optical disc memories is inherently imperfect because of errors introduced during the recording process, as well as noise and signal degradations introduced during the readout process arising from the presence of optical aberrations, cross talk, and *intersymbol interference* (ISI). ISI occurs because of the limited frequency response of the optical head, which is illustrated by the *modulation transfer function* given in Figure 9 (Braat, Dirkson, and Janssen 2003).

The frequency response of the optical head is measured in terms of the frequency of the spatial features along the data track, which is translated into a temporal frequency (as seen at the output of the detector) by multiplying it by the disc velocity, v . The so-called spatial frequency response of the optical channel results in a decrease in the amplitude of the replay waveform for high spatial frequency features in the storage layer. The maximum spatial frequency that can be resolved by the optical head is $2NA/\lambda$, which limits the minimum size of the features that can be resolved by the optical stylus (Bouwhuis et al. 1985).

As a result of the limited frequency response of the optical channel, as well as the presence of any signal degradations introduced during readout, the recovery of digital data from the high-frequency analog replay waveform

Figure 9: The modulation transfer function illustrates the variation in the amplitude of the high-frequency analog replay waveform as the spatial frequency of the features on the disc storage layer change. The characteristic cutoff frequency, which defines the maximum resolution of the optical head, is given by $2NA/\lambda$. The spatial frequency is translated to a temporal frequency via multiplication by the disc velocity, v .

is a complex process. To combat these effects, the digital data are encoded with an error-correction code and a modulation code before recording in order to permit the lossless recovery of stored data. Figure 10 illustrates a block diagram of the read-write channel in a typical optical recording system.

Data Encoding

In storage systems, encoding of the user data involves the addition of both an *error-correcting code* (ECC) and a modulation code to the user digital data. The ECC adds extra redundant data to the original user data to ensure that even under the influence of any signal degradations (random or burst) the user data can still be recovered on readout. The error-correction scheme used in the CD is the cross-interleaved Reed-Solomon code (Bouwhuis et al. 1985; ECMA International 2001), whereas the DVD uses the more powerful Reed-Solomon product code (Schouhamer Immink 2004) because of the greater storage density and the increased susceptibility to aberrations in high NA systems.

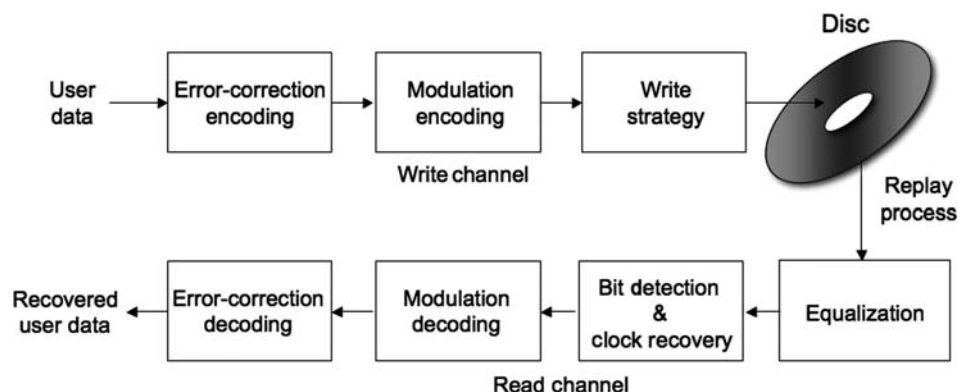

Figure 10: Block diagram of the read-write channel in a typical optical recording system

The choice of modulation, or channel, encoding scheme can be complex, and the scheme must be chosen so that the encoded data closely match the modulation transfer characteristics (Figure 9) of the optical channel and, to some degree, minimize the effects of signal perturbations resulting from the presence of optical aberrations (Schouhamer Immink 2004). The chosen modulation scheme must maximize the data storage density of the medium while maintaining the reliable recovery of data during readout (Bouwhuis et al. 1985). In the case of the CD system, the *eight-to-fourteen modulation* (EFM) scheme adopted is a *run length-limited* (RLL) scheme that serves to restrict the minimum and maximum run-length sequences of like symbols—that is, streams of 0's and 1's in the encoded data. The restriction in the minimum run length controls the highest signal frequency—and hence ISI—in the replay waveform by limiting the minimum length of the pits or recorded marks in the storage layer. The restriction on the maximum run length limits the maximum length of the pits or recorded marks to ensure that sufficient data transitions are available to enable recovery of the data clock (Schouhamer Immink 2004). The encoding process involves the translation of m binary symbols into n binary symbols ($n > m$) using a look-up table. In the case of the EFM scheme, 8-bit blocks of data are converted to 14 bits such that the minimum and maximum pit or recorded mark lengths correspond to run lengths of 3 and 11 like symbols, respectively. The DVD uses the EFMPlus modulation code, which has the same run-length characteristics as EFM but offers an increased code rate (Schouhamer Immink 2004).

After encoding, the data are written to the disc using an appropriate writing strategy such that the encoded data sequence is translated into an appropriate sequence of pits or recorded marks along the data track as illustrated in Figure 11.

The Read Channel

The purpose of the read channel is to take the high-frequency analog replay waveform from the optical head and recover the stored digital data. The read channel can be considered to be the reverse of the write channel, with additional stages to compensate for the frequency limitations of the optical channel and to alleviate ISI (using equalization), as well as sample the analog replay waveform, recover the stored user data (bit detection), and recover the data timing information (clock recovery).

Filtering of the analog replay waveform boosts the high-frequency signal content to compensate for the frequency constraints of the optical channel, as well as counteract any ISI in the replay waveform. The analog

waveform is then converted to a digital form using an analog-to-digital converter from which the digital data and data clock are recovered. Two approaches can be used to recover the encoded user data: threshold detection and maximum likelihood detection. *Threshold detection* is the most commonly used approach, which involves comparing the data sampled at the data clock frequency (provided by the recovered clock signal) with a threshold level and making a decision as to whether the sample value corresponds to a stored 0 or 1. The use of *maximum likelihood techniques*, common in magnetic hard drives (Wang and Taratorin 1999), is more complex but more effective in combating the effects of ISI (Mansuripur and Sincerbox 1997). Once the encoded data have been recovered, the modulation code is removed and the error-correction decoder corrects for any introduced errors so that the original stored user data are retrieved.

THE READOUT AND RECORDING PROCESSES IN OPTICAL MEMORIES

The readout and recording mechanisms in optical memories vary, depending on the storage format. The most common formats such as the CD and the DVD use the standard optical head to detect intensity variations in the light reflected back from the disc during readout. The recording process depends on whether the format is read-only, write-once, or rewritable. In formats such as the MiniDisc and some professional storage systems, the recording and readout processes differ considerably because of the use of magneto-optical recording media.

Read-Only Storage

In read-only optical memories such as the CD-ROM and the DVD-ROM, the data are embossed into the polycarbonate disc during manufacture as a series of phase pits along the data track, where the pit lengths are varied according to the data being stored. The high-frequency analog replay waveform is produced as a result of the reflected beam having its amplitude and phase modified by the pit structures as the optical stylus scans along the data track during readout as illustrated in Figure 12. When the optical stylus is incident on the land between pits, the storage layer reflects the majority of the light. However, when scanning over a pit, the light reflected from the bottom of the pit is half a wavelength out of phase compared with that reflected from the land, which results in a reduction in the intensity of the reflected light and hence a reduction in the signal from the detector (Pohlmann 1989).

Figure 11: Encoding of the user data restricts the minimum and maximum run-length number of like symbols in the user data. Pits or recorded marks on the disc are formed according to the run length of 1's in the encoded data sequence

Figure 12: The readout process in read-only formats. In (a), the depth of the pits is a quarter of a wavelength such that light reflected from the pit bottom is half a wavelength out of phase with the light reflected from the land. As a result, in (b) the signal from the detector reduces as the optical stylus scans across a pit

Write-Once Recording

Several recording techniques may be used to implement a *write-once, read many* (or WORM) optical memory such as ablative recording, dye recording, and phase-change recording. In each technique, the recording process changes some physical property of the storage layer in the presence of a write beam as illustrated in Figure 13. Data readout is performed using the conventional optical head, where the detector measures changes in the intensity of the light reflected from the disc.

Ablative Recording

In *ablative recording*, the storage layer is composed of a thin metal film that has a low melting point. When the write beam is applied, the metal film vaporizes to form holes in the storage layer (Marchant 1990). The resulting holes have a much lower reflectivity compared to the unrecorded metal film and, as a result, the amplitude of the replay waveform from the detector reduces as the optical stylus scans over a hole.

Dye Recording

In *dye recording*, the storage layer is composed of a light-absorbing organic film that distorts to form a pitlike structure when exposed to the write beam. The resulting pits in the dye storage layer behave in the same manner as the pits in the read-only formats such that, as the optical stylus scans across a pit during readout, a reduced signal is observed at the output of the detector (Marchant 1990). Dye recording films are used extensively in the recordable CD (CD-R) and recordable DVD (DVD-R/+R) formats.

Phase-Change Recording

In *phase-change recording*, the storage layer is composed of a material that exhibits two structural phases: crystalline and amorphous. Heating an amorphous film using the write beam results in the formation of a crystalline mark that exhibits a slightly increased reflectivity compared to the amorphous state. As a result, the amplitude of the signal at the output of the detector increases as the optical stylus scans across a recorded crystalline

Figure 13: Write-once recording techniques. (a) In ablative recording, the write beam burns a hole in the thin metal storage layer. The light reflected from the hole is of a lower intensity compared with the light reflected from the unrecorded film. (b) In dye recording, the write beam melts the recording layer to form a pitlike structure. The light reflected from the pit is of a lower intensity compared with the light reflected from the unrecorded film. (c) In phase-change recording, the write beam forms a recorded crystalline mark in the amorphous film. The light reflected from the mark is of a higher intensity compared with the light reflected from the unrecorded film

mark (Marchant 1990). The use of phase-change media is viewed as the cleanest of all recording techniques because it does not involve any material removal. However, its use as a write-once storage medium has been restricted because the polarity of the replay waveform differs from that of the other formats, which leads to compatibility issues. Phase-change media have been used extensively in rewritable formats because of the ability to write, read, and erase data.

Rewritable Recording

In rewritable systems, data can be recorded, read, and erased many times. Examples include the CD-RW, the DVD-RW/+RW formats, and the MiniDisc. The two most common rewritable recording techniques use either phase-change media (the CD-RW and the DVD-RW/+RW) or magneto-optical media (the MiniDisc). These two recording techniques are incompatible and require different recording and readout approaches.

Phase-Change Recording

Phase-change recording films have found favor in several rewritable optical disc formats such as CD-RW, DVD-RW/+RW, and the next generation of formats. Here the storage layer is composed of Ag-In-Sb-Te or Ge-Sb-Te type alloys in a complex quadrilayer stack structure (see Figure 14) that is carefully designed to control the thermodynamic recording process (Philips Electronics 1997; Kageyama et al. 1996; Yamada et al. 1991; Mansuripur and Sincerbox 1997).

In its original deposited form, the phase-change storage layer is in an amorphous state (as in the WORM case), which during the manufacturing process is annealed to change the phase of the unrecorded disc to its crystalline state. The state of the unrecorded crystalline storage layer can be changed to an amorphous state by locally heating it above its melting temperature ($\approx 500^\circ\text{C}$) using a

Figure 14: The CD-RW uses a grooved substrate to aid in tracking. The phase-change recording layer (Ag-In-Sb-Te) is sandwiched between two dielectric layers and coated with a metallic reflective layer to form a quadrilayer stack. The design of the stack is optimized to control the writing process.

high-power laser beam and then allowing it to cool, or quench, quickly. If the storage layer is in its amorphous state, then it can be changed back to its (erased) crystalline state by heating it to a temperature below the melting temperature but above the crystallization temperature, $\approx 200^\circ\text{C}$, using a laser beam of reduced power compared to that used when writing (Philips Electronics 1997; Mansuripur and Sincerbox 1997).

To prevent the formation of asymmetric recorded marks during recording, the write beam is pulsed at a high frequency during the recording of a mark (see Figure 15). Direct overwrite of any existing recorded data in the storage layer—that is, changing any amorphous recorded marks back to the crystalline, or erased, state—is achieved by setting the laser power to the erase power, P_e , between recorded marks. Ge-Sb-Te alloys can tolerate a greater number of overwrite cycles (100,000) compared to Ag-In-Sb-Te alloys (1000), which is why such alloys have found favor in rewritable formats such as CD-RW and DVD-RW/+RW.

Because the amorphous state exhibits a reduced optical reflectivity compared to the crystalline state, the recorded data can be easily recovered by monitoring changes in the intensity of the reflected light using the standard optical head as the optical stylus scans along the recorded data track.

Phase-change media are now being used in professional data-archiving products, such as *ultra density optical* (UDO), because of the long lifetimes (50+ years) they offer (Plasmon 2006).

Magneto-Optical Recording

Magneto-optical (MO) data storage materials have been used in professional storage applications for many years, whereas the application in consumer products has been limited because of the dominance of the CD and DVD formats. However, one commercial success has been the recordable MiniDisc developed by Sony. With a storage

Figure 15: In phase-change recording, a recorded mark is formed in the storage layer by pulsing the write beam at a high frequency. Direct overwriting of prerecorded data is achieved by applying an erase power beam between recorded marks

density of 177 Mb, the MiniDisc allows 74 minutes of compressed audio (using adaptive transform acoustic coding) to be stored to a 64-mm diameter disc (Yoshida 1994).

The recording layer in an MO disc is invariably made from a thin film of an amorphous rare earth and transition metal magnetic alloy, such as Tb-Fe-Co, which exhibits a perpendicular anisotropy—that is, it is magnetized perpendicular to the plane of the disc (Mansuripur 1995; McDaniel and Victora 1997). At room temperature, an MO material exhibits a high coercivity; as a result, it is difficult to change its magnetization state using an externally applied magnetic field. However, the coercivity of the magnetic film can be reduced through heating it using a focused laser beam. If the MO material is heated to its Curie temperature ($\approx 300^\circ\text{C}$), its magnetization reduces to zero, so its magnetization can be influenced by the presence of an external magnetic field (Mansuripur and Sincerbox 1997; Marchant 1990).

In MO recording, data are recorded to the MO storage layer in the form of recorded domains that are magnetized in the opposite direction to the unrecorded film. These domains are recorded by locally heating the MO storage layer to a temperature just below the film's Curie temperature using a write beam. The application of a small external magnetic field ($\approx 100\text{Oe}$), generated by an electromagnet placed in close proximity, results in the formation of a magnetic domain when the write beam is removed (see Figure 16). Erasure is achieved by applying an external field aligned in the same direction to the magnetization direction of the bulk MO storage layer.

In MO recording, data can be written in one of two ways: either by application of light-intensity modulation or magnetic field modulation. In *light-intensity modulation recording*, the externally applied magnetic field is held constant with the direction of magnetization aligned in the opposite direction to that of the unrecorded storage layer. The magnetic domains are then written by modulating the write beam according to the data being recorded. Here the size of the recorded domains, and hence storage density, is limited by the size of the optical stylus. In *magnetic field modulation recording*, the write beam is held constant and the externally applied magnetic field is modulated according to the data being recorded. In this case, crescent-shaped recorded domains are written to the MO storage layer, which can be smaller in size (in the data track direction) compared to the optical stylus used to write them, resulting in an increase

Figure 16: In MO recording, a magnetic domain is written by applying a write beam, which heats the MO layer to a temperature just below the magnetic film's Curie temperature. Application of an external field is then sufficient to allow local magnetization reversal to occur, thereby forming a recorded domain in the storage layer

in the attainable data storage density. In addition, direct overwriting of previously recorded data can be easily achieved using magnetic field modulation, whereas in light-intensity modulation recording the data track has to be completely erased before a new data track can be recorded.

Readout in MO systems is performed using the polar Kerr effect, whereby the plane of polarization of a linearly polarized incident read beam is rotated on reflection from the magnetic storage layer. The sense of rotation depends on the orientation of the magnetization of the MO storage layer as illustrated in Figure 17.

To detect the small rotation of the plane of polarization of the reflected light, the detection optics of the optical head are modified to include polarizing optics to change the rotation in the plane of polarization into a change in light intensity at the two detectors (see Figure 18). The optics are configured in such a way that in the absence of any polar Kerr signal—that is, there is no rotation in the plane of polarization—the detectors are illuminated equally.

However, in the presence of a polar Kerr signal—that is, rotation in the plane of polarization of the reflected light—the signals from the two detectors differ depending on the sense of rotation, and a bipolar MO signal is calculated by taking the difference between the signals (Mansuripur 1995).

Figure 17: The polar Kerr effect is used to distinguish between the recorded domains in the MO storage layer. On reflection from the perpendicularly magnetized MO layer, the plane of polarization of the incident beam is rotated by a small angle, θ_k . The direction of rotation depends on the direction of the magnetization in the magnetic layer

Figure 18: In MO readout, a modified optical head is used to detect the polar Kerr rotation in the plane of polarization of the beam reflected from the disc. A polarizer ensures that the read beam is initially linearly polarized. The detection arm is modified to include a polarizing beam splitter and two detectors (plus additional optical components). Any rotation in the plane of polarization of the beam reflected from the disc results in an imbalance between the signals from the two detectors, A and B. The MO replay waveform is generated by calculating the difference between the signals from the two detectors—that is, $A - B$.

THE EVOLUTION OF OPTICAL DISC MEMORIES: FROM THE CD TO THE NEXT GENERATION

The first consumer optical disc format was the video disc introduced by Philips in 1978. It used a double-sided 30-cm disc to store as many as 120 minutes of prerecorded video. The video disc was an analog system in which the analog video signal was encoded to the read-only disc during manufacture as a series of phase pits along the data track. The analog replay waveform was then recovered optically using the conventional optical head discussed previously. Ultimately, the video disc failed commercially for several reasons, but mainly because of its inability to record video, unlike the hugely successful, and competing, videocassette recorder. In parallel with the development of the video disc, researchers at Philips started the development of an equivalent system for storing audio. The first optical audio disc system used an analog system similar to that of the video disc. Because of the analog nature of the recording, however, sound fidelity was poor and imperfections introduced during manufacture resulted in audible clicks during replay (Bouwhuis et al. 1985). As a result, a digital system was developed, the compact disc, which utilized error-correction techniques to correct for any such errors (Philips Electronics 2006; Bouwhuis et al. 1985).

(c)

Figure 19: Electron microscope images (of equal magnification) of the pit structures in the CD, DVD, and Blu-ray disc formats with accompanying laser spots. Courtesy of Philips

Optical disc storage systems have evolved considerably from those early days, with each generation offering increased data storage capacity through technological advances. Figure 19 illustrates the CD-ROM, DVD-ROM, and Blu-ray disc media and clearly demonstrates how the storage density has increased, and the size of the focused spot has been reduced, with each subsequent generation. Table 1 lists the technical differences among the CD, DVD, HD-DVD, and Blu-ray disc formats.

The Compact Disc

The compact disc, developed through a partnership between Philips and Sony, was released to the consumer market in 1982. In its early days, the CD was aimed primarily at the distribution of high-quality, two-channel stereo (16-bit, 44.1-kHz sampling rate) digital audio content (CD digital audio, CD-DA) with the now familiar 1.2-mm thick, 12-cm diameter disc originally chosen to accommodate a 74-minute recording of Beethoven's ninth symphony (Braat, Dirkson, and Janssen 2003).

At the time of its introduction, the CD was revolutionary because it offered a huge increase in storage capacity over what was available at that time (even compared to magnetic storage devices), in addition to offering a removable storage medium that was cheap and simple to mass replicate because of the development of low-cost injection-molding fabrication techniques. The production of CD media begins with a glass master, onto which the recorded data pattern is transferred to a photo-sensitive resist layer using photolithographic techniques; this is then coated with a silver metal layer. Next, the master is coated with a thick layer of nickel to form a metal stamper; when removed from the master, the stamper has formed a negative replica of the final disc. The stamper is then used in an injection-molding process to form the final disc copy by pressing it against hot plastic (Williams 1996). After the polycarbonate disc substrate has been pressed using the stamper to form the disc, the data side of the disc is coated with a metallic layer to improve the reflectance properties of the disc. Finally, a protective lacquer layer is applied to form the label side of the disc. Figure 20 illustrates the CD disc structure.

Table 1: A Comparison of the Key Optical Disc Parameters for CD, DVD, HD DVD and Blu-ray Disc Formats

	CD	DVD	HD-DVD	Blu-ray Disc
Wavelength (nm)	780 (infrared)	650 (red)	405 (blue)	405 (blue)
Numerical aperture	0.45	0.6	0.65	0.85
Spot size (nm)*	867	542	312	238
Disc diameter (mm)	120			
Disc thickness (mm)	1.2			
Cover layer thickness (mm) (readout side)	1.2	0.6	0.6	0.1
User data capacity (Gb)	0.65–0.7	4.7/8.4/17 ^a	15/30 ^{ab} , 15 ^{ac} , 30/32 ^{ad}	23.3/25/27 ^e 46.6/50/54 ^f
Minimum bit length (nm)	833	400	204	160/149/138 ^g
Track pitch (nm)	1600	740	400	320
Modulation code	(2,10)RLL**		(1,10)RLL**	(1,7)RLL**
Data rate (Mbps) (nominal)	1.44	10	36.5	36
Disc velocity (m/s)	1.2	3.5	5	5
Video compression	MPEG-1 (VCD) MPEG-2 (SVCD)	MPEG-2	MPEG-2 MPEG-4 AVC VC-1	
Video resolution (playing time)	352 × 240/288 VCD 480 × 480/576 SVCD	720 × 480/576(133 mins typical)	1920 × 1080 HDTV(2 hours requires 22 Gb)

Figure 20: In the CD, the pit structure is embossed into the polycarbonate substrate during manufacture. The substrate is then coated with a metallic layer to improve the disc reflectivity, followed by a protective lacquer layer onto which the label is printed

The introduction of the *compact disc read-only memory* (CD-ROM) revolutionized the way that software was distributed and led to the development of new consumer devices such as game consoles. Because of the success of the personal computer, there soon became need for a recordable CD format for data-archiving purposes. As a result, the write-once CD recordable (CD-R) and CD rewritable (CD-RW) formats were introduced, both of which are backward-compatible with the CD-ROM format and offer the same storage capacity. In addition, they both use the same optical head for the recording and readout of data, but the mechanism by which information is stored on the disc is completely different. In the CD-R format, dye recording is used. Here the recording film is deposited onto a prefabricated groove structure embossed into the polycarbonate disc during manufacture, which forms a track for recording and also aids in tracking. The recording layer is then coated with a reflective metallic layer and a final protective lacquer layer, in much the same way as the CD. The CD-RW disc structure is similar to that of the CD-R, but utilizes a more complex rewritable phase-change recording layer.

The FWHM spot size in the CD system is approximately $0.8\text{ }\mu\text{m}$, which permits a track pitch of $1.6\text{ }\mu\text{m}$ and a minimum pit length of $0.833\text{ }\mu\text{m}$ (corresponding to a minimum run length of three bits) (ECMA International 1996). A pit depth of $\lambda/4$ maximizes the amplitude of the high-frequency replay waveform, although this also minimizes the push-pull tracking signal; hence, a pit depth of approximately $\lambda/6$ ($\approx 140\text{ nm}$) was chosen.

The data transfer rate at which the stored data is read from the CD depends on the speed at which the disc is spun. In older CD-ROM drives, the disc was spun at a *constant linear velocity* so that data were extracted from the disc at a constant rate. To enable this, the speed of the motor was varied, depending on the location of the data on the disc; as a result, the disc was required to spin faster when accessing data nearer the disc center. However, modern drives spin the disc at a *constant angular velocity* (CAV), so the data transfer rate depends on the location of the data on the disc; in this case, the data rate is slower near the center of the disc. The use of a CAV system has allowed the disc velocity to be increased, thus enabling much higher data transfer rates compared to the nominal

($1\times$) data rate of 150 Kb/s . The maximum data transfer rate in commercial CD-ROM drives is $52\times$ (7.8 Mb/s), although this rate cannot be sustained when transferring data from the whole disc. Increased transfer rates would require spinning the disc faster, which is limited by the strength of the polycarbonate disc and stresses induced when rotating at high speed.

The Digital Versatile Disc

Although the CD was developed for the distribution of digital audio and data, a format called the *video CD* (VCD) was developed for storing digital video. However, the video quality from the VCD was poor because of the MPEG-1 compression standard used. Improved video quality could be achieved using the MPEG-2 compression standard (the *super video compact disc*, or SVCD), but the storage limitations resulted in a limited recording time. Hence, the *digital versatile disc* was developed, driven primarily by the movie industry to offer a means of storing high-quality video and audio content for movie distribution.

At first glance, the CD and DVD appear to be similar, and the fundamental optical principles used for readout and recording remain largely unchanged. However, the DVD offers more than seven times the storage capacity of the CD: 4.7 Gb per disc. This has been achieved by reducing the track width to $0.74\text{ }\mu\text{m}$, and reducing the minimum pit length to $0.4\text{ }\mu\text{m}$ (corresponding to a run length of two bits). To resolve the reduced feature sizes on the disc, the size of the focused spot in the DVD is much smaller than in the CD; this was achieved by using a shorter-wavelength red laser (650 nm compared to 780 nm in the CD) and a higher NA objective lens (0.6 compared to 0.45 in the CD). One particular problem with increased NA imaging is the reduced tolerance to aberrations, in particular, the depth of focus, which is reduced from $\approx \pm 1.9\text{ }\mu\text{m}$ in the case of the CD to $\approx \pm 0.9\text{ }\mu\text{m}$ in the DVD. In addition, the act of focusing through the disc substrate leads to the introduction of unwanted coma into the focused spot in the presence of any disc tilt (Baat and Bouwhuis 1978), the amount of distortion being proportional to NA^{-3} . Hence, in the DVD standard the substrate thickness was reduced to 0.6 mm to alleviate these effects but still adequately protect the storage layer (Mansuripur and Sincerbox 1997; Baat, Dirkson, and Janssen 2003). To maintain the standard 1.2-mm thick disc, a DVD disc consists of a substrate containing a single storage layer bonded to a 0.6-mm thick dummy substrate.

The key technical advancement in the DVD standard was the introduction of dual-layer storage in which data can be stored on two closely spaced ($\approx 50\text{ nm}$) storage layers. The data on the bottom layer are read by refocusing the laser through the semitransparent top data layer. In addition to dual-layer recording, the DVD standard offers increased storage capacity by allowing data to be stored to both sides of the disc. In the case of the ROM format, several disc configurations were developed that offered various storage capacities (see Figure 21), ranging from 4.7 Gb on the single layer disc (DVD-5) to 17 Gb over four storage layers using the double-sided dual-layer disc (DVD-17) (ECMA International 2001).

Figure 21: Four types of DVD-ROM discs have varying storage capacity. DVD-5 has a single storage layer and offers 4.7 Gb of storage. DVD-10 has a single storage layer on both sides of the disc and offers 9.4 Gb of storage. DVD-9 has two storage layers on one side of the disc and offers 8.5 Gb of storage capacity. DVD-17 has two storage layers on both sides of the disc and offers 17 Gb of capacity

One problem with the development of the DVD was how to ensure backward compatibility with the CD standard because of the different wavelengths, pit widths, and so on used. Solutions to this included the development of two lens objective assemblies in which the correct objective lens can be switched into the optical path depending on the type of disc being read, and the development of dual focus lens assemblies that, by using a hologram lens, permit the reading of both CD and DVD discs using the same objective lens and optical path.

The development of the DVD standard mirrored that of the CD with the introduction of a read-only format (DVD-ROM) in which information is premanufactured onto the disc like the CD-ROM and on through to the development of recordable and rewritable formats. The development of write-once and rewritable DVD formats resulted in the introduction of three competing DVD recording formats: the DVD-R/DVD-RW and DVD-RAM formats developed by the DVD Forum (2004), the original

developers of the DVD format; and the DVD+R/DVD+RW formats, developed by the breakaway DVD+RW Alliance (2006). The DVD-R/RW and DVD+R/RW formats offer the same storage capacity as the single-layer DVD-ROM disc, are compatible with the majority of DVD players, and offer dual-layer recording capabilities (DVD+RW was the first). However, the two formats are incompatible. The DVD-RAM format offers improved recording features such as random read-write access, much like an HDD, which was made possible through the use of data sectors addressed using embossed land and pit areas on the disc. However, the main disadvantage of the DVD-RAM format, which led to its limited commercial success, was its incompatibility with existing DVD players.

The recording and readout processes in the DVD formats are similar to that of the equivalent read-only, write-once, and rewritable CD-formats: Either a dye recording film is used in the write-once formats, or a phase-change recording medium is used in the rewritable formats. To enable the efficient recording of data at high data transfer rates, media manufacturers encode their discs with recording information that recorders access before recording.

HD-DVD and Blu-ray Disc: The Format War

The next generation of optical disc memories promise storage densities far in excess of the CD and DVD formats and have been developed to satisfy the data storage capabilities and data transfer rates required for the recording and playback of high-definition video (two hours of 1920×1080 pixel resolution video requires 22 Gb). The two competing standards—HD-DVD led by Toshiba and the Blu-ray disc led by Sony—are being promoted by leading industry groups and major Hollywood studios and are sure to ignite a format war similar to that of the competing videocassette formats, Betamax and VHS, in the 1980s. Both standards offer ROM, write-once, and rewritable formats using single- or dual-layer discs (although HD-DVD does not currently support a write-once, dual-layer format) and are aimed at eventually replacing DVD in many applications such as movie distribution, software distribution, and data archiving (Blu-ray 2004; HD DVD Technology 2006).

In both standards, increased storage capacity is achieved through the use of a blue laser (405 nm). However, the main difference between the two standards is that the Blu-ray disc offers a much higher storage capacity (as much as 54 Gb) compared to the HD-DVD system (32 Gb). The increase in storage capacity of the Blu-ray disc has been achieved by adopting an objective lens with a higher NA of 0.85 compared to 0.65 in the HD-DVD standard (Blu-ray 2005; HD DVD Technology 2006). The HD-DVD system is an extension of the DVD format and uses a similar 1.2-mm thick substrate formed by bonding two 0.6-mm thick substrates (DVD Forum 2004). However, the Blu-ray disc uses a 1.1-mm thick disc containing a 0.1-mm protective layer through which the blue laser is focused onto the underlying storage layer.

Because the HD-DVD technology is similar to that of the DVD, little investment is required to modify the disc production line to produce HD-DVD media. However, in

the case of the Blu-ray disc, the technology is sufficiently different to require the development of new production lines, which will delay the introduction of Blu-ray consumer products. In addition, the Blu-ray disc system is more susceptible to both scratches and dust on the disc surface because of the reduced thickness of the protective layer as well as from the aberrations introduced as a result of imaging using a higher NA objective lens. Consequently, it was initially believed that Blu-ray media would be enclosed in a cartridge to protect the disc. However, disc manufacturers are developing hard coatings that should provide sufficient disc surface protection (TDK 2006).

THE FUTURE OF OPTICAL MEMORIES

Optical memories have evolved to offer increased data storage densities, primarily by reducing the size of the optical stylus in successive generations. However, any further reduction in the size of the focused spot beyond that of the Blu-ray disc may be difficult for several reasons. Currently, no short-wavelength—that is, *ultraviolet* (UV)—semiconductor lasers are available, and the materials currently used to make discs absorb UV light, thus resulting in low light transmission at these wavelengths. In addition, the tolerances for defocus and depth of focus limit the increase in the NA of the objective lens, which is also limited to a maximum value of 1 in air. Increased storage densities may be achieved through the use of multilayer storage, but this will only offer a short-term solution to extend the capability of today's formats. Consequently, future generations of optical storage products will require the development of new optical imaging techniques and novel data storage mechanisms that will permit recorded features much smaller than those achievable using conventional approaches. There is currently considerable research in both the storage industry and academia on new optical data storage approaches; these include optical imaging systems based on near-field optics such as the solid immersion lens, advanced magnetic recording techniques such as the *magnetically amplifying magneto-optic system* (MAMMOS), and volumetric storage mechanisms using holography.

Near-Field Optical Storage

The minimum size of the focused spot in conventional storage systems is restricted by the diffraction limit in air (although the focused spot is observed in the substrate, the beam diameter is the same as would be observed in air). However, in near-field optics the diffraction limit in air can be circumvented through the use of nano-sized apertures or the more attractive *solid immersion lens* (SIL) (Mansfield and Kino 1990). The SIL is a hemisphere made from a material of high refractive index ($n > 1$) placed such that its flat surface is coincident with the focal point of the objective lens (see Figure 22). Because the speed of light is reduced on propagation through a material of higher refractive index, the wavelength of the light focused inside the SIL is reduced by a factor of $1/n$. Consequently, the effective NA, NA_{eff} , of the optical system is increased to nNA , where NA is the numerical

Figure 22: In near-field recording using a solid immersion lens, the SIL is placed close to the focal point of the lens but is separated from the spinning disc by an air gap. The size of the optical stylus is reduced by a factor $1/n$ over that attainable in air. The inset illustrates that, in a practical recording system, the design of the SIL can take account of the presence of any cover layer on the disc, which must have the same refractive index as the SIL material, and that an air gap invariably exists between the flat bottom surface of the SIL and the disc surface

aperture of the focusing objective lens. Hence, the size of the focused spot is reduced by a factor of $1/n$ over that attainable in air. Further improvements in the resolution of an SIL-based imaging system may be achieved through the use of a stigmatic SIL, or supersphere, which permits a further reduction in the size of the focused spot by a factor of $1/n^2$ over that attainable in air (Terris et al. 1994).

The use of the SIL in optical memories offers several technical difficulties, most notably the inevitable presence of an air gap between the bottom flat surface of the SIL and the surface of the disc because the disc must move independently of the optical head. The air gap reduces the transmission efficiency of the optical system and introduces aberrations that lead to an overall loss in resolution (Mansfield et al. 1993). In a system where $NA_{eff} < 1$, the effect of the air gap is to introduce spherical aberrations. Providing that the air gap is held constant, these aberrations can be alleviated through the careful design of the objective lens. In systems where $NA_{eff} > 1$, rays incident at the SIL–air gap boundary at an angle greater than the critical angle, $\theta_c = \sin(1/n)$, will be totally internally reflected, and the evanescent fields associated with these rays exponentially decay as they propagate across the air gap. As a result, the air gap has to be kept as small as possible—ideally, < 100 nm—to maintain the benefits of near-field imaging and maintain a focused spot much smaller than that achievable in air (Hayashi and Kino 1995); this is particularly true in the application of the stigmatic SIL. The design of the SIL can take into account the thickness of any cover layer on the disc, in which case the laser beam is focused onto the surface of the storage layer in the disc as illustrated in the inset of Figure 22 (Hayashi and Kino 1995).

To maintain the benefits of near-field imaging, it is important that the air gap remains constant as the disc spins. As a result, near-field gap servomechanisms have been devised that, using a variety of techniques, can monitor the depth of the air gap and adjust the vertical position of the SIL to compensate for any variations in the air gap's depth. Measurement of the air gap can be achieved using a variety of techniques—for example optically—that can then be used to provide feedback signals to control the vertical position of the SIL above the disc surface and maintain a constant air gap. Philips has devised a technique in which the air gap can be held constant at 25 nm.

Near-field-based storage systems using both phase-change and magneto-optical storage media have been investigated by major optical disc manufacturers, such as Philips, as a possible next-generation optical memory after HD-DVD and Blu-ray disc (Hewett 2005). Storage densities in excess of $4\times$ using Blu-ray may be achievable (Milster 2000). An alternative near-field configuration that has been developed by Callimetrix and involves the fabrication of nano-size SIL-like structures within the disc itself, thus achieving near-field storage capabilities in a DVD-type platform (Guerra et al. 2001). However, the discs may be difficult and expensive to mass replicate.

Other techniques achieve near-field imaging capabilities by employing complex media structures such as the *super-resolution near-field structure* (Super-RENS) approach (Tominaga, Nakano, and Atoda 1998). The Super-RENS system uses a phase-change Ge-Sb-Te storage layer with an additional nonlinear Sb layer. The complex readout mechanism in Super-RENS is not well understood, but the nonlinear layer acts to produce a near-field region when illuminated using a conventional optical head, allowing the imaging of subdiffraction-limited recorded marks of diameter <60 nm in the underlying storage layer.

Advanced Magneto-Optical Recording Techniques

In phase-change recording, the size of the recorded domain is limited by the size of the optical stylus used to record data to the disc. However, in MO recording this is not the case, and marks much smaller than the size of the focused spot can be recorded using magnetic field modulation. However, the size of these features may be beyond the resolving capabilities of the optical head and, as a result, optical techniques such as near-field imaging, or the use of

complex media structures, must be adopted to resolve the recorded marks and recover the recorded data.

Magnetic Super Resolution

The *magnetic super resolution* (MSR) technique, as illustrated in Figure 23, offers one way to increase the MO storage capacity and permit the imaging of subdiffraction limit-sized recorded domains using a conventional optical head (Takahashi et al. 1994).

The MSR disc contains two magnetic layers: a perpendicularly magnetized recording layer, to which the data is recorded, and a readout layer, from which the data is recovered. At room temperature the magnetization of the readout layer is in-plane so it exhibits no polar Kerr signal; as a result it masks the underlying recording layer where the high-density domains are stored. Upon application of a focused laser beam, any domain present in the recording layer beneath the focused spot, which would not normally be resolved by the focused laser beam, is copied to the readout layer to contribute to the replay waveform; any surrounding recorded domains are masked by the in-plane magnetization of the rest of the readout layer. As the focused spot scans along the track the domain disappears and the next recorded mark along the data track appears. A commercial MO recording system using MSR is already available, the GIGAMO format developed by Fujitsu and Sony, which offers up to 2.3GB storage on a 3.5-inch disc.

Domain Wall Displacement Detection

Domain wall displacement detection (DWDD) operates in a three-layer magneto-optical recording medium consisting of a bottom recording layer, an intermediate switching layer, and an upper displacement layer (see Figure 24). At room temperature, the domains stored in the recording layer are copied to the displacement layer because of the strong exchange coupling between layers. However, when a focused laser beam is applied, the switching layer is heated above its Curie temperature (which is less than that of the recording and displacement layers), and the exchange coupling between layers disappears. As a result, the small domains in the displacement layer expand temporarily so that they can be resolved by the focused spot (Jenkins et al. 2003). DWDD is used in the latest version of the MiniDisc system, Hi-MD, developed by Sony, which permits a storage density of 1 Gb in the standard MiniDisc form factor.

Figure 23: In the MSR technique, the in-plane magnetization of the readout layer masks the underlying perpendicularly magnetized recording layer. On application of a focused laser beam, the readout layer heats up and the recorded domain present in the recording layer beneath the focused spot is copied to the readout layer and contributes to the replay waveform

Figure 24: In domain wall displacement detection, the recorded marks, which are too small to be resolved by the focused spot during readout, are copied to the displacement layer. On application of the focused spot, the copied marks expand beneath it and contribute to the replay waveform

Figure 25: In MAMMOS, the subdiffraction limit-sized recorded domains in the recording layer are copied into the readout layer and expanded when the read beam is applied. The expanded domain diminishes when the laser beam moves away from the recorded domain

The Magnetically Amplifying Magneto-Optic System

MAMMOS is an alternative MSR approach that uses the two-layer storage medium illustrated in Figure 25. The MAMMOS disc structure contains a Tb-Fe-Co recording layer on which high-density magnetic domains are recorded (and which are too small to be resolved by

the optical head) and a Gb-Fe-Co readout layer, from which the recorded data are recovered. Recording is performed using the conventional magnetic field modulation approach. However, during readout, the high-density domain is copied from the recording layer to the readout layer where it magnetically expands to cover the area of the focused spot by a thermal-magnetic process. As a result, the amplitude of the replay waveform is amplified (Awano and Ohta 1998). As soon as the optical stylus moves past the recorded mark, the copied domain immediately shrinks and disappears. This growing and shrinking process continues as the focused spot scans along the recorded track, resulting in a replay waveform exhibiting good signal-to-noise ratio characteristics. Storage densities of more than 150 Gb on a standard 12-cm disc may be possible using this approach; these can be further increased through the application of near-field SIL imaging and the utilization of a blue laser.

Hybrid Recording

Hybrid recording, or *heat-assisted magnetic recording* (HAMR), offers one way of extending the data storage capabilities of magnetic storage systems beyond the coveted milestone of 1 Tbit/in². Although a storage device incorporating hybrid recording is not an optical memory, it does rely on the thermo-magnetic recording process used in MO systems. To achieve a high data storage capacity in magnetic storage systems, recorded domains need to be as small as possible (≈ 25 nm in diameter for a storage density of 1 Tbit/in²). However, any reduction in the size of the recorded domain leads to thermal instability, so random thermal fluctuations can change the magnetization state of the recording medium. To combat this, recording materials of high coercivity (10 KOe) must be used; these are difficult to switch using the magnetic fields produced by conventional magnetic record heads. To overcome the problem of recording to high-coercivity media, a focused laser beam can be used to heat the magnetic recording medium, thus lowering the film's coercivity and allowing the data to be recorded using a conventional recording head. One problem with the practical implementation of HAMR is the design of a suitable light delivery path, and several techniques such as the use of an SIL and nano-apertures are being explored (Challener et al. 2003).

Holographic Memory

The development of holographic storage has been ongoing since long before the introduction of the first optical memory. However, the development of a commercial system has been hampered by the need for complex components such as spatial light modulators and large detector arrays, as well as by the lack of suitable recording media. This type of system has the potential to offer huge storage density improvements and significantly higher data-transfer rates compared to that permitted using conventional optical disc memories. These improvements are made possible because data are recorded to the storage medium in the form of pages of data containing more than a million bits and are correspondingly recovered in a parallel fashion (Inphase Technologies 2006).

Figure 26: The recording and replay process in holographic storage. (a) Recording is performed using two laser beams derived from the same source. The digital data are encoded onto the data beam as a page of light and dark pixels using a spatial light modulator. The data beam and reference beam interfere in the recording medium, and the resulting interference pattern is recorded. (b) Readout is performed by illuminating the holographic storage medium with a reference beam to regenerate the recorded data. The recovered data are then projected onto a camera, from which each pixel of data is recovered

Figure 26 illustrates the recording and readout of data using holography.

In holographic recording, the digital data are encoded onto a data beam as a page of light and dark pixels using a device called a *spatial light modulator*. The data beam interferes with a reference beam in the volume of the storage medium to form an interference pattern. Because the storage medium is light-sensitive, much like photographic film, the light-intensity pattern produced by the interference of the two light beams is recorded. If the recorded area in the medium is illuminated with a reference beam of identical characteristics to that used in the recording process, then the original data beam can be reconstructed and detected electronically using a detector, such as a charge-coupled device (CCD) camera, which is able to detect the individual pixels in the recovered beam (Coufal, Psaltis, and Sincerbos 2000; Ashley et al. 2000). Multiple pages of data can be written to the same position in the medium using some form of addressing technique, such as wavelength or angle multiplexing, as illustrated in Figure 27. Increased storage densities can

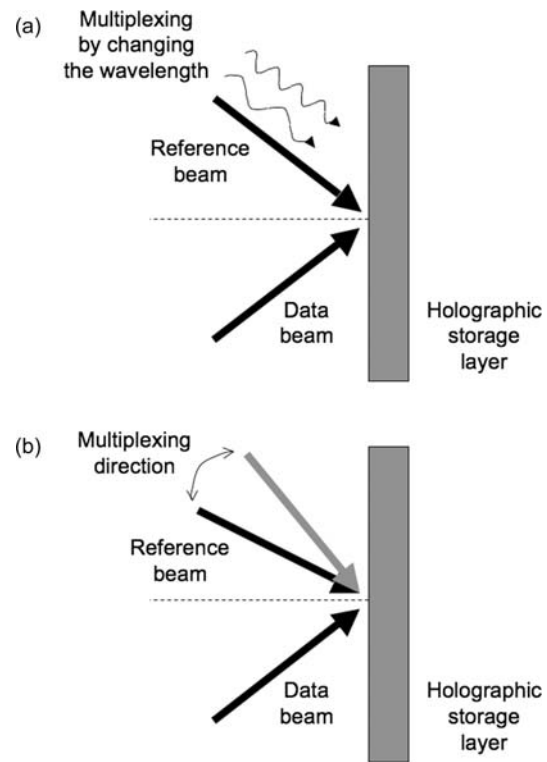

Figure 27: Multiplexing techniques for addressing pages of data in holographic storage. (a) In wavelength multiplexing, each page of digital data is recorded using a specific wavelength of illumination. The individual pages are recovered by illuminating the storage medium with a reference beam of identical wavelength to that employed in the recording process. (b) In angle multiplexing, each page of data is recorded with the reference beam at a prescribed angle of incidence to the holographic recording medium. The individual pages are then recovered by illuminating the storage medium with the reference beam at the angle used to originally record the desired page

also be achieved by focusing the beams onto the recording medium.

In *wavelength multiplexing*, a page of data is recorded to the holographic medium using a reference beam of a particular wavelength; additional pages of data can be recorded to the same volume of the storage medium through the use of a different wavelength. Each page of recorded data can then be recovered by illuminating the storage medium with a laser beam of identical characteristics to that used in the original recording process (i.e., a beam of the same wavelength).

In *angle multiplexing*, a page of data is recorded to the holographic medium with the reference beam aligned to a specific angle; additional pages can be recorded to the same volume of the storage medium by changing the angle of incidence of the reference beam. Each page of data can then be recovered by illuminating the storage medium with a reference beam applied at the same angle used for recording (Coufal, Psaltis, and Sincerbos 2000). Although practically difficult to implement, angle multiplexing has been adopted in commercial holographic

storage systems currently under development (InPhase Technologies 2006).

Major obstacles in the commercialization of holographic storage systems have been the availability of both suitable system components and, more importantly, the availability of suitable storage media. However, most of these problems have been solved, and polymer-based write-once media have been developed. Two companies are currently developing commercial holographic memory technologies: InPhase Technologies and Optware. InPhase Technologies (2006) has recently demonstrated the highest data storage capacity of any commercial storage technology; with a capacity of 515 Gbits/in², which is far in excess of that achievable in today's magnetic hard disk drives. Inphase hopes to introduce a commercial system on the market soon with an initial storage capacity of 300 Gb on a single disc with a data-transfer rate of 20 Mb/s, with capacities rising to 800 Gb and 1.6 Tb in future generations. However, holographic technologies currently only offer a write-once format aimed primarily at data-archiving applications, and, in addition, the high cost of such systems will initially preclude their use in consumer applications.

CONCLUSION

Over the last twenty-five years, optical memories have evolved to offer increased storage densities and the ability to record and erase digital data in a removable, reliable disc format. From the 650-Mb storage capacity of the CD to the 17-Gb storage capacity of the DVD, the advances in storage capacity have been achieved through the adoption of short-wavelength laser sources and high-NA objective lenses, thus resulting in smaller focused spot sizes for the recording and readout of digital data. The next generation of competing optical disc standards, HD-DVD and Blu-ray disc, promise sufficient storage capabilities to enable the storage of movie-length, high-definition video on a single 12-cm diameter disc. It is difficult to predict which one of these standards will triumph, but it is clear that the consumer will ultimately benefit from the huge data storage capacities offered. Future storage technologies promise even greater storage capabilities, far in excess of the CD and DVD standards, through the adoption of new imaging techniques and the development of innovative storage media.

GLOSSARY

Analog-to-Digital Converter (ADC): An electronic device that converts a continuous analog signal into a sequence of discrete binary digital values, typically at regular time intervals. The value of the digital code at the point of sampling is proportional to the amplitude of the analog signal.

Constant Angular Velocity (CAV): If the disk spins at a constant angular velocity, then it spins at a constant angular rotation per unit time; consequently, the linear speed of the disk with respect to the radial position of the optical head varies along with the rate that the data is read from the disk.

Constant Linear Velocity (CLV): If the disk spins at a constant linear velocity, then the linear speed of the disk with respect to the radial position of the optical head is constant. Consequently, to read data from the disc at a constant data rate, the speed of the disc has to vary (the rotational rate increases as one moves toward the center of the disc).

Eight-to-Fourteen Modulation (EFM): Eight-to-fourteen modulation is a DC-free run-length limited (RLL) coding scheme where each 8-bit block of data is converted into a 14-bit codeword using a lookup table; the encoded data are then recorded to the optical disk. The coding of data using this approach ensures that a regular alternating pattern of digital 0's and 1's are recorded in order to prevent a continuous stream of like symbols being recorded.

Error-Correcting Code (ECC): An error-correcting code is used to enable the recovery of stored data even if they are corrupted during recovery. ECC is added to the recorded data sequence as extra redundant data, the form of which depends on the error-correcting scheme employed.

Full Width at Half Maximum (FWHM): The full width at half maximum is a measure of the width of a function or distribution at half its maximum value. In optics, the FWHM is often used as a measure of the width of the focused spot profile and is the distance between the points where the (typically Gaussian) profile is one-half the amplitude of the maximum (or peak) intensity.

Intersymbol Interference (ISI): Intersymbol interference is a form of signal distortion arising because of the temporal spreading and consequent overlap of replay pulses during replay. ISI results in the inability to distinguish between different recorded states, making recovery of stored data difficult.

Modulation Transfer Function: The modulation transfer function is a measure of the variation in the magnitude of a signal as a function of the spatial frequency distribution of features on the disk.

Numerical Aperture (NA): Numerical aperture is a dimensionless quantity that indicates the resolving power of a lens. The size of the smallest object that can be resolved is proportional to the inverse of the lens NA.

Signal-to-Noise Ratio: The signal-to-noise ratio is a measure of the signal quality with respect to the background noise corrupting it. SNR is defined as the ratio of the signal power to the noise power, and it is often expressed in logarithmic decibel units (dB).

Spatial Light Modulator: A spatial light modulator is an optical device that can be used to spatially modulate the intensity of a light beam.

INTRODUCTION

Work on the characterization of optical fiber began as soon as the first fibers were developed. The National Bureau of Standards (NBS) took the lead in 1976 when telephone companies around the world were just beginning to test optical communications systems in the field. Most of the fiber then available was multimode fiber, in which several hundred optical modes propagate in a core that is typically 50–100 μm in diameter. The typical operating wavelength was approximately 850 nm. Data rates were relatively low, often a few Mb/s. Many of the early problems in optical fiber characterization related directly to multimode propagation in the fiber. Differences in attenuation among the modes led to variations in measured attenuation, depending on how the light was launched into the fiber. Methods of measuring physical parameters such as attenuation, refractive index profile, and fiber geometry such as core and cladding diameters were published in a series of NBS *Technical Notes*, that were later collected in two volumes titled *Optical Fiber Characterization* (Danielson et al. 1982; Chamberlain et al. 1983).

Today, almost all of the communication field fibers operate as single mode. Operating wavelengths now cover 1300 nm to 1600 nm. Compared to multimode fiber, single-mode fiber offers both reduced attenuation and substantially higher bandwidth. Thus, today's long-distance and metropolitan networks consist solely of single-mode fiber. Nevertheless, multimode fiber has found an important niche in high-speed, local area data networks with concepts such as "fiber to the desk" and "Gigabit Ethernet." The larger core fiber offers inexpensive connections, high launching efficiency with large area sources, and the use of inexpensive plastic optics. Therefore, the contribution of NBS's *Optical Fiber Characterization* remains technically relevant to current high-speed local area networks.

Fiber manufacturers commonly perform the following characterizations for their fibers: refractive index profile, fiber geometry such as core and cladding diameters, cladding noncircularity and core cladding nonconcentricity error, mode field diameter at 1310 nm and 1550 nm, effective area at 1310 nm and 1550 nm, and cutoff wavelength. These fabrication parameters are critically important in theoretical prediction of the performance of the resulting fiber.

Therefore, it is important to independently perform these tests when deciding on potential fibers for a new fiber communication network. Their postcharacterization for an existing fiber network becomes somewhat less an issue because one needs to focus on the characterization of the whole network. There are many physical aspects of the network that are not known accurately and that are nearly impossible to prevent from varying because of the dynamic environmental fluctuations, especially aerial field fibers. In this chapter, we will discuss how to characterize the parameters that are important for existing fiber networks.

ATTENUATION

The power of a signal propagating in an optical fiber decreases exponentially with distance, with material absorption and Rayleigh scattering making the dominant contributions to the loss (Agrawal 2001; Saleh and Teich 1991). The attenuation coefficient of a fiber is usually specified in units of dB/km according to the relation $\alpha = (-10/L)\log[P(L)/P(0)]$, where $P(0)$ is the power at the input of the fiber and $P(L)$ is the power at distance L . An example of the attenuation spectrum of an optical fiber is shown in Figure 1.

Rayleigh scattering is caused by variations in the refractive index that occur over distances shorter than the light wavelength, with the refractive index variations resulting from density fluctuations frozen into the fiber material during manufacture (Iannone et al. 1998; Agrawal 1997). The loss resulting from Rayleigh scattering is proportional to $1/\lambda^4$, where λ is the wavelength. For a typical silica fiber, the Rayleigh scattering loss is approximately 0.14 dB/km in the 1550-nm wavelength region (Bickham and Cain 2002b).

Material absorption can be classified as *intrinsic absorption* caused by pure silica or *extrinsic absorption* caused by the presence of impurities (Agrawal 1997). In the attenuation spectrum of Figure 1, the relatively steep increase in attenuation at wavelengths above 1600 nm results from the absorption caused by vibrational resonances of the silica molecules. For the remaining wavelength range of 1200 nm to 1600 nm, the contribution of intrinsic absorption is relatively small. The main

Figure 1: Attenuation spectrum of a silica-germania optical fiber. Reproduced from Bickham and Cain 2002a

source of extrinsic absorption is the presence of OH ions. Overtones of the OH vibrations produce a peak in the attenuation spectrum at 1380 nm, which is clearly visible in Figure 1 (Bickham and Cain 2002b).

In addition to Rayleigh scattering and material absorption, attenuation in an optical fiber can also be caused by two types of bending (Keiser 2003): (1) macroscopic bends with radii that are large compared with the fiber diameter and (2) random microscopic bends of the fiber axis. A long fiber span is normally composed of a number of shorter fiber segments, and the loss of such a span will also include contributions from splices and from the connectors at the ends of the span.

In optical system design, it is important to know the optical power levels at the input of optical amplifiers, at the input of fiber spans, and at the photoreceiver. Therefore, the loss of each fiber span in an optical link must be known. The loss of an installed fiber span is typically characterized through an insertion-loss measurement or through optical time-domain reflectometry. For a more complete characterization, both measurements are taken (Feuerstein 2005) because insertion-loss measurements tend to give the more accurate loss values whereas optical time-domain reflectometry gives valuable information on the spatial distribution of loss along the span.

Figure 2 shows the setup for an insertion-loss measurement of a fiber span using a laser source and optical power meter. The measurement process consists of two steps: (1) a calibration measurement and (2) a measurement through the span. The proper calibration setup depends on the end points defining the loss of the span (Talbot and Michel, undated). As an example, consider the case where the span loss is defined between points A and B in Figure 2b—that is, between the input of the patch panel at the transmit site and the output of the patch panel at the receive site. The span loss then includes the loss of the fiber cable and the losses of the patch panel connectors. In this case, the calibration measurement of step 1 is taken with the laser source connected directly to the power meter with a patch cord as shown in Figure 2a. In step 2, the connections are as shown in Figure 2b, with the laser source connected to the patch panel at the transmit site (using the same patch cord from step 1) and the power meter connected to the patch panel at the receive site (using a second patch cord). Patch cord 1 in Figure 2 should remain connected to the laser source throughout measurement steps 1 and 2 in order to maintain a constant coupling of optical power from the laser to the patch cord. After measurement steps 1 and 2 are completed, the fiber span loss (in dB) is calculated by subtracting the power measured in step 2 from that measured in step 1 (where both powers are expressed in units of dBm).

It can be useful to take loss measurements at multiple wavelengths because the fiber attenuation is wavelength-dependent. For example, measurements of loss can be taken at 1550 nm and 1625 nm to characterize both C and L bands (Feuerstein 2005). The loss can also be characterized as a function of wavelength by using a tunable laser source or by using a broadband source in combination with an optical spectrum analyzer.

A portion of the light propagating in an optical fiber is returned back toward the source because of Rayleigh scattering and Fresnel reflections. An *optical time-domain reflectometer* (OTDR) characterizes loss and reflection as a function of distance along a fiber span by launching a short pulse and analyzing the returning power as

Figure 2: Insertion loss measurement. (a) Setup for the calibration measurement and (b) setup for the measurement through the span

a function of time. In addition to the total span loss, an OTDR can measure the loss and reflectance of the splices, connectors, and fiber segments making up the span.

The features of a typical OTDR trace are shown in Figure 3 (Beller 1998; Keiser 2000). The vertical axis corresponds to the back-reflected power level in dB, calculated as $5\log(\text{power})$ rather than $10\log(\text{power})$ because of the round-trip nature of the pulse propagation. The horizontal axis corresponds to the distance along the fiber relative to the position of the OTDR. This distance is calculated as $d = tv_g/2$, where d is the distance, v_g is the group velocity (the velocity at which the pulse propagates in the fiber), and t is the time elapsed between the launch of the pulse from the OTDR and the measurement of the back-scattered power. The factor of 2 in the calculation is, again, because of the round-trip nature of the measurement.

The straight-line segments of the OTDR trace are the result of Rayleigh scattering in the fiber. The slope of a straight-line segment is equal to the attenuation coefficient of that fiber segment in units of dB/km.

The spikes in the OTDR trace are the result of discrete reflections. There are three reflections in Figure 3: They occur at the input of the span (because of the connection of the OTDR and fiber), at a connector pair within the span, and at a nonterminated fiber end at the output of the span. The reflections at the input and output of the span may conceal useful information at these locations—for example, the loss and reflectance of patch panel connectors. If desired, this information can be obtained by connecting launch and tail reels of fiber at the input and output of the span. The reels of fiber should be longer than the OTDR dead zone (Feuerstein 2005), where *dead zone* refers to the distance over which information is lost because of saturation of the OTDR receiver as the result of a reflection (Beller 1998).

Abrupt changes in the backscattered power level are caused by discrete sources of loss such as splices and fiber bends. An OTDR measurement of a splice or connector loss will be affected by a difference in the backscattering characteristics of the two fibers spliced or connected. This uncertainty can be overcome through bidirectional OTDR measurements in which measurements are taken from both ends of a span and averaged (Corning Incorporated 2001).

The spatial resolution l in an OTDR measurement is given by $l = v_g \tau/2$, where τ is the width of the OTDR pulse

and it is assumed that the OTDR receiver bandwidth is large enough that the pulse is not significantly broadened on detection (Gold 1985). There is an inherent trade-off that must be made between spatial resolution and dynamic range, another important OTDR parameter that is related to the maximum loss that can be measured as well as the time required (with averaging of the backscattered signal) for the measurement of a given loss (Beller 1998). The dynamic range can be increased through an increase in pulsewidth (which increases the energy of the backscattered signal) and a decrease in the receiver bandwidth (which leads to a reduction in noise power). In contrast, higher spatial resolution calls for a decrease in pulsewidth and a corresponding increase in the receiver bandwidth.

In summary, the loss of a fiber span can be obtained through insertion-loss or OTDR measurements. If possible, both measurements should be taken to give a more complete characterization of the span. Insertion-loss measurements tend to give more accurate values of the end-to-end span loss, whereas the OTDR gives a distributed measure of loss that can identify and locate sources of unexpectedly high loss such as bad splices, macrobends, and even catastrophic failures such as fiber breaks.

Further details on the operational fundamentals and applications of OTDRs can be found in Beller (1998) and Keiser (2000), whereas a detailed discussion of insertion-loss measurements can be found in Hentschel and Derickson (1998).

DISTRIBUTED STRESS AND TEMPERATURE MONITORING OF OPTICAL CABLES

Polarization mode dispersion (PMD) is a limiting factor for high-speed optical communication systems at 10 Gb/s or higher, and PMD is sensitive to cable strains through the environmental conditions, especially wind and large temperature gradients. It is critically important to measure the cable strains, especially for aerial or submarine fibers.

Because communication fibers are in the range of tens to hundreds of kilometers, such a measurement can be achieved with distributed fiber sensors, particularly the Brillouin optical time domain amplification system; this kind of system has the advantages of a long sensing range and the capability of providing the strain at every spatial resolution over the entire sensing fiber, rather than at discrete points, by using the fiber itself as the sensing medium. Spatial information along the length of the fiber can be obtained through optical time domain reflectometry by measuring propagation times for light traveling in the fiber. This allows for continuous distributions of the cable strain in distributed fashion, which can be obtained by the distributed Brillouin scattering or Rayleigh scattering. The most commonly used measurement technique is the Brillouin scattering-based distributed sensing because it provides long sensing length. The longest reported distributed sensor length using spontaneous Brillouin scattering is 57 km with a spatial resolution of 20 m (Maughan, Kee, and Newson 2001), whereas

Figure 3: Features of a typical OTDR trace

for a Rayleigh scattering-based distributed sensor, the reported sensor length is in the range of tens of meters (Gifford et al. 2005). The short sensing length in Rayleigh scattering-based distributed sensors is a result of the bandwidth of the broadband source because coherent phase detection is often used as the demodulation process resulting from the weak dependence of the temperature on the Rayleigh scattering comparing to Brillouin scattering (Li, Zhang, and Yoshino 2003). This has limited applications in cable strain monitoring, which requires tens to hundreds of kilometers of fiber to be monitored.

The distributed Brillouin sensor uses Brillouin scattering, which arises from the interaction of light with acoustic phonons propagating in the fiber core. Scattering is in the backward direction with the scattered light experiencing a frequency shift proportional to the velocity of the acoustic phonons. The sensing capability of this scattering phenomenon arises from the dependence of the acoustic velocity, and hence the Brillouin frequency shift, on both strain and temperature.

The concept of using Brillouin scattering for fiber-optic sensing was first proposed in 1989 (Horiguchi and Tateda 1989), and it was termed *Brillouin optical time-domain analysis* (BOTDA). This approach involved launching a short pump pulse into one end of the test fiber and a *continuous wave* (CW) probe beam into the other end. The frequency difference between the two lasers could be set to a particular value corresponding to the Brillouin frequency of the optical fibers, and the CW probe would experience gain at locations along the fiber. The gain as a function of position along the fiber could thus be determined by the time dependence of the detected CW light. By measuring the time-dependent CW signal over a wide range of frequency differences between the pump and probe, the Brillouin frequency for each fiber location could be determined. This allowed for the strain or temperature distribution along the entire fiber length to be established.

The first strain distribution measurement was reported on submarine cables (Tateda et al. 1990) and the use of distributed fiber sensors based on Brillouin scattering. The reported strain distribution was obtained over a 1.3-km cable (Horiguchi, Kurashima and Tateda 1989; Horiguchi and Tateda 1989). Later, another strain test on the bent slot-type optical cables was reported (Horiguchi et al. 1992).

Temperature measurement using Brillouin scattering was proposed in 1989 (Culverhouse et al. 1989) utilizing the linear relationship between Brillouin shift and temperature in a single-mode fiber and measured by a Fabry-Perot interferometer. Then a distributed temperature

measurement on a 1.2-km *single-mode fiber* (SMF) with a 3°C temperature resolution and a 100-m spatial resolution was demonstrated with a BOTDA system (Kurashima, Horiguchi, and Tateda 1990) as shown in Figure 4.

The next development in BOTDA was the use of Brillouin loss rather than Brillouin gain (Bao, Webb, and Jackson 1993) to increase the sensing length. Instead of the frequency of the pump being greater than the frequency of the probe, the opposite was implemented. The CW probe therefore experienced loss, rather than gain, at locations along the fiber at which the frequency difference between the lasers matched the Brillouin frequency of the fiber. As the pump pulse is not depleted in this case, longer sensing lengths of 50 kilometers for 10-m spatial resolution was reported using the Brillouin loss mechanism (Bao et al. 1995).

Another development using Brillouin scattering is a single-ended BOTDA system (Fellay et al. 1997). An amplitude modulator generates frequency-shifted sidebands that can serve as a probe. By eliminating the second laser, the cost of the system is reduced. However, the added costs of the frequency modulator, drivers, and *erbium-doped fiber amplifiers* (EDFAs) result in minimal cost savings. This system has been used for temperature monitoring in the field. Fiber was embedded in the Luzzone Dam in the Swiss Alps to monitor the temperature of the concrete during curing (Thévenaz et al. 1998).

Thus, Brillouin scattering-based systems were well suited for long-range sensing, such as communication cable strain or temperature monitoring. On the other hand, strain monitoring for civil engineering and aerospace structures required much shorter spatial resolutions than were achievable, as well as shorter sensing length than communication fibers. Recent research efforts have been directed toward reducing the spatial resolution to the point where it is practical for structural monitoring applications. The first 10-cm spatial resolution was demonstrated in 1999 using BOTDA technique (Bao et al. 1999). This is remarkable: It had been believed that 1-m spatial resolution would be the best that could ever be achieved because of the finite lifetime of the acoustic phonons (Hotate and Hasegawa 1998; Horiguchi et al. 1995). The most recent developments on this technique have been focused on structural health monitoring of various civil structures, which is outside the domain of fiber communications (Ohno et al. 2001).

One problem with the implementation of Brillouin scattering-based sensing systems in the field is the sensitivity of the Brillouin frequency shift to both strain and temperature. This leads to ambiguity in the

Figure 4: Gain-based BOTDA configuration

measurement because we do not know whether the frequency shift was caused by the strain or temperature changing. In a laboratory environment, the temperature is essentially constant, and its effects can generally be neglected when measuring strain. In many field situations, this is not the case.

An early solution to this problem proposed the use of two fibers placed adjacent to one another, with one fiber isolated from any strain effects (Bao, Webb, and Jackson 1994). The isolated fiber would be used to monitor the temperature, while the other fiber would measure the effect of both strain and temperature. Recent innovative approaches to measuring strain and temperature simultaneously have been developed. By combining the Landau-Placzek ratio with the frequency shift, the temperature and strain were determined simultaneously (in the spontaneous Brillouin scattering regime) at a spatial resolution of 40 m (Parker et al. 1998). Most recently, an improved system of a temperature resolution of 4°C, a strain resolution of 290 micro-strains, and a spatial resolution of 10 m were reportedly achieved for a sensing length of 15 km using the same principle (Huai, Lees, and Newson 2000). Centimeter resolution has been achieved with simultaneous temperature and strain sensing using Brillouin loss-based distributed sensor with polarization-maintained fibers (Bao, Yu, and Chen 2004) and photonic crystal fibers (Zou et al. 2004).

In summary, the Brillouin scattering-based distributed sensors provide long-distance sensors with meter to submeter spatial resolution. With both BOTDA and the Brillouin optical time-domain reflectometer, the measurement range is only limited by the fiber loss. This is especially important for long-haul fiber characterization for strains that would induce PMD as the system limitation for > 10-Gb/s communication systems.

CHROMATIC DISPERSION

The group velocity associated with the fundamental mode in an SMF varies with wavelength, leading to pulse broadening and intersymbol interference in fiber-optic communications (Agrawal 1997). This phenomenon is known as *chromatic dispersion*, and it is the result of two physical mechanisms: material dispersion and waveguide dispersion (Saleh and Teich 1991; Yariv 1997). *Material dispersion* results from the wavelength dependence of the refractive indices of the fiber core and cladding regions. *Waveguide dispersion* is caused by the wavelength dependence of the optical power distribution in the core and cladding; because the phase velocities in the core and cladding are different, the group velocity of the mode varies with wavelength.

The chromatic dispersion of a fiber is characterized by the dispersion parameter D (Agrawal 1997):

$$D = \frac{d}{d\lambda} \left(\frac{1}{v_g} \right) = \frac{1}{L} \frac{d\tau_g}{d\lambda}$$

where λ is the wavelength, v_g is the group velocity, L is the length of the fiber, and τ_g is the group delay (i.e., the time that it takes for a signal to propagate through the fiber).

D is normally specified in units of ps/nm/km. Wavelength components of a signal spaced by $\Delta\lambda$ propagating through a fiber of length L will have a difference in group delay of $DL\Delta\lambda$. Chromatic dispersion thus leads to a broadening of the pulses used in optical communications because the different wavelength components of a pulse have different arrival times at the receiver.

In addition to causing pulse broadening, chromatic dispersion also has a major impact on the nonlinear interactions between channels in *wavelength-division-multiplexed* (WDM) systems (Chraplyvy 1990). The dispersion of an optical link, including contributions from fiber, components, and (potentially) dispersion-compensating fiber, must be kept within the specified limits of a given system to meet the target bit error rate. Measurements of dispersion are carried out by manufacturers of optical fiber and components, optical system vendors, and service providers.

In this section, we provide an overview of three techniques that are commonly used to measure chromatic dispersion: the modulation phase-shift, interferometric, and time-of-flight techniques. The three techniques have the following procedure in common: (1) The relative group delay of different wavelength components (i.e., the variation of the group delay with wavelength) is measured for the *fiber under test* (FUT); (2) these results are then normally smoothed by fitting appropriate equations to the measured data (Cohen 1985); and (3) the dispersion parameter is calculated as a function of wavelength according to

$$D(\lambda) = \frac{1}{L} \frac{d\tau_r(\lambda)}{d\lambda} \quad (1)$$

where $\tau_r(\lambda)$ is the relative group delay as a function of wavelength. Several fitting equations have been used in step 2, including five- and three-term Sellmeier functions and polynomials of various orders (Cohen 1985). The best choice of fitting equation depends on the type of fiber (for example, dispersion-shifted versus nondispersion-shifted) that is being measured (Hernday 1998). The three chromatic dispersion measurement techniques use different methods to determine the relative group delay as a function of wavelength in step 1.

The *modulation phase-shift method* (Hernday 1998) is used to measure the dispersion of both short and long lengths of optical fiber as well as optical components. Figure 5a shows the measurement setup. The output of a narrowband tunable laser is modulated with a sinusoidal signal before being transmitted through the FUT. At the output of the FUT, the phase of the detected optical signal is measured relative to the phase of a reference signal (as shown in Figure 5a, the electrical modulation source can also provide the reference signal). The measurement is repeated at multiple optical wavelengths, and the difference in the group delays of adjacent wavelengths is given by (Hernday 1998)

$$\Delta\tau(\lambda_{avg}) = - \frac{\phi(\lambda_{avg} + \Delta\lambda) - \phi(\lambda_{avg} - \Delta\lambda)}{360f_m}$$

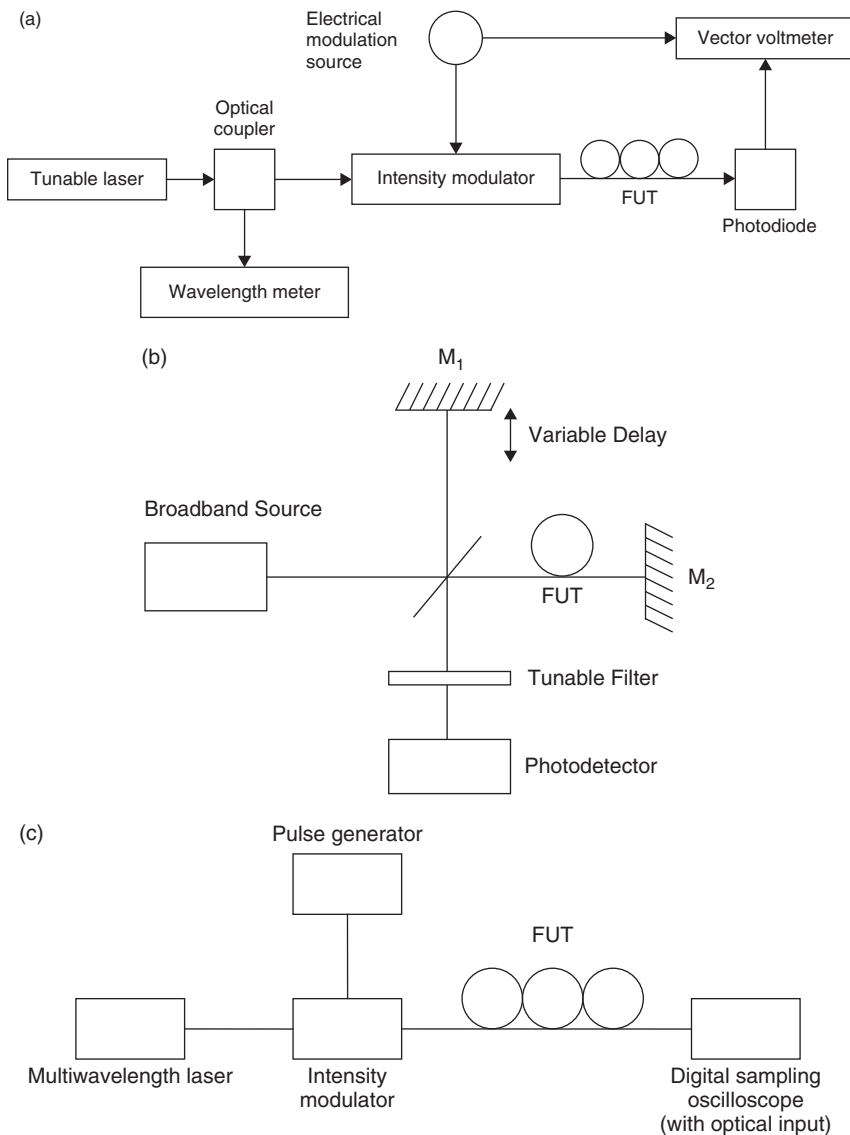

Figure 5: Setup for chromatic dispersion measurement with (a) the modulation phase-shift method (Hernday 1998), (b) the interferometric method, and (c) the time-of-flight method (Maran et al., 2004)

where $\phi(\lambda)$ is the relative phase (in degrees) measured for wavelength λ , f_m is the frequency of the sinusoidal modulation, and λ_{avg} is the average value of the adjacent wavelengths, which are spaced by $2\Delta\lambda$. The relative group delay as a function of wavelength is generated from the values of $\Delta\tau$, the data are smoothed through the appropriate curve fitting, and the dispersion parameter is then calculated through Equation (1).

The *interferometric method* is used to measure the dispersion of short lengths of optical fiber (on the order of 1 m) (Tateda, Shibata, and Seikai 1981; Thévenaz, Pellaux, and Von der Weid 1988) as well as optical components (Knox et al. 1988). The limitation to short lengths of fiber is a consequence of the stability requirements of the interferometer (Thévenaz, Pellaux, and Von der Weid 1988).

The technique has been implemented with both Michelson and Mach-Zehnder interferometers. An implementation with a Michelson interferometer is shown in Figure 5b. The light from a broadband source is split into two beams, with one beam propagating through the FUT and the other through a variable delay line. The variable

delay line has been implemented as an air gap with a movable mirror (Tateda, Shibata, and Seikai 1981; Knox et al. 1988) and as a stretched fiber in an all-fiber interferometer (Thévenaz, Pellaux, and Von der Weid 1988). The beams are reflected off the mirrors M_1 and M_2 , recombined, filtered with a tunable optical filter, and detected with the photodetector.

Interference fringes can only be detected when the group delay difference between the signals in the two arms of the interferometer is less than the coherence time of the filtered light. For each setting of the tunable filter, the delay line is swept and the delay corresponding to the center of the fringe pattern is determined. By repeating the measurement at different wavelengths, the relative group delay as a function of wavelength can be determined. The relative group delay data can then be smoothed by curve fitting and the dispersion parameter calculated according to Equation (1).

Thévenaz, Pellaux, and Von der Weid (1988) reported chromatic dispersion measurements with the interferometric method on fibers 1 to 2 meters in length with

a resolution of group delay and chromatic dispersion better than 5 fs and 0.1 ps/nm/km, respectively.

In the *time-of-flight method* (Cohen 1985; Maran et al. 2004) of chromatic dispersion measurement, a number of different wavelengths are modulated with narrow pulses and injected into the FUT. The time delay between the pulses in different wavelengths is measured at the output of the FUT using a fast photodetector and a sampling oscilloscope. These relative group delay data are then smoothed by curve fitting and differentiated according to Equation (1) to obtain the dispersion parameter.

The measurement method employed by Maran et al. (2004), shown in Figure 5c, uses an erbium-doped fiber laser with approximately twenty equally spaced laser lines, and all of the wavelengths are transmitted through the FUT simultaneously. This results in a fast measurement of chromatic dispersion that is well suited to long installed fibers.

There is a limit to the lowest value of dispersion that can be accurately measured with the time-of-flight method because the separation of the pulses must be large enough to accurately determine their relative delay. The limit depends on the spacing of the wavelength components and the width of the modulation pulses. For example, with a wavelength spacing of 2 to 3 nm and a pulse width (full width at half maximum) of 83 ps, Maran et al. (2004) found that a minimum length of approximately 10 km of nondispersion-shifted fiber was required to accurately measure dispersion in the C-band.

Inaccuracy in the measurement of dispersion can result from changes in fiber temperature during the measurement. The effects of temperature drift on measurements with the modulation phase-shift method can be reduced by alternating the phase measurements between the test wavelengths and a fixed reference wavelength (Hernday 1998). Changes observed in the phase of the reference wavelength are used to correct the phase measurements of the test wavelengths.

Temperature drift can also impact measurements made with the interferometric method. However, this method is typically used to measure short lengths of fiber for which the temperature would normally be relatively stable. If required, steps can be taken to stabilize the temperature during the measurement. For example, the FUT can be placed in a temperature-controlled chamber.

With the time-of-flight technique, it is possible to obtain a measurement relatively quickly when the pulses in the different wavelengths are transmitted in the FUT simultaneously (Maran et al. 2004). This makes the technique well-suited to the measurement of long installed fibers because the time required for measurement is typically less than the time scale of the temperature drift.

POLARIZATION MODE DISPERSION AND POLARIZATION-DEPENDENT LOSS

Despite the best fabrication effort, the perfect cylindrical symmetry desired for single-mode operation is an ideal almost impossible to achieve technically. Therefore, the core of the SMF is more likely to be in the shape of

an ellipse having two orthogonal axes. The “effective” index of refraction of a waveguide, which determines the speed of light, depends on the glass material itself as well as the shape of the waveguide relative to the traveling wave. Therefore, light polarized along one axis travels at a different speed than does the light polarized along the orthogonal axis. As a result, when a light pulse is passing through the optical fiber, some of the light may be polarized in one axis and some may be polarized along the orthogonal axis. To first order this speed difference will cause temporal spreading of the pulse at the output. The propagation time difference between the two axes is termed *differential group delay* (DGD). PMD is a key impairment factor in a single-channel system operating at greater than 10 Gb/s. Another closely related polarization effect is called *polarization-dependent loss* (PDL), which describes the phenomenon of the polarization dependence of the attenuation. For a given fiber network span and at a given wavelength with angular frequency ω , the

PDL (defined in dB units) is $\alpha = 10 \log \left(\frac{T_{\max}}{T_{\min}} \right)$ where

T_{\max} and T_{\min} are the maximum and minimum transmission coefficients. Although PDL could exist in normal SMFs because of imperfect fabrication processes like those resulting in PMD, its dominant contributions in a network come from discrete optical components such as optical modulators, filters, switches, and such active components as EDFAs that can exhibit *polarization-dependent gain*. Further complication arises from the fact that different sections of the fiber network have different DGDs and PDLs, both in terms of their magnitudes and their principal polarization axes, and they vary as a function of time because of dynamic environmental effects such as wind-induced vibration, temperature gradient-induced stress, and microbending at supporting points of aerial fibers. Therefore, the PMD and PDL of a fiber network are a temperature-dependent, stochastic, random process that acts on each WDM channel differently at different times. Thus, their characterization has to be statistical in nature, usually requiring long-term measurement (Waddy, Chen, and Bao 2005).

PMD and PDL interact with each other (Gisin 2004), making the characterization of their statistical properties somewhat involved. For example, the PMD statistics of a network is Maxwellian if PDL can be neglected and if the network can be approximated as a continuous highly mode coupled system (Nelson and Jopson 2004; Gordon 2004). On the other hand, if the network involves some lumped PMD elements, the overall PMD statistics becomes non-Maxwellian (Antonelli and Mecozzi 2004). Furthermore, if the PDL of a network cannot be neglected, then its PMD statistics again becomes non-Maxwellian (Chen, Cameron, and Bao 1999). Interaction of PMD and PDL would naturally cause the PDL of a system to become frequency-dependent (Chen et al. 2003, “Polarization”). Its statistical properties are, however, independent of PMD values in the highly mode coupled continuous limit (Galtarossa and Palmieri 2003).

For a network in which environmental condition changes slowly (e.g., the buried fiber network), one could use many standard PMD and PDL monitoring methods (Williams 2004) to characterize the PMD and

PDL parameters over a given wavelength window. The most notable method is called *Jones matrix eigenanalysis* (Heffner 1992, 1993). However, for a dynamic field fiber network such as aerial fiber cables, the reliable measurement method requires inherently quick speed so that data acquisition time is much less than typical time scales for dynamic environmental fluctuations (Waddy et al. 2001; Waddy, Chen, and Bao 2002). We therefore recommend using the Poincaré sphere method to monitor the complex PMD vector (Chen et al. 2004) for a fiber network because of its minimum scan steps. In this method, one requires a coherent tunable laser source, a polarization controller, and a polarization analyzer (Figure 6). When a coherent tunable laser source is launched into the fiber network having both PMD and PDL, and assuming that all the wavelengths have the same input state of polarization, then its normalized output Stokes vector $\vec{S}(\omega)$ variation as a function of the angular frequency of the light is determined by the complex PMD vector $\vec{W}(\omega) = \vec{\Omega} + i\vec{\Lambda}$ (Gisin 2004; Li and Yariv 2000):

$$\frac{d\vec{S}}{d\omega} = \vec{\Omega} \times \vec{S} - (\vec{\Lambda} \times \vec{S}) \times \vec{S}$$

By doing three independent laser scans (i.e., for three input state of polarizations) in the measurement wavelength window and measuring their respective normalized output Stokes vector $\vec{S}(\omega)$, one can find the spectrally resolved complex PMD vector $\vec{W}(\omega)$ (Chen et al. 2004). This information can either be used as a feedback signal to drive a PMD compensator or give some detailed fiber status report when one evaluates the autocorrelation of the complex PMD vector (Chen et al. 2003, "Effect"). Once the complex PMD vector is obtained, one can find the corresponding DGD—

$\tau = \sqrt{\frac{1}{2} \left[\Omega^2 - \Lambda^2 + \sqrt{(\Omega^2 - \Lambda^2)^2 + 4(\vec{\Omega} \cdot \vec{\Lambda})^2} \right]}$ —and the differential attenuation slope (DAS): $\eta = \vec{\Omega} \cdot \vec{\Lambda} / \tau$.

The overall PDL of a fiber network can also be monitored using the respective Poincaré sphere method (Chen, Zhang, and Bao 2006) for the PDL vector $\vec{\Gamma}(\omega)$:

$$\frac{d\vec{\Gamma}}{d\omega} = \vec{\Lambda} + \vec{\Omega} \times \vec{\Gamma} - (\vec{\Gamma} \cdot \vec{\Lambda}) \vec{\Gamma}$$

By measuring only one such PDL vector $\vec{\Gamma}(\omega_0)$ at a given frequency ω_0 and knowing the corresponding PMD vector, one could integrate the above equation to get the PDL vector at any other wavelength. The relationship between the PDL value in dB and the magnitude of the PDL vector is $PDL_{dB} = 10 \log \frac{1+\Gamma}{1-\Gamma}$. Lastly, it is noted that one can increase the measurement speed by replacing the tunable laser with a wideband light source to measure all of the Stokes parameters in "parallel," which will ultimately

be the quickest monitoring set to give the spectrally resolved PMD and PDL information. When the input light source used in the test set cannot guarantee 100 percent polarization, then a modified equation for the Stokes vector $\vec{S}(\omega)$ should be used to find the complex PMD vector $\vec{W}(\omega)$ (Dong et al. 2005).

We mentioned techniques to measure the overall PMD and PDL parameters of a fiber-optic network; it is, however, also possible to use polarization-sensitive reflectometric techniques to measure the distributed PMD values (Galtarossa and Palmieri 2004) even though the circular birefringence component is lost in the round-trip measurement. Therefore, a complete theory of distributed PMD and PDL characterization for a fiber-optic network needs yet to be developed.

NONLINEAR REFRACTIVE INDEX

The nonlinear effects *self-phase modulation* (SPM), *cross-phase modulation* (XPM), and *four-wave mixing* (FWM) have a significant effect on the performance of long-haul optical communication systems. All three effects result from the intensity dependence of the refractive index. This intensity dependence can be seen by writing the refractive index in the form (Agrawal 1997)

$$n = n_0 + n_2 P / A_{eff}$$

where n_0 is the linear part of the refractive index, n_2 is the nonlinear refractive index, P is the optical power, and A_{eff} is the effective core area of the fiber. Measured values of n_2 for different types of silica fiber have been found to range between approximately 2×10^{-20} and 4×10^{-20} m²/W (Agrawal 2001).

In this section, we present a brief description of SPM, XPM, and FWM in fiber-optic systems and introduce measurement techniques for n_2 that are based on these effects. In practice, the measurements obtain the value of n_2/A_{eff} . If required, n_2 can be determined by acquiring the value of A_{eff} in a separate measurement (NamiHIRA 2004).

In SPM, an optical signal experiences a phase shift because of its own intensity, which is given by (Batagelj et al. 2005):

$$\phi_{SPM} = \frac{2\pi}{\lambda} \frac{n_2}{A_{eff}} L_{eff} P m_1 \quad (2)$$

where λ is the wavelength and m_1 is a parameter that depends on the polarization properties of the signal and the fiber. The effective fiber length is given by $L_{eff} = [1 - \exp(-\alpha L)]/\alpha$, where L is the fiber length and α is the fiber attenuation coefficient (in units of km⁻¹). For a pulse propagating in an optical fiber, the nonlinear phase shift resulting from SPM leads to *frequency chirping* in which the instantaneous frequency varies across the pulse (Bayvel and Killey 2002). The frequency chirp,

Figure 6: Setup for PMD measurement—polarization controller (PC) and polarization analyzer (PA)

in combination with chromatic dispersion, leads to pulse distortion, which can result in an increased bit error rate in optical communications. The impact of SPM strongly depends on the sign and magnitude of the chromatic dispersion.

Each measurement technique considered in this section exhibits a dependence on the polarization properties of the signal and the fiber under test. For consistency, we define n_2 throughout this section such that m_1 in Equation (2) takes the value 1 when the signal maintains a linear state of polarization as it propagates through the fiber (e.g., in a polarization-maintaining fiber). In a long (on the order of 1 km or more) telecommunications fiber, the signal polarization state varies randomly with propagation because of PMD; in that case, m_1 in Equation (2) takes the value 8/9 (Kato et al. 1995).

In a measurement method for n_2/A_{eff} based on SPM (Agrawal 2001; Batagelj et al. 2005), the outputs of two CW DFB lasers are combined and launched into the FUT, as shown in Figure 7a. SPM-induced phase modulation generates peaks in the optical spectrum at multiples of the beat frequency between the two lasers. The nonlinear phase shift resulting from SPM is a function of the ratio of these peaks in the optical spectrum. The value of n_2/A_{eff} can be determined using Equation (2) and the measured value of ϕ_{SPM} , with knowledge of the other parameters in the equation.

In XPM, an optical signal experiences a phase shift because of the intensity of a co-propagating signal that is given by (Kato et al. 1995)

$$\phi_{XPM} = \frac{2\pi}{\lambda} \frac{n_2}{A_{eff}} L_{eff} 2m_2 P_2 \quad (3)$$

where P_2 is the power of the co-propagating signal and m_2 is a polarization-dependent parameter. XPM leads to distortion of a given channel in a WDM system as the phase modulation imparted by the co-propagating channels are converted to intensity fluctuations by chromatic dispersion (Bayvel and Killey 2002).

Figure 7b shows a measurement technique for n_2/A_{eff} based on XPM (Kato et al. 1995). A high-power depolarized pump signal co-propagates in the FUT with a low-power CW probe. With a depolarized pump signal, the polarization factor m_2 has a value of 2/3. Intensity modulation of the pump leads to phase modulation of the probe through XPM. The value of n_2/A_{eff} is obtained by varying the pump power and measuring the frequency components induced in the probe spectrum by the XPM-induced phase modulation.

When three waves with frequencies ω_i , ω_j , and ω_k co-propagate in an optical fiber, a new wave is generated through FWM at frequency $\omega_{ijk} = \omega_i + \omega_j - \omega_k$ (Agrawal 1997). The power of the generated FWM product is given by (Batagelj et al. 2005)

$$P_{ijk} = \left(\frac{D}{3}\right)^2 \left(\frac{2\pi n_2 m_3 L_{eff}}{\lambda A_{eff}}\right)^2 P_i P_j P_k e^{-\alpha L} \quad (4)$$

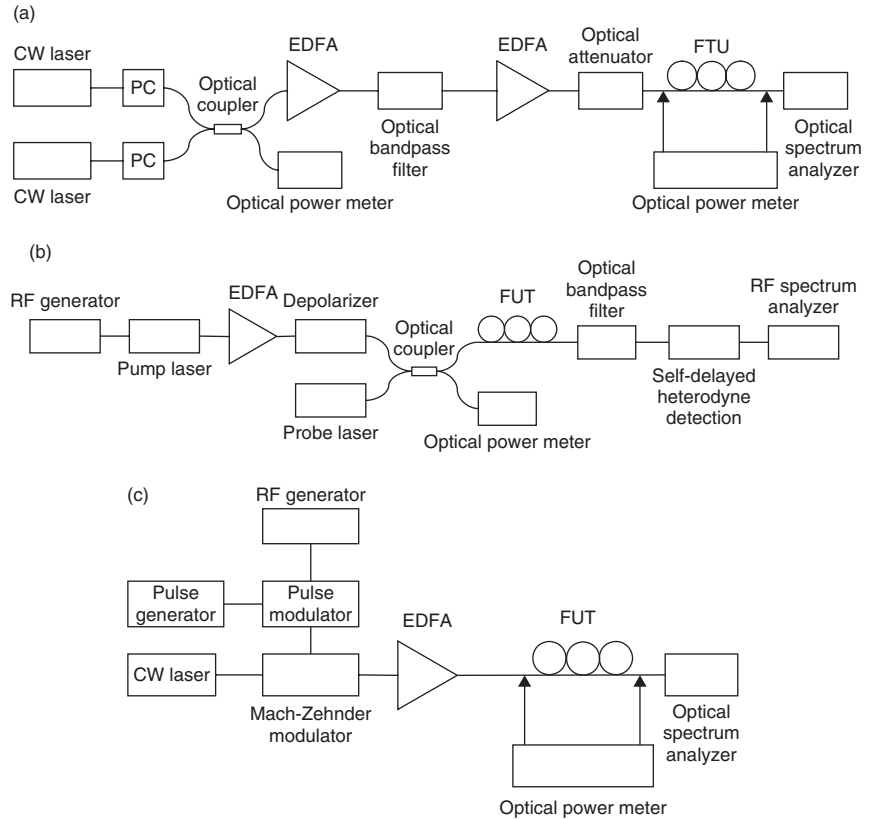

Figure 7: Setup for the measurement of n_2/A_{eff} with methods based on (a) self-phase modulation, (b) cross-phase modulation, and (c) four-wave mixing (Batagelj et al. 2005); polarizing controller (PC), erbium-doped fiber amplifier (EDFA), fiber under test (FUT)

where P_i , P_j , and P_k are the input powers of co-polarized waves at frequencies ω_i , ω_j , and ω_k , respectively; η is the FWM efficiency; m_3 is a polarization-dependent parameter that takes the value 8/9 in a long telecommunications fiber (Namihira et al. 2002); and D is the degeneracy factor, which takes the value 3 when $\omega_i = \omega_j$ and the value 6 when $\omega_i \neq \omega_j$. The FWM efficiency η (Song et al. 1999) is a function of the fiber length; the fiber loss coefficient; the frequency values $\omega_{i,j,k}$; the chromatic dispersion; and, because of intensity-dependent phase matching, n_2/A_{eff} and the input powers $P_{i,j,k}$. The FWM efficiency decreases with increasing group velocity mismatch between the interacting signals, so that an increase in the frequency spacing of the signals or an increase in the chromatic dispersion results in a reduced FWM efficiency (Chraplyvy 1990).

FWM leads to interferometric cross talk in WDM systems whenever a FWM product falls at the same frequency as one of the WDM channels. For a system with N channels, the number of products is equal to $1/2[N^3 - N^2]$ (Tkach et al. 1995). FWM can be a major detriment when WDM channels are located in a region of low chromatic dispersion because of the enhancement of the FWM efficiency. For example, C-band channels, with wavelengths close to the zero-dispersion wavelength, may be severely limited by FWM when transmitted through dispersion-shifted fiber.

Measurement of n_2/A_{eff} based on FWM has been implemented using a single laser source (Batagelj, Vidmar, and Tomazic 2005). The measurement setup is shown in Figure 7c. The laser is externally modulated so that two co-polarized sidebands are produced in the optical signal, with their frequency spacing determined by the modulation frequency. The two sidebands interact in the fiber to produce FWM products, and an optical spectrum analyzer is used to measure the power in the optical sidebands and the FWM products at the output of the fiber. The value of n_2/A_{eff} can be obtained with the use of Equation (4) and knowledge of the other relevant parameters.

Note that measured values of the nonlinear refractive index will depend on the pulsewidths or modulation frequencies used in the measurements. In addition to a contribution from the third-order electronic susceptibility, n_2 also includes contributions from the Raman susceptibility and electrostriction; the relative contributions of the latter two mechanisms depend on the pulsewidth or modulation frequency used in the measurement (Agrawal 2001; Buckland and Boyd 1997).

Descriptions of additional techniques for characterization of the nonlinear refractive index can be found in Agrawal (2001) and Batagelj et al. (2005).

CONCLUSION

The performance of existing fiber networks are affected by various dynamic physical parameters. Many of these physical parameters can be quite different from those characterized by fiber manufacturers because of cabling and installation processes as well as dynamic environmental fluctuations. PMD, PDL, stress, and nonlinear effects are critically important to characterize the optical fiber network for high-speed communication systems (≥ 10 Gb/s). In this chapter, we have reviewed different

methods to characterize optical fibers for their linear and nonlinear properties, and methods that are rapid in data acquisition have been emphasized for dynamic field fiber networks. A fiber network should be completely characterized before upgrading to higher bit-rate (≥ 10 Gb/s) communication systems.

GLOSSARY

Attenuation: In an optical fiber, refers to the decrease in the power of a signal as it propagates through the fiber. Material absorption and Rayleigh scattering make the dominant contributions to the attenuation.

Chromatic Dispersion: The group velocity associated with a given mode in an optical fiber varies with frequency, leading to pulse broadening and intersymbol interference in fiber-optic communications.

Nonlinear Refractive Index: The refractive index n of a silica fiber is intensity-dependent, and it can be written in the form $n = n_0 + n_2 P/A_{\text{eff}}$. The coefficient n_2 is known as the nonlinear refractive index.

Polarization-Dependent Loss (PDL): A measure of the peak-to-peak difference in transmission of an optical component or system with respect to all possible states of polarization. It is the ratio of the maximum and the minimum transmission of an optical device with respect to all polarization states.

Polarization Mode Dispersion (PMD): The type of dispersion that occurs in single-mode fiber because of a lack of perfect symmetry in the fiber and from external pressures on the cable. Light travels over a single-mode fiber in two polarization states. Over long distances, PMD causes each one to arrive at the receiving end at a different time.

Stimulated Brillouin Scattering: An interaction between the optical signal and the acoustic waves in the fiber that causes the optical power to be scattered backward towards the transmitter. It is a narrow-band process that individually affects each channel in a DWDM system. It is noticeable in systems that have channel powers in excess of 5 dBm to 6 dBm. In most cases, stimulated Brillouin scattering can be suppressed by modulating the laser transmitter to broaden the linewidth.

INTRODUCTION

Why optics? Optical fields show several interesting physical properties that permit any technology that uses light to reach high performance (Born and Wolf 1999). The use of light in advanced technologies allows the production of high-performance components and systems. Some advantages of optical technologies arise in telecommunications applications as well as in nonintrusive sensing methods (Agrawal 2002; Razzak and Hamam 2006). Indeed, by using light, we can benefit from interesting optical properties to attain high immunity and safety. Doubtlessly, optical fiber-based systems are the most commonly used technology to benefit from several advantages of light for information transmission (Taga 1996; Othonos and Kali 1999). This explains why optical fiber and optical components constitute a large part of existing telecommunications components. It is worth mentioning the advantage of using fiber-based components that can easily enable the coupling of light between fiber elements thanks to their small size (a few micrometers) (Hamam 2006). Although optical fields are more desirable for data transmission than electronics signals, the coupling carried out in the optical domain is much more complicated.

Why Optical Coupling?

Optical coupling is a crucial function for many applications, especially for optical communications, where the need for more than simple point-to-point connections is fundamental (Dowd et al. 1996). Multiport connections in optical systems are essential for sharing and monitoring systems. Thus, we need optical components that are able to redistribute optical signals (combining or splitting) throughout the system. An example of the use of such components is in broadcast-and-select networks, where we need to share information between several destinations using a star coupler (Laude 2002; Ruan and Du 2001). So each destination has to filter (i.e., accept or refuse) any received signal. This makes the design and implementation of the system easier. On the other hand, in monitoring and surveillance applications, we sometimes need to regroup several data ports into the same terminal or split the signal into two signals, one of which is of relatively low energy. The latter signal can then be analyzed without disturbing the system signal, thus enabling system characterization under real conditions. Furthermore, this allows the sharing of expensive equipment by means of centralized monitoring (Yilmaz 2006).

An optical coupler is a device able to implement all the functions mentioned above.

What Is an Optical Coupler?

An *optical coupler* (OC) is a device able to connect three or more ends by redistributing the optical power over its ports in a desired ratio. The redistribution may result from combining incoming signals to the output port (the case of an optical combiner) or from splitting the optical power over two or more output ports (the case of an optical splitter). Hence, *optical coupler* is a general term that designates both optical combiners and optical splitters. The manner with which the power is redistributed is not specified here and may differ from one device to another (see the next section). In the electronics field, the term *optical coupler* (or *opto-coupler*) refers to a device that is used to transfer an electrical signal from a circuit to another by using light (GlobalSpec, undated, "About optocouplers"). This opto-coupler also isolates the two circuits from electrical perturbations. The component is also known as an *opto-isolator* or a *photo-coupler*, but it will not be considered here.

How to Fabricate an Optical Coupler

Optical-fiber-based communications systems are among optical technology fields that need optical couplers. To meet the technological constraints regarding fiber dimensions and the nature of the optical signal, couplers based on optical waveguides present an interesting solution that enables cost-efficiency and high performance (Owyang 1981).

The optical waveguide fabrication process—photolithography (Klein 1988), thin-film deposition (Seshan 2002), and ion deposition (Mentzer 1990)—enables the manufacturing of complex circuits that integrate several components into the same substrate. These highly integrated components are commonly known as *optical integrated circuits* (OICs) (Hunsperger 1991; Kyo-Seon and Sotiris 1988). An OIC can contain lasers, guides, filters, detectors, and so on and can be fabricated by means of a hybrid or a monolithic approach. In monolithic integration, the same substrate can be used by choosing an appropriate material to include all components: sources, filters, detectors, and so on. In hybrid integration, on the other hand, several different materials are used, and discrete components are bonded together to form the circuit. The choice of manufacturing technology depends on several parameters such as physical performance and production cost. Recent progresses in optical polymers may make the development of polymer waveguides much less expensive. Spin coating is one technology that can be used for this purpose, although the difference in the thermal expansion coefficients of the polymer and the silica wafer makes thermal stress the main issue in addition to high propagation losses. OC can also be obtained using bulk optics or classical components (lenses, beam splitters, mirrors, gratings, etc.).

Optical Couplers and Switches

Optical couplers and switches can be distinguished as follows. In couplers, connections are fixed, conserving

optical path and optical power. In switches, path reconfiguration is possible (Xiaohua 2003). Again, when only power attenuation is considered, we deal with variable optical attenuators (Lagali et al. 2001).

How to Model an Optical Coupler

To explain how the main categories of waveguide-type couplers work, we first introduce the theory underlying waveguides. Coupled-mode theory allows a description of the evolution of the amplitude of each waveguide (Kawano and Kitoh 2001; McCall 2000). This theory is based on coupled-mode theory for microwaves, which was developed in the 1950s (Pierce 1954; Barnes 1964). An overview of the theories used to describe optical couplers is given in the next section.

OVERVIEW OF THEORIES RELATED TO OPTICAL COUPLERS

Because a comprehensive description of the theories related to optical couplers goes beyond the scope of this handbook, we present only a general overview to introduce the theories. For more in-depth study, consult the references at the end of the chapter.

Optical Waveguide Theory

Optical waveguide devices are mostly coplanar structures. Because they can be fabricated with high precision, optical devices can also attain a high degree of integration. This permits the integration of several functions on an extremely small chip (Mentzer 1990).

The fundamental theory that describes couplers as optical waveguides is *electromagnetic theory*. This theory involves mathematical equations that predict the variation of both the electric and the magnetic fields during propagation in the medium. Those mathematical equations are known as *Maxwell's equations* (Pollock and Lipson 2003).

By combining these equations and taking into account the physical properties of the optical waveguide, we obtain what are commonly referred to as the *vector wave equations* for the electric and magnetic fields (Pollock and Lipson 2003). They determine each of the three field components with respect to the coordinate system employed (Cartesian coordinates are frequently used) and time. If we limit our attention to one coordinate—the x component of the field, for example—we obtain a *scalar wave equation* that is commonly referred to as the *Helmholtz equation* (Kawano and Kitoh 2001). Either analytical or numerical methods can be used to solve the Helmholtz equation for a given medium and geometry (Weisstein 1999).

Optical Waveguides

The optical waveguide is the fundamental element that allows the transfer of light energy between several passive or active optical components. To explain the way this transfer occurs, we introduce the concept of guided modes. This concept presents one aspect of the complexity

Figure 1: Three-layer planar waveguide structure

of the problem. It is worth analytically studying simple structures such as planar waveguides because the latter represent the basis of more sophisticated structures (Kawano and Kitoh 2001; McCall 2000; Pierce 1954; Barnes 1964; Pollock and Lipson 2003; Weisstein 1999; Taylor and Yariv 1974).

Planar Waveguides

A planar waveguide as sketched in Figure 1 is a region bounded by parallel infinitely extended planes ($+\infty$ and $-\infty$ for both the y - and z -directions). The planes are separated from each other by a finite distance x_0 in x -direction. We then obtain a three-layer planar waveguide structure. The medium between the two planes has a refractive index of n_2 (core layer). The semi-infinite regions are composed of materials with refractive indexes n_1 and n_3 , respectively (the cladding layers). In general, the core refractive index is slightly larger than those of both cladding layers, which are generally identical.

As with any guiding structure, we look for a solution to the wave equation. To determine simple solutions, many assumptions should be made to reduce the problem complexity such as using only *transverse electric* (TE) plane waves (Pollock and Lipson 2003). Again, we will not go into detail here, but the references at the end of the chapter can be consulted for more information.

Waveguide Modes and Guiding Conditions

Solving the wave equation for a given medium and waveguide can sometimes be done by employing rigorous mathematical methods or, more generally, by numerical methods (Kawano and Kitoh 2001; McCall 2000; Pierce 1954; Barnes 1964; Pollock and Lipson 2003; Weisstein 1999; Taylor and Yariv 1974; Belanger 1993). If a solution exists—called a *mode*—it can be interpreted as a form of optical field that can propagate through the medium with guidance. An optical mode in a waveguide is defined as an allowed traveling optical wave that is characterized by relevant spatial optical energy distribution across the waveguide (Kasap 2001).

The modal solutions of the scalar wave equation for the slab waveguide have a wavelike solution in the core and an exponentially decreasing solution into the cladding on either side. The boundary conditions at each of the two interfaces (three layers) also have to be satisfied, leading to a continuous distribution of the field (Pollock and Lipson 2003).

Depending on the value of the modal propagation constant β , several cases are distinguished (Figure 2). The constant β is a complex parameter associated with the transmitted waveguide that describes the behavior of

Figure 2: Modes in the planar waveguide

the wave along the waveguide. It is composed of two parts that describe the signal attenuation and the phase. Consider a waveguide excited by a constant frequency source with the three refractive indexes satisfying $n_2 > n_3 > n_1$. This is the case of many components in which we have a thin layer (layer 2) deposited on a substrate (layer 3) placed in the air (layer 1).

For $kn_3 < \beta < kn_2$ (k is the free-space wave number), we get a field distribution in which we have a sinusoidal distribution in the core and an exponential profile in each cladding. Thus, we have confined guided modes. We notice that β can take only one or more discrete values that depend on the thickness of the waveguide core (region 2). Those modes are referred to as the *zeroth*, *first* . . . *transverse electric modes* and are denoted as TE_0 , TE_1 . . . (or TM_0 , TM_1 . . .).

In the case of $kn_3 > \beta > kn_1$ (when β can have any continuous value in this range), the confinement can be only on the side of layer 1 where the mode field has an exponential form. In the others layers, it has a sinusoidal form. This mode is carried by the waveguide but is not confined within it because a part of the light escapes as radiation into layer 3. However, it may be considered as a useful effect for coupling light to layer 3.

When $\beta < kn_1$, the field oscillates (sinusoidally) in all regions, leading to an unguided mode.

For $\beta > kn_2$ we find an exponential profile in all three regions. This mode cannot be excited physically and does not propagate and is sometimes referred to as an *evanescent mode*.

There is a lower limit to frequencies that will excite a particular mode. Below this limit, a specific mode is no longer guided—with the exception of the fundamental or first mode, which has the largest value of propagation constant and will always propagate. This kind of guiding condition is referred to as the *cutoff* condition, and it depends on the waveguide's optogeometric characteristics (Pollock and Lipson 2003).

A planar waveguide is a classical structure that is relatively easily analyzed by waveguide theory (Pollock and Lipson 2003). In this structure, the power confinement occurs only in one dimension. In several applications, a two-dimensional confinement (such as channel waveguides or optical fibers) is desired. However, these structures are generally more complex and require heavy mathematical analysis. Simplifying assumptions are generally unavoidable to reduce the complexity of the problem (Nishihara, Haruna, and Suhara 1989). Because optical

Figure 3: Evanescent wave generation

fibers are increasingly being adopted in both sensing and telecommunication applications, we devote the next subsection to this specific waveguide. Moreover, a special subsection is reserved for fiber-optic couplers. However, as stated above, we limit ourselves to an introduction to the theoretical analysis of modes.

Evanescent Wave and Evanescent Wave Coupling

An evanescent wave can be considered as a light guided in the inner part of an optical fiber's cladding. It is a wave that shows an exponential decay with distance. In the optical domain, this wave can be found when sinusoidal waves are totally and internally reflected between two different index waveguides as shown in Figure 3.

In an optical guide coupler, the evanescent wave offers a way to couple power or transport energy from one side arm to the other so that an optical wave will be excited within the second waveguide, which is why it is called *evanescent* wave coupling. Thus, a propagating wave mode can arise.

Optical Fibers

An optical fiber is an optical waveguide that possesses cylindrical symmetry (Belanger 1993; Kasap 2001; Nishihara, Haruna, and Suhara 1989; Buck 1995). In the case of a step profile fiber, the core, with radius (a) and constant refractive index n_1 , is surrounded by the cladding, which has a constant refractive index n_2 that is slightly smaller than that of the core (Figure 4). In the standard single-mode fiber used in telecommunications, the core radius is approximately $8\text{ }\mu\text{m}$, and the diameter of the cladding is approximately $125\text{ }\mu\text{m}$. For the multimode fiber, the dimensions of both core and cladding are $50/125$ and $62.5/125$, respectively. Together, core and cladding are protected by a plastic jacket to suppress fiber bending and breakage.

Regarding the symmetry of the fiber, it is convenient to use cylindrical coordinates to solve the wave equations (Belanger 1993). Because the refractive index of the cladding is slightly smaller than that of the core ($n_1 - n_2 = \Delta n \approx 10^{-3}$), we can use the weak guidance approximation to reduce the vector wave equation to a scalar wave equation. We can also assume that the radial and angular field variables are separable. By solving the scalar wave equation in the core and cladding and then matching these solutions through the boundary conditions, we obtain the dispersion equation that allows us to determine the modal fields and propagation constants. Because the mathematical details go beyond the scope of this chapter, see Marcuse (1971) and Snyder and Love (1983).

Figure 4: Optical fiber structure

Mode Conversion and Optical Coupling

Each mode propagates along the z -direction (without loss of generality, the z -axis of the waveguide or fiber denotes the propagation direction) independently of all other propagating modes. Together they constitute an orthogonal basis of modes, so we can decompose each excitation beam in terms of this basis and express it as a sum of these modes. When a beam that is composed of a superposition of modes comes across irregularities in either the geometry or the index profile of the waveguide, light may be coupled into other modes; a power transfer occurs from the initial to the new modes (Nishihara, Haruna, and Suhara 1989).

The theory of the modes coupling (or simply the coupling theory) in the optical wave guide was developed by several researchers including Marcuse (1971), Snyder (1972), and Taylor and Yariv (1974). This theory uses the principle of field decomposition based on the elementary fields. In mathematical terms, it is based on a complete set of solutions of the Helmholtz equations, and each element of this set is a guided mode. To this decomposition, a continuum of modes can be added to describe losses resulting from radiation. These modes are often referred to as *radiation* modes.

Coupled-Wave Theory

Coupled-wave theory, also called *coupled-mode theory* (CMT) (Lifante 2003), provides a mathematical description of the interaction between two or more waves (modes) and the exchange of optical power between them as they propagate (Kawano and Kitoh 2001; McCall 2000). To illustrate this phenomenon in the optical domain, we will take as an example a *fiber Bragg grating* (Kogelnik and Shank 1972; Kashyap 1999).

Principle

The CMT is often used to analyze passive couplers and, more generally, passive structures (Bilbao 2004; Haus

1984). This theory is derived from the variational principle for the propagation constant of the waveguide wave solutions. Simple solutions consist of a linear superposition of the individual modes of the waveguide or fiber. Then the coupled-mode equations are derived.

Now we briefly present the coupling principle for time-dependent oscillators. In a separate subsection, we introduce the principle of coupling in space.

Coupling Modes in Time

Consider two weakly coupled lossless oscillators with different time-frequency dependencies (ω_1 and ω_2) and amplitudes (a_1 and a_2). Under the weakly coupling condition, the formalism describing the coupling of those oscillations is given in Haus and Huang (1991).

The two angular frequencies are assumed to be real. It is interesting to consider the case of two oscillators excited with equal angular frequencies. If the first oscillator is excited ($a_1 = 1$) at $t = 0$ and the second one is unexcited ($a_2 = 0$), then the initial conditions are matched by a superposition of equal amplitude symmetric and antisymmetric solutions. The phases of the two solutions evolve at different rates; after a certain time known as the *beat period* (Haus and Huang 1991), the entire exciting signal is transferred back to the first oscillator. Hence, the excitation oscillates back and forth between the two oscillators. When the frequencies of the two uncoupled oscillators are unequal, and initially only one oscillator is excited, then full transfer cannot occur (Haus and Huang 1991).

Coupling Modes in Space

Let us now consider the coupling of two propagating waves in space with propagation constants β_1 and β_2 . In other words, the two waves have the common time-frequency dependence $e^{j\omega t}$ and longitudinal spatial dependencies $e^{-j\beta_1 z}$ and $e^{-j\beta_2 z}$, respectively. The coupling can result from either a uniform perturbation or a periodic structure such as a grating (Haus and Huang 1991). In a uniform structure, the interaction between the waves occurs when the propagation constants β_1 and β_2 are of the same sign (i.e., both are either positive or negative) and approximately equal. For periodic structures, coupling among space harmonics (Bloch waves or Brillouin components—see Kittel 1996) becomes possible. A Bloch wave is equivalent to a plane wave modulated by a periodic function (Bloch envelope) (Kittel 1996).

CMT is inherently directional. Two cases exist—codirectional and contradirectional coupling—as depicted in Figures 5 and 6. Similar to the case of time coupling, the total power propagating is conserved.

Power transmitted to each output side of the coupler depends on the coupling length l as shown in both Figures 5 and 6. For example, when we would like to couple some percentage of power from one fiber side coupler to the other side, then the length of the coupler should be a particular coupling length or its odd multiple. This coupling length depends on the wavelength of the propagated light. To have different splitting ratio, we should vary this length.

The power coupled out of each leg of the output side of the coupler is a function of length of the coupler and a periodic function (Lohmeyer et al. 1999).

Figure 5: Codirectional coupler

Figure 6: Contradirectional coupler

WAVEGUIDE STRUCTURES AND TECHNOLOGIES

There are several different types of waveguides, depending primarily on the method that is used to fabricate the waveguide.

Buried Waveguide Types

As indicated by its name, a *buried waveguide* has the core buried in the substrate or cladding as shown in Figure 7. Buried waveguides may be formed by, for example, ion-diffusion (Jackel, Ramaswamy, and Lyman 1981; Armenise and De Sario 1982) or ion-exchange (Izawa and Nakagome 1972) techniques. Ion-diffusion techniques use the penetration of titanium (Ti) into lithium niobate crystal or glass to modify their optical properties (Burns et al. 1979; Jiang et al. 1992).

The ion-exchange process uses molten salt or silver film techniques. The substrate is immersed in a bath containing molten salt where the ion exchange occurs. A multistage ion-exchange process is necessary to form

Figure 7: Buried-type optical waveguide

a buried waveguide. An applied electric field is used to better control operations. Others techniques can be used such as light or electron beam irradiation or plasma-enhanced chemical vapor deposition.

Ridge or Relief Waveguide Types

Ridge waveguides (see Figure 8) are formed by removing undesired material from the substrate using a patterning process. The most commonly used technique is

Figure 8: Ridge-type optical waveguide

photolithography (Takato et al. 1988; Herzig 1997). The main photolithography steps are described in Figure 9. A resist that is sensitive to ultraviolet light is spread over a thin film that is spread over the substrate, usually by spin coating. By using a binary amplitude mask, areas of resistance are exposed through the transparent regions of the mask. Photochemical changes occur in these regions of the resist. The exposed areas become more soluble and are removed by using appropriate chemical solutions. The unexposed areas of resist maintain their initial insolubility.

Strip-Loaded Waveguides

One technique of confining a waveguide in two dimensions (x and y) without totally surrounding the waveguide by material with a lower refractive index is to place a dielectric strip on top of the substrate (Figure 10). The added strip should have a refractive index that is lower than that of the dielectric substrate. Thus, the effective index of the set of the strip and the region beneath is lower than the rest of the substrate, which ensures the guidance function of the waveguide (Gray 1986).

Another technique consists of cladding a dielectric medium with a charged metal. The refractive index close

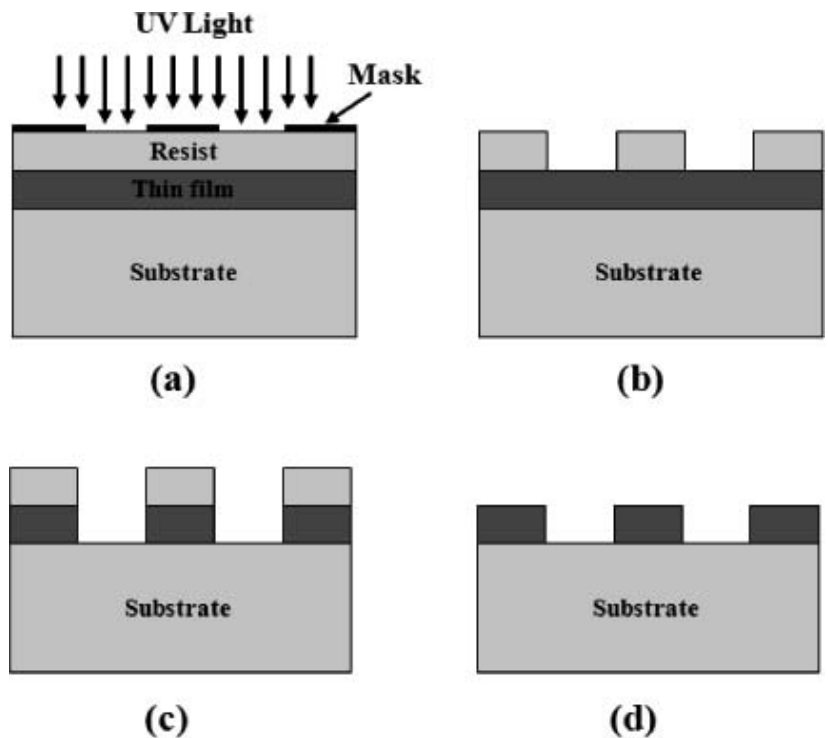

Figure 9: Photolithography process to create ridge-type optical waveguide: (a) resist exposition, (b) resist removal, (c) thin-film removal, and (d) final waveguide

Figure 10: Strip loaded-type optical waveguide

Figure 11: Induced-type optical waveguide

to the strip becomes slightly smaller, thus forming the channel waveguide. Metal strip-based waveguides are useful for applications such as electro-optic modulators. Metal strips can also be used as electrodes and to form waveguide functions. One such application is the generation of 50-GHz to 60-GHz *continuous wave, millimeter wave* by applying optical technology for optical-to-radio systems and ubiquitous communications (Park 2006).

Induced Waveguides

By using a material with a high electro-optic coefficient, such as the case of crystals—for example, lithium niobate (LiNbO_3) or NiTiO_3 —an induced waveguide can be formed after applying an electric field generated by planar electrodes placed over the crystal (Yariv 1976; Streetman 1980). The electric field (see Figure 11) induces a small change in the refractive index of the material because of the electro-optics effect (Pockel's effect) and then forms an induced waveguide that is buried.

COUPLING PARAMETERS

In designing optical couplers, it is necessary to quantify parameter values that determine the performance of the device as well as to satisfy the specifications required by the user (i.e., the application).

Center Wavelength and Bandpass

The performance of the coupler depends on the source wavelength. Couplers are usually specified over either one wavelength window or multiple windows. The *center wavelength* is the nominal wavelength of coupler operation. In other words, it is the average wavelength between the wavelengths at the extremes of the coupler's bandwidth. The operation of the coupler normally occurs at this wavelength at the center of the bandwidth. The *bandpass* is the range of values of frequency for which the transmitted signals can pass through the coupler. This said, in many cases, couplers will perform adequately

Figure 12: A WDM coupler of type 2×2 (the two wavelengths enter through inputs 1 and 2)

over a range outside their bandpass, but adherence to specifications would not normally be guaranteed in this region.

Coupling Ratio

The *coupling ratio* or *splitting ratio* is defined as the ratio of the optical power from one output port of the coupler to the sum of the total power from all outputs (see Figure 12). In other words, this ratio defines the optical power distribution of the input signals among the output ports. It is measured at the specified center wavelength and is generally expressed as a percentage. It can be expressed as follows:

$$\begin{aligned} \text{coupling ratio (\%)} &= \frac{\text{optical power from one output port}}{\text{total power from all output ports}} \times 100\% \end{aligned} \quad (1)$$

For a 1×2 *wavelength-division multiplexing* (WDM) coupler (Figure 12) with output powers P_1 and P_2 , the two coupling ratios are

$$\text{coupling ratio 1 (\%)} = \frac{P_1}{P_1 + P_2} \times 100\% \quad (2)$$

and

$$\text{coupling ratio 2 (\%)} = \frac{P_2}{P_1 + P_2} \times 100\% \quad (3)$$

Excess Loss

The *excess loss* is defined as the ratio of the total optical power from the output ports to the total input power; it is normally expressed in dB as

$$\begin{aligned} \text{excess loss (dB)} &= -10 \log \left(\frac{\text{total optical power from all output ports}}{\text{total input power}} \right) \end{aligned} \quad (4)$$

Insertion Loss

The *insertion loss* is defined as the ratio of the optical power launched at the input port of the coupler to the optical power from any single output port. In other words, it is the fraction of power transferred from input port

to one of the output ports and is generally expressed in dB. It includes the coupler splitting loss and excess loss and is the most commonly used parameter in system design. The insertion loss can be expressed by the following formula:

$$\begin{aligned} &\text{insertion loss (dB)} \\ &= -10 \log \left(\frac{\text{optical power of one of the output ports}}{\text{total input power}} \right) \quad (5) \end{aligned}$$

Typical Insertion Loss

The *typical insertion loss* is the expected value of the insertion loss measured at the specified center wavelength. Generally, the average insertion loss between input port and one output port at the center wavelength is calculated.

Maximum and Minimum Insertion Losses

Two other parameters are frequently used—namely, the *maximum* and *minimum insertion losses*. These are the upper and lower limits of the insertion loss of the coupler, respectively. These limits are measured with respect to the entire wavelength range specified in the bandpass. In other words, the maximum insertion loss, for example, is the insertion loss between the input port and one output port across the entire bandwidth.

Directivity

The *directivity* expresses the fraction of power transferred from one input port to another input port. It is equal to the insertion loss between these two input ports. Directivity is also referred to as *near-end isolation* or the *near-end cross talk*. It is generally expressed in dBs (positive) and is measured with all output ports optically terminated. The minimum directivity is the lower limit that applies over the entire wavelength range specified in the bandpass.

Return Loss

The *return loss* is the fraction of the optical power launched into an input port to the optical power returning to the same input port. Like directivity, return loss is expressed as positive dB and measured with all output ports optically terminated. Like directivity, the minimum return loss is the lower limit that applies over the entire wavelength range specified in the bandpass.

Reflectance

The *reflectance* is the negative of the return loss. In many instances, reflectance and return loss are used synonymously.

Wavelength Isolation

The *wavelength isolation* expresses the fraction of power in wavelength channel that is blocked from input port to output port. It is equal to the insertion loss at the specific wavelength blocked from input port to output port. It is

generally expressed in dBs. In wavelength multiplexing and demultiplexing, wavelength isolation is a measure of how well different wavelengths are separated at the output of a wavelength-division demultiplexer. This isolation is also referred to as *far-end cross talk*.

Minimum Wavelength Isolation

The *minimum wavelength isolation* is the lower limit of the wavelength isolation measured over the entire wavelength range of the specified bandpass.

Uniformity

The *uniformity* for a coupler is defined as the maximum variation of insertion loss between one input port and any two output ports, or between any two input ports and one output port, over the entire bandwidth. In concrete terms, it measures the difference between the highest and lowest insertion losses among all of the coupler output ports. It is generally expressed in dBs. Uniformity is not available for nonuniform couplers and applies only to couplers with a nominally equal coupling ratio.

Flatness

The flatness for a coupler is defined as the maximum variation (the peak to peak) of insertion loss between the input port and one output port across the entire bandwidth.

Polarization-Dependent Loss

The *polarization-dependent loss* is the maximum variation of insertion loss between input port and output port over the entire polarization state.

OPTICAL COUPLER FEATURES AND CHARACTERISTICS

The OC is a key component in many applications. Several types of OCs are used in telecommunications and in other fields. We mainly distinguish *optical taps* used for monitoring and *directional couplers* used for power sharing, such as in telecommunications. In the latter case, the equal power at each output port is generally required. In practice, a typical situation occurs when only one optical source is used to deliver one optical signal for many systems or optical paths. However, optical taps used for monitoring systems divert only a small part of the signal from the main optical path to be monitored. Most of the signal's power propagates along the system regardless of whether or not part of the signal is extracted. Other examples of OC uses are given at the end of the chapter.

The power redistribution is not the only factor to distinguish OCs from one another. Distinctions can be made with respect to coupler parameters and the modulation parameter of the optical field (magnitude, phase, polarization, and frequency). This variety of use of OCs gave birth to several types of couplers using different technologies such as bulk optics (discrete-type), fused fibers (fiber-type), and waveguide-type.

It is worth mentioning that optical couplers are completely different from opto-couplers, although the names are similar. *Opto-couplers* facilitate the transfer of an electrical signal between two circuits while electrically isolating the circuits from each other. An opto-coupler is generally composed of an infrared LED-emitting section at the input and a silicon photodetector at the output. Often, other circuitry is included as part of the device. The input for opto-couplers can be AC or DC. The output can be a photocell, a photodiode, a phototransistor, or a photo-darlington (GlobalSpec, undated, "About fiber optic couplers"; Marstone 1999). However, as mentioned previously, this opto-electronic device is outside the scope of this chapter.

Splitting or Coupling

Optical splitters and couplers are indeed linked together. An optical splitter is nothing other than a directional coupler and will be regarded as such in this chapter. The optical splitter can be defined as a transmission coupling device for separately sampling (through a known coupling loss) either the forward (incident) or the backward (reflected) wave in a transmission line. Note that a directional coupler may be used to sample either a forward or a backward wave in a transmission line. Although a unidirectional coupler has available terminals or connections for sampling only one direction of transmission, a bidirectional coupler has available terminals for sampling both directions.

Fiber-Optic Coupler Features

Fiber-optic couplers are optical devices that enable the connection of three or more fiber ends by dividing one input between two or more outputs, or by combining two or more inputs into one output. Both single-mode and multimode fibers may be coupled by means of fiber-optic couplers. Types of couplers include single-window, dual-window, and wideband. Single-window couplers are designed for a single wavelength with a narrow wavelength window. Dual-wavelength couplers are designed for two wavelengths with a wide wavelength window for each. Wideband couplers are designed for a single wavelength with a wider wavelength window. Typical wavelengths for fiber-optic couplers are 633 nm, 830 nm, 1060 nm, 1300 nm, and 1550 nm (Gelikonov, Gelikonov, and Sabanov 2000).

Important coupler performance specifications to consider for fiber optic couplers include: number of input ports, number of output ports, insertion loss, splitting ratio, and polarization-dependent losses. Various coupler types are available (see "Coupler Types" below). Couplers may be typically of star or tee (T) types. Star couplers have M inputs and N outputs ($M \times N$). T couplers have 1 input and N outputs ($1 \times N$).

Insertion loss is the attenuation caused by the insertion of an optical component. The *splitting ratio* is the distribution of power among the output fibers of a coupler; also referred to as *coupling ratio*. The *polarization-dependent losses* are defined as the attenuation caused by polarization.

Common features for fiber-optic couplers include pigtails, rack mounting, polarization maintenance, and bidirectionality. A *pigtail* is a short length of fiber attached to a fiber-optic component such as a laser or coupler. A *rack mountable* coupler can be rack mounted for convenience and efficiency. In a *polarization-maintaining* coupler, the polarization of the incoming signal is preserved between input and output ports. A bidirectional coupler has bidirectional transmission on a single fiber. An important environmental parameter to consider is the operating temperature (Othonos and Kali 1999).

Optical Coupler Characteristics

Because numerous technologies exist to manufacture optical couplers, many couplers have been developed. There is no optimal coupler for all applications. To choose an OC for a specific application, many specifications must be considered in addition to those discussed above in "Coupling Parameters."

Number of Ports

The capacity of an optical coupler is defined as the number M of inputs and the number N of outputs and is generally noted as $M \times N$. For example, a T coupler has one input ($M=1$) and two outputs. This is also the case of Y-branch coupler. However, a star coupler has N inputs and N outputs ($N \times N$). Typically N and M range from 1 to 64 (see the next section).

Bandwidth

The width of the 3-dB zone is centered at the operating wavelength. Depending on the application, the bandwidth should be narrow or large to filter out undesired wavelengths or to behave in a similar way for a large range of wavelengths. A coupler designed for a wavelength band centered at one wavelength is referred to as a *single-window coupler*. Similarly, a dual-window coupler is a device designed for two distinct bands.

Thermal Stability

Losses occur when the temperature changes. Usually, the thermal stability value is obtained by observing the attenuation variation of intensity of the OC over an operating range of temperature.

COUPLER TYPES

Coupler Configurations

Often, the function of the coupler varies according to the number of input and output ports. In the literature, we can discern basic types of couplers that lead to many other types.

Passive and Active Optical Couplers

The OC can be passive or active. The *passive* OC redistributes the optical signal naturally without the need of any other external power (for example, from electro-optic conversion). However, the *active* OC needs an external source of energy to operate properly (Kashima 1995). This should be not confused with an optical switch whereby the

coupling ratio changes with the electric field (Xiaohua 2003; Lagali et al. 2001; Kawano and Kitoh 2001; McCall 2000).

Directional Couplers

Unidirectional couplers use only one direction to couple light. However, a *bidirectional* coupler is a coupling device that enables coupling to occur for both the forward and backward wave but in different manners (Yariv 1973). An example of a unidirectional coupler is the planar waveguide optical coupler in which the coupling arises at a characteristic propagation length, which is referred to as the *coupling length*. All of the power coming from the first waveguide is transferred to the second one. Thus, at one-half coupling length, the power is equally divided on the outputs. The control of coupling length and coupling ratio is crucial to devices based on directional couplers. The coupling length is determined by the separation between waveguides as well as by refractive index profiles and frequency; in practice, it is difficult to achieve accurately. Optical couplers based on optical fibers are examples of bidirectional couplers. Many bulk optics-based couplers are also of this type.

Basic Types of Couplers

X Couplers

Principle. An X coupler, named because of its shape, is made by crossing two waveguide cores in the shape of an X (Asous and Shaari 1998) (see Figure 13). At the overlapping region, it is possible that power transfer occurs from the first guide to the other. It is at the same time a splitter and a combiner. It is also commonly called a 2×2 coupler. An X coupler combines the optical signals into one signal and then splits it into the two outputs. An example of an X coupler is the tapered fiber. X couplers are geometrically simple given that they do not require a specific coupling length of the two waveguides. A small cross angle is generally used to avoid radiation mode coupling.

X couplers can be considered as directional couplers. In this case of configuration, directivity measured between the power transmitted to port 2 and the input power in port 1, is given by

$$\text{Directivity (dB)} = -10 \log \left(\frac{P_2}{P_1} \right)$$

By measuring the reflected back power through port 4, directivity is expressed by

$$\text{Directivity (dB)} = -10 \log \left(\frac{P_4}{P_1} \right)$$

Figure 13: X coupler

Figure 14: Combiner of different wavelength

This directivity is approximately 40 dB to 45 dB for a typical fused-fiber coupler (Hecht 2002). For this reason, in practice, the 2×2 coupler device is often transformed into a 1×2 coupler by cutting one fiber end. A particular case of this 2×2 coupler is the 3-dB coupler. In fact, one-half of the power entering a particular port at one side of the coupler exits from each of the two output ports.

Applications. This type of coupler is used as a power feed for an erbium-doped fiber amplifier. It intentionally combines or multiplexes two different wavelengths into a single port (see Figure 14). For example, the low-intensity incoming optical signal at 1500 nm can be combined with the high-intensity pump light at 980 nm.

In this configuration, we may choose a coupling length such that 100 percent of the optical signal at port 1 and 100 percent of the pump light at port 4 leave at the same port (2 or 3) (port 2 in Figure 14). This process ensures minimal loss of signal power (Dutton 1998). Such couplers allow the injection of laser pump power into the active medium (erbium-doped fiber) to initiate amplification (Figure 15).

As a second possible application, an optical X coupler can be found in *Passive optical networks* (PONs). In fact, PONs are a challenging technology for local access networks that is competitive with other wired and unwired solutions currently used in digital subscriber lines and broadband wireless delivery. The choice of using only passive components makes PON deployment cheaper than using other optically based networks such as SONET and SDH. Indeed, in PON, no signal conversion is necessary; the signal remains in the optical domain and permits maximum bandwidth access to the end users. PON is well suited for broadcasting-like services (point-to-multipoint architecture) and is a good infrastructure to provide “triple-play” voice, data, and video services. Optical couplers (combiners and splitters) are among the components that are crucial to implement this technology. They allow communication between *optical network units* (ONUs) at remote nodes and the *optical line terminal* (OLT) located at the central office. The use of the word *passive* comes from the fact that this segment of the network (between OLT and ONUs) requires no power supply.

Optical splitters, as depicted in Figure 16, are the essential element that makes a passive distribution of signal from the OLT to as many as sixty-four ONUs. In fact, splitting the signal means splitting the optical power, so this factor must be carefully considered when designing the network, especially the power budget. In a coarse WDM context—a technology that multiplexes multiple optical carrier signals into a single optical fiber by using

Figure 15: Laser pump injection to an erbium doped fiber amplifier

Figure 16: Basic PON in tree architecture

different wavelength to carry different signals—a WDM PON provides a much higher bandwidth compared with that of a standard PON architecture. Moreover, optical add-drop multiplexing brings significant network flexibility by allowing the access of services for a group of subscribers without perturbing the rest of the signal that is designated to other groups.

Another type of network—a loop network—can be implemented by employing several directional couplers. The use of a 2×2 coupler enables stations to communicate with each other by sending and receiving information over two different loops (see Figure 17).

Figure 18 shows a four-port configuration that includes a network of 3-dB splitters that divides an input mix of signals into as many outputs as necessary.

Fabry-Perot filters separate each individual signal from the others (Figure 18). These filters can be replaced by fiber Bragg gratings (see Figure 19) and circulators

Figure 17: Example of loop network with directional coupler

Figure 18: Splitter array with Fabry-Perot filters

(Dutton 1998). This offers more accuracy in selecting signals but at increased cost.

In interferometer applications, optical fiber Michelson interferometers can be set up by using a coupler. Generally, this type of coupler is a 50:50 fiber coupler (Wu 2006). With the Michelson interferometer (Figure 20), physical parameters can be measured by using the difference in phase between the light reflected in the output arms by both the sample and the mirror. For example, this device can be used as a key element for measuring ultrasonic Lamb waves (Pierce, Culshaw, and Philip 1996).

A simple configuration using optical couplers is the fiber-based Mach-Zehnder interferometer as illustrated in Figure 21.

The optical field is split into two parts at the first coupler. Then the two separate parts of the beam traverse

Figure 19: Demultiplexer using in-fiber Bragg gratings with 3-dB couplers

Figure 20: Michelson interferometer

Figure 21: Fiber-based Mach-Zehnder interferometer using two optical couplers

two optical paths of different lengths, leading to a relative phase shift. When recombined together by the second coupler, this phase shift causes fringes that appear in the interference pattern. This device can also be made by using waveguide technology instead of optical fibers.

More sophisticated components using similar configurations include, for example, Mach-Zehnder modulators in which the phase shift is controlled by an external electric signal (Figure 22). In the case of optical sensors, the modulation may be produced by the measurand. The Mach-Zehnder interferometer configuration is not the

Figure 22: Waveguide-type Mach-Zehnder electro-optical modulator

only physical effect that can be exploited. There are other types of interferometers such as the Fabry-Pérot interferometer, Sagnac interferometer, and so on.

Figure 23: Y coupler

Figure 24: Typical T coupler

Y and T Couplers

Principle. Because of their geometry (Tsuji et al. 2006), Y-shaped couplers (or Y junctions) can be referred to as Y couplers (Figure 23) (Kuznetsov 1985). They are frequently built in planar waveguide technology because of the difficulty of fabrication in fiber technology (Pierce, Culshaw, and Philip 1996). Preferably, these waveguides are created within a glass substrate (Bordes, undated).

Generally, Y couplers split the input power equally into the two outputs ports. Sometimes, this type of coupler is referred to as a *symmetric 50/50 coupler*. However, we can vary this value to another ratio with respect to the given application by introducing a slight asymmetry between the two output arms—for example, 10/90 or other values. Moreover, because of reciprocity, light entering at port 2 will lose 50 percent of its power (i.e., 3-dB insertion loss).

Port 1 can be denoted as the stem port, while ports 2 and 3 are the arm ports branching at a small angle from the one input. This type of coupler is rarely used as a separate planar device because of the costly connection with fiber that can lead to significant loss in power if not properly matched (Dutton 1998).

When only a small fraction of input power is tapped off, the coupler is commonly called a *T coupler* (Figure 24) or an *optical tap*. The T coupler originally had application as an electrical tap that could relay a signal picked up from a passing cable.

Applications. By cascading $(N-1)$ Y junctions, we can obtain a $1 \times N$ coupler called a *multiport coupler*. The example shown in Figure 25 presents a coupler network of seven Y couplers and eight outputs.

In network communication use, we can create a bus network by connecting several directional couplers or

Figure 25: 1×8 coupler

T couplers in our case. This arrangement permits the connection of a series of stations to a single backbone cable (Figure 26).

For this type of topology, connecting stations can lead to single-direction, bidirectional, or duplex transmission configurations. Note that the transmission loss increases as the number of stations increases.

Optical switching is a function that allows reconfiguring a node in an optical network. Depending on the desired destination, the optical signal has to pass through the switch to be diverted to another destination. The example shown in Figure 27 is a simple $1 \times N$ coupler equipped with optical gates at the output ports. The signal can be detected at these ports whether the optical gates are activated or not.

Tree Couplers

Principle. Unfortunately, the elementary coupler normally includes only a limited number of ports (generally, two) because of fabrication limitations. Hence, to obtain a larger number of inputs or outputs or both, many couplers can be cascaded. Tree couplers, or $1 \times N$ couplers, have only one input and several output ports (see Figure 28). The single input contains the optical field that is split between the output ports equally or in a desired ratio.

We note that the power of the output beams decreases rapidly with the number of outputs. The maximum number of ports is limited by the technology being used and also by limitations in optical pulse power detection. In a waveguide-type coupler, the limitation in terms of technology arises partly from the maximal angle of the

Figure 26: Example of bus network with T couplers

Figure 27: Optical coupler-based optical switch

Figure 28: Tree coupler (1:N)

Y-branch couplers without incurring significant radiation loss. To increase the number of output ports, we can imagine several Y couplers connected together, the use of Damman gratings (Dammann 1971), or holograms in a bulk optics coupler configuration (Herzig 2004).

In general, tree couplers are directional couplers. Indeed, the optical carrier is split through the outer ports. The signal power decreases rapidly with the number of ports. The permissible number of ports is a function of the receiver sensitivity. If they are used in the opposite direction, they can recombine several inputs into one output—but at the expense of an unacceptably high loss of 3 dB per junction.

Figure 30: Two types of star couplers—(a) directional and (b) nondirectional

Figure 29: PON access network

Applications. In a laser transmitter module, tree couplers can be integrated. For example, the transmitter (TTCex) provides ten optical outputs. Each output is, in turn, split into thirty-two other outputs by the use of a 1:32 tree coupler. Hence, we can broadcast to 320 destinations (Taylor 2002).

Optical splitters also play an important role in the PON access network (see Figure 29). Because of those devices, subscribers can access a variety of services and applications at an extremely high speed rate. For an even higher split number, a PON repeater could be integrated with an optical amplifier (Gagnon, undated).

Star Couplers

Principle. This multiport coupler can be considered as an X coupler with more than two inputs and outputs that keeps the same functionality of the X coupler (Okuno et al. 1989). The star couplers are made around a central mixing element, allowing multiple inputs and outputs not necessary equal in number. This configuration allows two basic types of coupler (see Figure 30).

The first coupler is directional; signals enter the input ports and are distributed through the output ports and vice versa (Figure 30a). The second coupler is nondirectional and is known as a *reflective star*. It takes the input signals and distributes them equally among all fibers (inputs and outputs together) as with the star coupler shown in Figure 30b.

The advantage of this configuration is that each input delivers power to all outputs. This is a crucial feature that is needed for broadcast-and-select networks. We can also get a similar configuration in a reflective mode. One technique for the fabrication of star couplers uses the fused-taper technique (Yodo, Hasemi, and Shimizu 1993).

Figure 31: Example of reflective star coupler

Figure 32: Fused-fiber star coupler (Kuznetsov 1985)

Several different types of star couplers can be built. For example, the reflective star coupler can be built by connecting together ports on one side as shown in Figure 31. In this configuration, we use a directional coupler on the opposite side to separate the transmitted and the received signals (Bordes, undated).

To create a fused-fiber star coupler (Figure 32), a number of fibers are twisted together before being heated and elongated under tension (Kuznetsov 1985).

To interconnect multiple 3-dB couplers, we use a concatenation (see Figure 33). This is easy to construct, but

it can result in a considerable loss of optical power because of the arrangement, which often needs extremely tight radii. Moreover, as the number of required ports increases, the cost becomes exponentially greater (Dutton 1998).

Applications. Star couplers can be employed as the central element in a star network (Figure 34). This type of coupler divides all outputs, allowing every station to hear every other station, unless the network adopts a protocol that prevents two stations from communicating simultaneously. But the biggest disadvantage is that this configuration has a large insertion loss, especially when the number of ports (i.e., stations) increases (Force, Inc., undated).

In an OCDMA network, nodes share the optical bandwidth by using optical codes. In this system, each channel corresponds to an OCDMA code. Thus, each station encodes its signal and broadcasts it to all other stations via the star coupler (Figure 35). By using an appropriate code to decode the mixed optical signal, end nodes can detect and recover a particular message (Xue, Ding, and Yoo 2005).

In an all-optical bandpass filter, light emitted from the tunable laser diodes at different wavelength (Figure 36) is fed to the phase modulator through the coupler star (Zeng and Yao 2004).

Wavelength-Selective Coupler

Principle. Wavelength couplers (or WDM couplers or WDM multiplexers) are devices that redistribute optical power with respect to their wavelength (Figure 37). Each wavelength or band is redirected to a particular output.

Figure 33: Six-way star

Figure 34: Example of 4×4 star topology

Figure 35: OCDMA network using a star coupler

Figure 36: All-optical microwave bandpass filter

Diffraction gratings or prisms have the ability to spatially separate optical spectra. This natural function is the basis of many WDM couplers that exist in the market. Other technologies exist such as arrayed waveguide WDM couplers (Takahashi et al. 1990).

Applications. Because of the high density in dense WDM networks in terms of the use of the 1550-nm erbium-doped fiber amplifier band, the best solution for transporting control information in the 1310-nm band simultaneously is the use of a wavelength-selective coupler. This device

Figure 37: Wavelength-selective coupler

allows coupling 1310-nm signals with other signals in the 1550-nm band (Dutton 1998).

A sparse WDM system integrates wavelength-selective couplers to multiplex (mix) and demultiplex (separate) optical signals. In general, the combiners and separators use 3-dB splitters or Y junctions to mix or separate signals (see Figure 38). This configuration is used for a small number of channels. When the number increases, the combined signal can be amplified (Dutton 1998).

Multimode Interference Couplers

Principle. In *multimode interference* (MMI) couplers, the central multimode waveguide couples the single-mode input waveguides to single-mode output waveguides (see Figure 39).

This coupler is based on the well-known *self-imaging* or *Talbot effect* (Xia et al. 2004). When the input guide is connected to the relatively thick central region, the input beam excites many optical modes in the multimode

region. Note that each mode propagates with a slightly different velocity so that the input is self-imaged at a given Talbot distance. For shorter distances, the phenomenon generates a number of identical images in the cross-section. The number of outputs depends on the length of the coupling region.

The MMI coupler is one of the most extensively used devices in integrated optics because of its special characteristics: large operation bandwidth, fabrication tolerance, and polarization independence (Soldano et al. 1993).

Applications. An optomechanical pressure sensor is composed of two MMI couplers, two arms, and a membrane (see Figure 40). The arms (1 and 2) are placed in the center and at the edge of the membrane, respectively. We can assume that the input MMI coupler behaves like a 3-dB coupler because the input light is split into two equal power lights (Soldano and Pennings 1995).

Two cases can be distinguished. If the membrane does not sustain a pressure, then the light split by the input MMI coupler will recombine with the same phase at the output of the MMI coupler. However, when a pressure is applied to the membrane, a phase shift is observed between the two arms. Two mechanisms are involved: the path length modulation and the photo-elastic effect (Hah, Yoon, and Hong 2000).

In sensor applications, MMI couplers are the most used. For example in a chemical sensor, as depicted in Figure 41, the multimode section of this coupler can be covered with an appropriate sensing material, depending on the given application. In the multimode section, individual modes propagate at different speeds. This difference

Figure 41: Schematic for a chemical sensor

results from the MMI parameters, including the refractive index of the covering layer (sensing layer in Figure 41) of the multimode section (Kribich et al. 2005). Hence, this difference between mode speeds leads to a phase shift. Therefore, constructive and destructive interferences take place and affect the electromagnetic field intensity profile. As a consequence, the image position shifts, which depends, in turn, on the sensing layer index so that the input intensity profile can be computed (Kribich et al. 2005).

Polarization Couplers

Principle. Controlling the state of light polarization is of interest for several fields including fiber communication and sensing. Although the polarization dependence may be advantageous in a specific application (for example, sensing), it is not relevant in communication systems where intensity is the measurand (Ho 2005). Hence, optical components that can manipulate polarization have application, especially in polarization splitters, polarizers, and circulators.

The polarization splitter is based on two-mode interference in a directional coupler structure. These two modes—the *symmetric* and *asymmetric* modes—are guided for both vertical and horizontal polarizations. These modes are excited by an incoming wave with equal power and propagate with different velocities. At the end of the structure, the power splitting ratio can be determined by measuring the relative accumulated phase of these two modes. This type of splitter is used to separate or to recombine the polarization components TE and

TM (Figure 42) (Herrmann 1998). However, one can find polarization-maintaining couplers based on, for example, Hi-Bi fibers.

Applications. In a dual-frequency stabilization system, the emitting lasers (see Figure 43) excite the two different

Figure 42: Passive directional coupler as polarization splitter

Figure 43: Optical coupling component of the stabilization system

input ports of the first polarization-maintaining coupler (C1). At the output of C1, light propagates along one fiber to reach the second 2×2 coupler (C2). The second output fiber of C2 guides lights to photodiodes and to a high-speed photodetector (Batal et al. 1998).

COUPLER TECHNOLOGIES

There are many ways to fabricate couplers. The choice of which technology to use depends on the required performance. In this section, we will address the most commonly used technologies for making OCs.

Macro- and Micro-Optics

Macro-optics, also known as *bulk optics*, include conventional lenses and mirrors that are more commonly used in laboratories. *Micro-optics* are based on planar and lithographic fabrication techniques. Under this aspect, micro-optics employs a micro-technology manufacturing method (Sinzinger and Jahns 2003) to produce extremely small optical components and structures at the micro and nanometer scales. This quality fits well with the fiber components and the fibers themselves. However, both macro- and micro-optics still obey the same classical optical principles.

Figure 44 illustrates an optical coupler made up of bulk optics. An input optical fiber (input 1) delivers an optical field that is collimated by a first lens after passing through a beam splitter. One part of the beam goes to the output fiber 1, and another is directed to the output fiber 2 after traveling through a convergent lens. The beam splitter may be a power or polarization splitter. In addition, a half mirror or other bulk optic device (diffractive grating, thin-film filters, etc.) may be used to split the optical field (Hecht 2002).

Fused-Fiber Couplers

Fused tapered optical couplers can be made by bringing the two cores of two optical fiber closer together through heating and stretching of the two (Figure 45). First, the fibers are stripped of their claddings, and the cladding

Figure 44: Optical coupler using bulk optics: lenses and beam splitter

Figure 45: Optical coupler based on fused fibers

Figure 46: Optical coupler based on planar waveguide

diameters are reduced by immersion in hydrofluoric acid. This close proximity permits power exchange between the evanescent waves traveling within the cladding of the first fiber and then coupled into the core of the second fiber (Yariv 1973; Daxhelet, Lacroix, and Gonthier 1995; Green 1993).

Planar Waveguide Couplers

The structure and the operational principle of the planar waveguide-based optical couplers (Figure 46) are similar to that of fused, tapered fibers except that a planar waveguide is used instead of optical fibers. Waveguide parameters (index of refraction of the core and the surrounding media, the coupling length, etc.) are predetermined to obtain the desired coupling ratio and to match the peak of power to the desired wavelength (Hecht 2002).

CONCLUSION

Optical couplers are basic components with a broad range of practical applications in optical communications generally and sensing systems in particular. The need for such components arises from the large number of applications that require them. In this chapter, we briefly described the basic theories related to these optical devices. By listing some of the parameters, types, technologies, functionalities, and applications of these devices, we have tried to give a design and technology overview of optical couplers and their possible applications in computer network. For further details, the reader should consult the references provided in this chapter. Certainly, such components will have gravitational interest in the near future of networking, especially with the migration toward all-optical networks. Progress in designing, implementing, and using optical couplers is directly linked to advances in telecommunication and sensing systems as well as to fabrication technologies.

GLOSSARY

- Circulator:** Passive three-port devices that couple light from ports 1 to 2 and ports 2 to 3 and have high isolation in other directions.
- Computer Network:** Two or more connected computers that share a telecommunication medium for the purpose of communicating and sharing resources.
- Continuous Wave:** Usually refers to the constant optical output from an optical source when it is biased (i.e., turned on) but not modulated with a signal.
- Coupler:** An optical device that combines or splits power from optical fibers.
- Coupling Ratio:** The ratio of optical power from one output port to the total output power expressed as a percentage.
- Demultiplexer:** A module that separates two or more signals previously combined by compatible multiplexing equipment.
- Erbium-Doped Fiber Amplifier:** Optical fibers doped with the rare earth element erbium, which can amplify light in the 1550-nm region when pumped by an external light source.
- Fabry-Perot (FP):** Generally refers to any device, such as a type of laser diode, that uses mirrors in an internal cavity to produce multiple reflections.
- Fiber Bragg Grating (FBG):** A technique for building optical filtering functions directly into a piece of optical fiber based on interferometric techniques. Usually this is accomplished by making the fiber photosensitive and exposing the fiber to deep ultraviolet light through a grating. This forms regions of higher and lower refractive indexes in the fiber core.
- Mode Coupling:** The exchange of power among propagating modes in a given waveguide structure. For optical fiber, the nonuniformities in the index of refraction, impurities, and geometric perturbation favor the appearance of mode-coupling phenomena.
- Optics:** The science that deals with the physical properties of light. It highlights both light propagation and light behavior under different structures.
- Passive Optical Network (PON):** A point-to-multipoint network architecture in which passive optical splitters are used to enable a single optical fiber to serve multiple buildings.
- Pigtail:** A short optical fiber permanently attached to a source, detector, or other fiber-optic device at one end and an optical connector at the other.
- Star Network:** A network in which all terminals are connected through a single point, such as a star coupler or concentrator.
- Waveguide Coupler:** A coupler in which light gets transferred between planar waveguides.
- Wavelength-Division Multiplexing (WDM):** Sending several signals through one fiber with different wavelengths of light.

INTRODUCTION

The function of an optical filter is to select one wavelength and reject all other wavelengths. Fixed wavelength and tunable optical filters are now playing a crucial role in multichannel optical networks. The recent rapid progress in optical networks has necessitated the availability of more channels at a reduced cost. These trends are underscoring the need to develop filters with large port counts and narrower passbands. Applications of filters in optical networks include *multiplexing* (MUX) and *demultiplexing* (DMUX) of laser wavelengths, noise rejection, and gain equalization after an optical amplifier. Filters are finding an ever-increasing role in *coarse wavelength-division multiplexers* (CWDMs) with channel spacing on the order of 20 nm, and in *dense WDM* (DWDM) networks with channel spacing less than 0.2 nm.

A group of optical filters operate based on absorption, reflection, or diffraction of bands of light, whereas many filters and multiplexers are based on the phenomenon of constructive and destructive interference between monochromatic coherent optical waves. Gratings are an exception and utilize the diffraction property of light. Hybrid filters, in which a number of different filters (for example, gratings and dielectric or absorption filters) are used in conjunction to provide superior performance characteristics over a single filter. Numerous techniques have been developed to achieve high-contrast optical filtering. A given filter's design is driven by its performance requirements and specifications and by physical and environmental requirements and specifications. Some filters operate solely based on changes in the optical properties of an optical material and involve no moving parts. Often, the nonlinear optical material's properties are utilized to achieve the desired characteristics. Examples of such filters include absorption, electro-optic, fixed Fabry-Perot, and Bragg gratings.

The second class of filters involves a moving mechanism such as a *micro-electromechanical system* (MEMS). Examples are movable gratings and Fabry-Perot cavities.

Based on their filtering mechanisms, optical filters can be put into three main categories: thin-film filters, interleaver filters, and grating filters.

1. Thin-film filters include multiple cavity transmission, Fabry-Perot, photonic band-gap, and ring resonator filters. Thin-film interference filters rely on the thickness of each alternating high and low index layer to determine which wavelengths of the incident light are either reflected or transmitted.
2. Interleaver filters include lattice filters (e.g., Mach-Zehnder interferometric and birefringent filters), waveguide-arrayed filters (e.g., waveguide grating router and planar waveguide circuit-based filters), and Michelson interferometer-based (e.g., interference) filters. Therefore, a variety of phenomena is utilized to construct the interleaver filters.
3. Grating filters include bulk gratings, fiber Bragg gratings, and acousto-optic tunable filters. These filters work based on the dispersion power of ruled reflection gratings to separate or combine different wavelengths.

Other filter types include absorption, electro-optic, fused-fiber, gain-flattening, and dispersion-compensation filters. The properties of each filter are summarized below.

The general requirements for the filter response and noise rejection for wavelength-division multiplexing MUX and DMUX applications include:

- low insertion (output-to-input) loss,
- narrow and uniform transmission passband,

- high degree of isolation of out-of-band signals (low magnitude of cross talk),
- polarization independence (all polarizations are accepted without loss),
- high steepness of the filter edges,
- tunability over a wide spectral range with high tuning resolution and speed,
- low dispersive properties and group delay ripple,
- high stability (i.e., environmentally insensitive) and reliability,
- linear phase response and constant time delay (if applicable) for optimum bandwidth utilization, and
- low cost, compactness, light weight, and low power consumption (if active).

Table 1 summarizes the current typical amplitude response characteristics of several commonly used filters. These characteristics are changing rapidly with ongoing developmental research.

Table 1 indicates the availability of a variety of high maturity tunable filters with the capability to accommodate more than one hundred channels, introducing minimal to moderate insertion loss. As expected, the electro-optically tuned filters provide the fastest tunability, whereas mechanically or thermally tuned filters are the slowest in tuning rate.

The undesired dispersive properties of optical filters that affect a WDM system's performance are driven by a filter's dispersive properties. A filter's phase response characteristics consist of the first derivative of the spectral phase response determining the total time delay through the filter, as well as higher-order derivatives of the spectral phase response driving the total time delay through the filter. Lenz et al. (1998, "Dispersive properties," "Optimal dispersion") offer techniques to minimize the dispersion effects. The phase response of filters that demonstrate phase can be derived from their amplitude response through a linear (Hilbert) transformation.

Filters developed based on arrayed-waveguide gratings or fiber Bragg gratings may demonstrate significant group delay ripple. The technique of grating apodization may be necessary to avoid this problem. On the other hand, short path-length Mach-Zehnder interferometer filters demonstrate little delay ripple (Othonos and Kalli 1999). Variations in the group delay spectrum of fiber-optic devices are especially problematic at data-rate regimes exceeding 10 Gb/s.

Figure 1 illustrates the amplitude response and the phase response of an ideal rectangular filter that demonstrates phase responsivity (Lenz et al. 1998, "Dispersive properties"). The phase response is shown to become nonlinear and to diverge at the edges of passband.

Wavelength Add-Drop Multiplexers and Demultiplexers

Optical multiplexers combine, in fiber and free space, individual wavelengths before launch into the fiber. Demultiplexers undo the job of the multiplexer. Multiplexers and demultiplexers utilize a variety of technologies, including interleavers, frequency slicers, thin-film filters, periodic filters, Fabry-Perot cavity filters, acousto-optical tunable filters, Mach-Zehnder interferometers, fiber Bragg gratings, and arrayed-waveguide gratings. This chapter briefly describes most of these technologies. The cascading of multiplexers, demultiplexers, and switches will form static (no switch involved) or dynamic multiple *wavelength cross connects* (WXC). The static WXC are functionally limited, whereas dynamic WXC have a wider range of applications.

A few measurable parameters are commonly utilized to specify a filter. The *passband* is defined as the range of wavelengths that a filter selects. It is characterized by a gain curve representing its boundaries and the spectral distribution of the wavelengths. *Channel spacing* is the minimum frequency spacing between channels to avoid cross talk. Typically, a cross-talk level 30 dB below signal level is desired. The *maximum number of equally*

Table 1: Summary of Certain Characteristics of Filters Commonly Used in Fiber-Optic Networks*

Filter Technology	Maturity	Channel Spacing (GHz)	Cross Talk (dB)	Insertion Loss (dB)	Tuning Range (nm)	Tuning Time (sec)
Dielectric thin film	High	30–200	–15	<1–3	N/A	N/A
Fabry-Perot (FP)	High	50–100	<–10	~1	500	1E2–1E-3
Electrooptic FP	High	50–100		1–3	50	1E-8

*Some data are typical while others are state of the art (2007).

Figure 1: Amplitude response (solid line) and phase response (dotted line) of the ideal rectangular filter, assuming that the filter demonstrates phase responsivity (after Lenz et al. 1998, "Dispersive properties," with permission)

spaced channels is defined as the ratio of the total tuning range for the filter to its channel spacing. The *spectral width* (channel width) represents the spectral content of a channel and is a measure of the deviation from an ideal purely single wavelength channel and is normally described by the 3-dB point. The transfer functions of manufactured optical filters are generally asymmetric accompanied by passband ripple. To a coarse approximation, Butterworth and Bessel functions may be used to describe the filter shape. Some of the most common fiber-optic networking filters applied to signal filtering and multiplexing and demultiplexing are briefly described below.

THIN-FILM FILTERS

Multiple-Cavity Transmission Filters

Multiple-cavity transmission filters constitute a mature technology that is competing well with some of the more advanced filter technologies. The structure of the thin-film multilayer interference filter is based on that of the interferometric effect. Typically, a thin-film filter is composed of one or more cavities and mirrors that together result in a narrow-bandpass filter that is useful to applications such as WDM. *Dielectric thin-film filters* (DTFs) are formed by layers of quarter-wave thick dielectric stacks with alternating high and low indexes of refraction. Silicon dioxide (SiO_2) and titanium dioxide (TiO_2) are among the high-index dielectrics used in the fabrication of these devices. The resulting cavities interfere with the incident light waves, selectively transmitting or reflecting specific wavelengths. This relatively low-cost approach is highly suitable for the development of CWDM and DWDM passband filters (Lin, Kao, and Chi 2003). The narrower the required wavelength spacing (for WDM), the tighter the tolerance on the thickness of a given stack and the larger the number of deposited layers. For example, a 100-GHz bandwidth filter may require as many as 200 layers. High-end coatings require an even distribution of the coating material across the substrate with thickness controlled to the atomic level. Thermally stable DTFs with a flattop passband and extremely sharp skirts for high adjacent channel isolation are now developed routinely. Their use

precludes the need for tight control of laser wavelengths over a system's lifetime. High insertion loss, on the order of a few dBs, for the narrowest passband filters is a drawback for some applications. In general, low insertion loss and passband ripple filters have been developed for WDMs with forty or more channels.

Fabry-Perot Filters

Fabry-Perot (FP) filters were derived from the classical FP interferometers, also known as *FP etalons*. An etalon's cavity may consist of two plane parallel mirrors or two spherical mirrors. Other cavity (interferometer) examples include a resonator formed by highly reflective mirrors on the opposing sides of a precisely fabricated transparent refractive material, and, more elegantly, by the polished end surfaces of two fibers aligned relative to each other and separated by air gap $<200\ \mu\text{m}$ thick to emulate an air-spaced etalon (Atherton et al. 1981).

In the FP filters, interference of light waves along the optical path of the cavities provides the basis for selecting a particular wavelength. The cavity is electromechanically induced to tune in or out of resonance with the incident light rays. The FP interferometric filter consists of a single input port and a single output port. It is typically used to select one wavelength channel from a series of channels. As described below, several distinguishing characteristics describe an FP filter.

The finesse of an FP interferometer is a measure of the width of the transfer function and thus its wavelength-filtering resolution to determine the maximum number of discernible channels. The *finesse* (F) of an FP cavity is defined by the ratio $F = \text{FSR}/\text{FWHM}$, where the *free spectral range* (FSR) is the distance between the transmission peaks and the *full width at half maximum* (FWHM) is defined to be the 3-dB bandwidth of a channel. In effect, the FSR is the period at which the shape of the passband (the transfer function) repeats itself after a certain frequency. Thus, the filter transmits a frequency that is a distance of $n \times \text{FSR}$ from the preferred frequency ($n = \text{an integer}$). The finesse of a given cavity is driven by the quality of its mirrors (polishing of substrate, reflectance of and the degree of contamination of coatings), and the angle of incidence of the input beam. The finesse is related to the

mirror *Reflectance* (R) by $F = \pi R^{1/2}/(1-R)$. For high-quality FPs, the finesse varies in the range of 100 to more than 1,000,000. The filter bandwidth decreases and the FSR increases as the number of passes through a filter or multiple-filter stage increases. The finesse and FSR together limit the number of channels that can be enclosed within the FSR. The higher the finesse, the more channels can fit within the FSR.

To select different wavelengths, the interferometer may be tuned by adjusting the cavity length or by varying the cavity's index of refraction. This may be accomplished with the aid of a mechanical actuator or an electromechanical transducer—for example, a piezoelectric actuator. Mechanical tuning suffers from low reliability, whereas piezo tuners may suffer from thermal distortions and hysteresis. Alternatively, when the FP cavity's medium is made of liquid crystals or other electro-optical materials, the refractive index can be modulated by an electric current to select individual wavelengths (Hirabayashi 2005). Low power consumption, high tuning bandwidth, fast tuning times (1 μ s), and low cost are among the attractive features of these devices (Li, Chiang, and Gambling 2000).

Photonic Band-Gap Filters

Photonic band-gap (PBG) filters are made of photonic band-gap structures that are a subset of photonics structures. Variable narrowband or wideband filtering of incident light can be achieved by constructing a filter consisting of alternating high- and low-index semiconductor, dielectric, metal, or a combination of these layers, typically one-quarter of a wave thick, deposited on a substrate (Scalora, Bloemer, and Baglio 2002). An actuator (e.g., MEMS) varying the air gap between two PBG stacks provides the dynamics for fast filtering and switching (Trimm et al. 2005). These filters have the potential to offer small cost cost-effective filtering and switching for fiber-optic networks.

INTERLEAVER FILTERS

An *interleaver filter* is a periodic optical element for combing or separating a comb of DWDM signals. An interleaver filter inexpensively and effectively doubles the number of channels in a WDM system by separating the WDM signals into two groups of odd and even channels. These filters have a rectangular spectral response that is useful in relaxing the specifications for other fiber-optic devices such as arrayed-waveguide grating. Unlike the single-channel add-drop filters that synthesize a narrowband filter on top of a wide rejection band, the periodic property of the interleaver filter reduces the number of Fourier components required for a flat passband and high-isolation rejection band (Cao et al. 2004). Interleaver filters may be classified based on their structure as *finite impulse response* or *infinite impulse response* (Oguma et al. 2004). Interleaver filters may also be classified under three broad categories: (1) *lattice filters*, which include birefringent filters and Mach-Zehnder filters; (2) *waveguide filters*, which include arrayed-waveguide routers and planar light-wave circuits; and (3) *Michelson interferometer-based filters*, which include interference filters.

Parameters of importance in the design of a interleaver filter are:

1. passband characteristics that include low insertion loss, a wide and nearly flat-top shape with sharp roll-off on the band edges, and minimal chromatic aberration;
2. stopband characteristics that provide high extinction across the passband of the alternate port where, typically, stopband width is traded for the maximum extinction;
3. polarization-dependent characteristics whereby the filter designer's goal is to minimize dependence on the degree of frequency shift between the different polarization states, the polarization-dependent differential insertion loss, and the differential group delay between the two paths (also known as *polarization-mode dispersion*); and
4. reduction of chip size, improved stability, fabrication tolerance, and mass producibility.

Lattice Filters

Lattice filters are constructed based on a cascade of differential delay elements. The delay in each element is an integral multiple of a unit delay. In a large-scale lattice filter, phase adjustment could be cumbersome because of the existence of many delay lines. Between the delay elements, power is exchanged across the different paths. As described below, the category of lattice filters includes Mach-Zehnder interferometric and birefringent filters.

Mach-Zehnder Interferometric Filters

In a *Mach-Zehnder interferometer* (MZI) filter, typically an integrated optic or a fiber-optic device, the input monochromatic beam is channeled into two waveguides that converge into a combiner at its output (Figure 2). A phase difference is induced between the two arms of the interferometer by an adjustable delay element located in one of the two arms. In this manner, 180-degree out-of-phase wavelengths are filtered. Narrowband filtering is accomplished by cascading a number of these devices together. A filter based on a chain of MZIs isolates one of $N = 2^n - 1$ optical channels, where n is the number of interferometers in the chain (Kuznetsov 1994).

MZ interferometers can be tuned the same manner as Fabry-Perot filters and belong to the class of electro-optic filters that may be tuned by varying the voltage on one their arms. The ensuing change in their indexes of refraction affects the phase relationship between the two arms, resulting in different wavelengths at the output of the interferometer. Mechanical compression of one of the waveguides—for example, via a piezoelectric transducer—is another means of tuning an MZI filter. Tuning speed is on the order of several milliseconds, or orders of magnitude less than that for FP-type interferometers.

Birefringent Filters

Birefringent filters rely on the birefringence property of optically anisotropic crystals (e.g., lithium niobate,

Figure 2: Principles of a Mach-Zehnder interferometric filter

LiNbO₃), wherein a relative delay between ordinary and extraordinary rays aligned along the fast and slow axes of the material can be produced. As a result, light rays with a single polarization state can be made to interfere with themselves. The line-narrowing property of the birefringence filter (linear retarder) stems from reflection losses at undesired wavelengths. When placed at the Brewster's angle, the selected wavelength (e.g., p-polarized) will experience no reflection loss, whereas the remaining wavelengths with orthogonal (s-polarized) will experience reflection losses. Typically, a stack of (two to four) such filters is required to generate the extremely narrow filter profile. The birefringent filter may be tuned by rotating its crystal plates (Hirabayashi and Kuokawa 1992).

Waveguide Filters

As the name implies, *waveguide photonic fibers* are based in waveguiding effects in a varieties of architectures such as arrayed gratings, planar light-wave circuits, and photonic crystals.

Arrayed-Waveguide Gratings

Arrayed-waveguide gratings (AWGs) are planar devices that utilize the principles of interferometry and are a generalization of the Mach-Zehnder interferometers. Their architecture consists of multiple waveguides with different lengths, all converging at a single point (McGreer 2002). Interference between signals from different waveguides occurs at the crossover point. In an AWG, multiple copies of the same signal, shifted in phase by differing amounts, are added together. Because of its multiple input and output, a single AWG can do the job of multiple Bragg gratings. An AWG may be tuned via thermo-optic tuning. Relatively high insertion loss is the main drawback of these filters. AWGs are typically polarization-dependent, although polarization-independent versions have been demonstrated. Athermal AWGs are now commercially available and do not require extra thermal control. The AWG MUX-DMUX is now a key component of photonic networks. Figure 3 illustrates the structure of an arrayed-waveguide grating.

Planar Light-Wave Circuit Filter

A *planar light-wave circuit* (PLC) filter is formed by a fiber-matched, silica-based waveguide on silicon (Himeno, Kato, and Miya 1998; Yamada et al. 1995). PLC devices can be mass produced to meet the demand for more channels at a reduced cost. Wavelength $N \times N$

Figure 3: The structure of an arrayed-waveguide grating

MUX-DMUX and programmable filters for high-bandwidth transmission systems have been constructed with PLC devices. Features of PLCs include high channel number, low insertion loss, high reliability, wide wavelength range, wide operating temperature range, excellent design flexibility, compact size, stability, and mass reproducibility. Multiwavelength wideband WDM filter arrays are constructed based on PLC-MZI architecture (Seo et al. 2002).

Michelson Interferometer-Based Filters

Michelson interferometer-based interference filters are multilayer thin-film devices consisting of several layers deposited on a substrate to form one or several cavities arranged in series. Akin to Fabry-Perot interferometers, the filtering of light is based on the destructive interference phenomenon. Width of the gap space (a thick film of dielectric material) between the two reflective surfaces determines which wavelengths are in phase and pass through the coated surfaces and which transmissions are filtered out through destructive interference. This gap is designed to have a thickness of one-half wave at the desired peak transmission wavelength. The reflecting layers consist of multilayers of thin films, each approximately a quarter-wave thick. The number of layers in the thin-film stack may be adjusted to tailor the width of the bandpass. Interference filters may be designed as a bandpass or as an edge filter. Multicavity filter designs provide sharp cutoffs for spectral passband. Figure 4 illustrates the transmission spectrum and group delay of a thin-film filter with three and five cavities.

GRATING FILTERS

Grating filters are made from passive optical elements that are capable of separating individual wavelengths in their diffraction pattern. Wavelength and angle of incident on the grating determines the reflected light's angle. Compact wavelength demultiplexers have been constructed using a gradient index rod lens and a reflection grating replicated on a glass wedge. Grating-based demultiplexers are well suited for separating a large number of densely spaced wavelength channels.

Figure 4: (a) Transmission spectrum and (b) group delay of a thin-film filter with three cavities (thin line) and five cavities (thick line). Squarer transmission results with increased number of cavities at the cost of ripple in the passband and higher dispersion near the passband edges (after Lenz et al. 1998, "Dispersive properties," with permission)

Two types of all-fiber filters—fiber Bragg gratings and long-period gratings—are now commercially available. Both are based on gratings written in the core of a single-mode fiber. Both free-space and fiber-based gratings are explained below.

Bulk Gratings

Free-space bulk diffraction gratings utilize the dispersive power of ruled reflection gratings and are used in MUX and DMUX, *reconfigurable optical add-drop multiplexers* (ROADMs), and *wavelength-selective switches* (WSSs). Ruled gratings provide higher dispersion and efficiency than other grating types. Gratings are typically blazed such that the reflected power is maximized for the first order of diffraction. The inherent property of a diffracted peak corresponding to a different angle for different wavelengths is utilized in multiplexing and demultiplexing of light beams with different wavelengths. Figure 5 schematically illustrates the concept of multichannel multiplexing with a bulk grating.

Fiber Bragg Grating

The *fiber Bragg grating* (FBG) is formed by photo-etching a periodical variation of the index of refraction onto the core of the optical fiber or by etching a phase mask into the fiber in the form of a diffractive optical element

(Hill and Meltz 1997). The FBG filter relies on Bragg reflection, wherein the grating's period (distance between the grating lines) is comparable to the incident light's wavelength. The Bragg condition is satisfied when the Bragg spacing (i.e., the grating period) is an integer multiple of the half wavelength. The Bragg grating selectively reflects a specific wavelength back into the fiber's core while transmitting other wavelengths. Figure 6 schematically illustrates a Bragg grating etched into the fiber's core. Figure 7 shows the reflection spectrum and the corresponding group delay of an apodized FBG.

Low insertion loss is a key advantage of these filters because the grating (the filtering mechanism) is an integral part of the fiber itself. Typical performance characteristics include reflectance losses on the order of 1 percent and a wavelength selectivity bandwidth of 0.1 nm. Thermal isolation of the device is required to avoid index-of-refraction fluctuations. FBGs are fairly insensitive to the polarization state of the input signal. FBGs have found applications as filters in add-drop modules and in chromatic-dispersion compensation modules (Kashyap 1999). The channel-selection properties of FBGs are typically excellent. An FBG added to the output of a circulator results in an effective bandpass filter.

Long-Period Fiber Gratings

The *long-period fiber grating* (LPFG) utilizes gratings with a period much longer than the incoming wavelength. On reflection from the grating, the incident light dissipates

Figure 5: Optical channel multiplexing with a bulk grating

Figure 6: A Bragg grating etched into the fiber's core

Figure 7: Reflection spectrum (dotted line) and the corresponding group delay (thin solid line) of an apodized fiber Bragg grating (after Lenz et al. 1998, "Dispersive properties," with permission)

into the fiber's lossy cladding modes (contrasted with the FBG, where it is reflected back to the fiber core). Fabrication of these devices is similar to the FBGs. These devices are useful in multichannel optical amplifiers and spectral gain profile flattening. Mechanical and thermal tuning both elongate the fiber, thereby tuning the Bragg grating by controlling the grating's period.

It is possible to make the bandpass curves broader and flatter by utilizing step-index, multimode, large core diameter fibers, where the core diameter of the output fiber is significantly larger than that of the input fiber (Aoyama and Minowa 1979). Also, cascading of multiple gratings, each with a different center wavelength, leads to intricate transmission spectra.

Acousto-Optic Tunable Filters

Acousto-optic tunable filters (AOTFs) are based on the well-developed acousto-optic effect in which a Bragg grating is set up in a waveguide (a crystal) through acoustic waves that are created by an external transducer (e.g., a piezoelectric crystal). The periodicity with which the generated change in the medium's index of refraction (e.g., for LiNbO_3 or tellurium dioxide, TeO_2) is equal to the wavelength of the acoustic wave (Chang 1981). The wavelength-filtering effect of these devices results from transmission of those wavelengths that satisfy the Bragg condition. The filter's passband is inversely proportional to the acousto-optic interaction length. Both polarization-dependent and polarization-independent devices have been developed. AOTFs also have applications in wavelength-selective space switches. The undesired cross talk that accompanied some AOTFs has been successfully suppressed by utilizing an optical fiber-based AOTF and multiple nonguiding cladding modes in the fiber (Kim et al. 1997). These filters are particularly suited to active gain flattening because arbitrary filter shapes are producible by simultaneously applying several RF signals to the AOTF.

An AOTF's unique capability to select several wavelengths simultaneously is particularly suitable to the development of a two-input, two-output wavelength cross connects. This is accomplished by simultaneously launching multiple

acoustic waves, thereby satisfying the Bragg condition for multiple optical wavelengths. As a tunable filter or wavelength cross connect, current AOTFs benefit from fast tuning time and wide tuning range but suffer from a high level of cross talk and relatively high filter bandwidth (100 GHz). Cascading two such devices can result in nearly 20 dB in suppression of the side lobes.

OTHER FILTERS

Absorption Filters

Absorption filters are commonly manufactured from a selected impurity in a crystal, dyed glass, pigmented gelatin resins, or silicon and germanium deposited as a thin film. Both atomic and molecular absorption bands have been utilized along with induced absorption via the Kerr or the Faraday effect to achieve wavelength selection. The impurities or chemical densities are also varied to adjust the absorption frequency. Absorption filters follow the Kramers-Kronig relations. The transmittance of an absorbing filter is an exponential function of thickness and the absorption coefficient at a given wavelength.

These filters can demonstrate narrowband pass characteristics and are used for frequency stabilization of transmitters (Latrasse et al. 1994). Sharp rejection spectra or interference filters may be fabricated when absorption filters are combined with other filters (Musikant 1985). Because the absorption peak depends on the property of the material forming it, wavelength tuning or absorption edge sharpening is more difficult relative to other filters.

Electro-Optic Filters

The *electro-optic tunable filters* (EOTFs) are constructed from crystals that demonstrate a strong electro-optic effect. An electric field applied to the crystals via electrodes causes a change in the index of refraction. This effect can be used as an interferometric filter to vary the optical path lengths (Green 1993). EOTFs are distinguished by their exceptionally fast tunability feature, which is on the order of nanoseconds (Pinnow et al. 1979). One configuration

utilizes a thin (~150 micron thick) platelet of lithium tantalate (LiTaO₃) or LiNbO₃ crystals within which a spatially periodic electric field is imposed (Pinnow et al. 1979). Light may travel longitudinally or transversely to the birefringent plates formed around the platelet. Transparent or finger electrodes are applied to the electro-optic crystal. The structure of a *Fabry-Perot semiconductor filter* (FPSF) is akin to Fabry-Perot diode lasers. Electrical tuning via injection current of the comblike spectral response of the FPSF allows wavelength selection (i.e., filtering). Wide (~10 nm) wavelength tuning has been achieved. Stepwise wavelength tuning over a range of 9.0 nm with a buildup time as short as a few microseconds has been demonstrated. Flexibility in producing variable filter bandpass, simultaneous operation at multiple wavelengths and side-lobe suppression are among the attractive features of electro-optic filters.

Gain-Flattening Filters

Gain-flattening filters (GFFs) are used primarily with fiber amplifiers. A GFF is typically designed to have a spectral response that closely matches the inverse gain profile of the amplifier (Wysocki, 1997). Etalons, thin-film filters, long-period gratings, chirped fiber Bragg gratings, or a combination of these filters have been utilized to develop this type of filter. In chirped fiber gratings, the Bragg wavelength varies with position. The GFF may be located at the output of amplifiers or between two stages of amplifications. Both passive and dynamic GFFs have been developed. Dynamic channel equalizers can equalize or block individual channels across the C or L bands. In a feedback loop, it can compensate for fluctuations of transmission amplitudes on individual channels or completely block or attenuate a channel. Advanced gain-flattening filters deviate only 0.02 dB from the target shape.

Dispersion-Compensation Filters

At data rates of 10 Gb/s and higher, chromatic dispersion in the fiber becomes a significant factor, causing signal deterioration. An optical *dispersion-compensation filter* must be compact, flexible, cost-effective, and able to simultaneously and overall channels alleviate the channel-to-channel variation of the dispersion and the dispersion slope of the transmission link being utilized. Implementation options include specially designed dispersion-compensating fibers with a large negative dispersion and dispersion slope, chirped fiber Bragg gratings, lattice Mach-Zehnder filters, Michelson interferometer-based (optical all-pass) filters, and specially modulated transmitters (Painchaud et al. 2006; Koch and Brenna 2003).

Fused-Fiber Filters

Single mode fibers may be fused together through application of high temperatures at the fiber joint. *Fused fibers* minimize the packaging requirements and are used in filtering as couplers for multiplexing, ring fiber resonators, and attenuators. For example, a variable loss and coupling add-drop filter-based fused-fiber grating has been

developed with controlled transmission properties (Choi, Lee, and Yariv 2002). One configuration of a fused-fiber filter utilizes a long-period grating written into the waist of the coupler (Lauzon 1998). The filter may be tuned to specific wavelengths by adjusting the period of the grating. Such a filter could have approximately 1 nm of wavelength selectivity and is particularly suited to MUX and DMUX in DWDM networks.

Hybrid Filters

By combining two or more filters, we can take advantage of the individual properties of each filter, effectively producing superior characteristics. For example, Lumeau, Glebov, and Smirnov (2006) combined a Fabry-Perot etalon and a volume Bragg grating sequentially to achieve a filter with the narrow spectral band of the etalon and the broad rejection bandwidth of the grating. The spectral sensitivities of the etalon and the Bragg grating were 220 and 320 pm, respectively. The selectivity of the hybrid filter was 220 pm, with separation between channels of 800 pm and a throughput of 95 percent. With a higher-quality etalon, wavelength selectivity down to 10 pm is anticipated.

MULTIPLEXERS

Wavelength-division multiplexing is a powerful technique used to increase the capacity of an imbedded fiber. In this technique, each optical signal is assigned a specific wavelength. Multiple wavelengths are multiplexed and transmitted and amplified as a group through a single fiber. Other features of WDM systems include signal format independence by which data are transmitted irrespective of the data format, wavelength routing whereby wavelength becomes another dimension like time and space, and wavelength switching in which optical layers may be reconfigured efficiently. A fiber-optic multiplexer is an instrument that can optically couple one input channel to tens of different output channels.

Optical filters make up the core of most MUX and DMUX components. For dynamic WDMs with circuit switching at moderate to high speeds that require dynamic filtering functions, tunable optical filters are essential. Static and tunable filters efficiently and selectively add or drop specific wavelength channels from a multiple-wavelength fiber-optic network. Dispersive optical elements such as prisms and diffraction gratings, reflective optics such as interference filters, along with fiber directional couplers and integrated waveguides are utilized in forming MUX and DMUX devices (Senior and Cusworth 1989). Most multiplexers can be used in reverse as demultiplexers, therefore discussion of one type pertains to other applications as well. Table 2 summarizes the generalized characteristics of passive device types for multiplexing and demultiplexing.

A variety of architectures have been developed for wavelength multiplexing and demultiplexing in response to the ever-increasing growth of number of wavelength channels in a WDM system. Table 3 compares the merits of some of the more popular multiplexing and demultiplexing architectures.

Table 2: Typical Devices Characteristics for Multiplexing and Demultiplexing (Generalized)

Device	Insertion Loss (dB)	Channel Bandwidth (nm)	Channel Separation (nm)	Mechanism
Filter	1	4	10	Interference, absorption
Grating	>3	10	40	Dispersive
Prism	>3	20	30	Dispersive
Directional coupler (fiber)	0.2	40	100	Power transfer between adjacent fibers
Waveguide	1.5	100	10	Integrated, no discrete optics

Table 3: Merits of Some Common Multiplexing and Demultiplexing Concepts

Architecture	Approach	Features	Drawbacks
Serial (example: thin film)	Demultiplexes one wavelength at a time	Scalable to a limited number of channels	Moderate loss and uniformity; requires narrow filters
Common stage (example: AWG)	Demultiplexes all wavelengths in a single stage	Low loss and high uniformity	Limited number of channels (<50); requires narrow filters
Multistage (example: lattice)	Divides wavelengths into bands; demultiplexes each band separately	Large number of channels	Requires a guard space between bands
Interleaving (example: AWG)	Interleaves multistage demultiplexers	Modular; wider filters for latter stages	Complex implementation

Table 4: Distinguishing Characteristics of Different Filter Types

Requirement	Suitable Filter
10's of MHz bandpass	Fabry-Perot
A few GHz bandpass	Fiber Bragg grating
<10 channels	Electro-optic or semiconductor
<100 channels	Fabry-Perot or acousto-optic
1 msec tuning time	Mechanically tuned (circuit-switched transmission)
1 μ sec tuning time	Acousto-optic (packet switching)
1 nsec tuning time	Electro-optic and semiconductor (packet switching)
500-nm tuning range	Mechanically tuned
250-nm tuning range	Acousto-optically tuned
15-nm tuning range	Electro-optic
<1-dB loss	Semiconductor
Excellent channel selection	Fiber Bragg grating
Good channel selection	Dielectric and arrayed-waveguide grating
Poor channel selection	Fabry-Perot, Mach-Zehnder, acousto-optical

CONCLUSION

In summary, optical filtering that performs channel selection is a major dynamic network functionality in the WDM environment. A wide variety of filters that are capable of selectively isolating single wavelengths from wavelength-multiplexed optical systems have been developed. Each has its own advantages and disadvantages. Many of the filters described here are commercially available. At this time, no filter provides all of the best features simultaneously. Selection of a filter is highly driven by the specifics of an application. For high-speed, highly dynamic networks, electro-optic and acousto-optic tunable filters provide the capability for nsec to μ sec tuning speeds.

Table 4 summarizes suitable filters categorized by applications of wavelength and channel selection, tuning speed, tuning range, and multiplexing and demultiplexing requirements.

GLOSSARY

Acousto-Optical Tunable Filter (AOTF): A filter that can be tuned by altering the refractive index by the applied acoustic waves.

Arrayed Waveguide Grating (AWG): A device for multiplexing or demultiplexing multiple wavelengths into a common path (typically, fiber optics).

Demultiplexing (DMUX): Separation of wavelengths arriving on a common path.

Dense Wavelength-Division Multiplexing (DWDM): Multiplexing of a variety of wavelengths that are spaced no more than a few GHz apart.

Dielectric Thin-Film (DTF) Filter: A filter made by depositing alternating layers of quarter-wave film.

Electro-Optical Tunable Filter (EOTF): An optical filter based on polarization conversion.

Fabry Perot Interferometer (FPI): An optical resonator consisting of plane-parallel reflecting ends.

Fiber Bragg Grating (FBG): A grating formed onto a fiber to reflect different wavelengths depending on the grating's period.

Free Spectral Range (FSR): In an FP interferometer, it represents the distance (in frequency space) between adjacent transmission peaks.

Full Width at Half Maximum (FWHM): A value for the extent of a function measured at half of the maximum amplitude.

Gain-Flattening Filter (GFF): A filter used (for example, in an amplifier) to equalize the amplification gain for different wavelengths.

Long-Period Fiber Grating (LPFG): A fiber-optic structure with properties that vary periodically along the length of the fiber.

Mach-Zehnder Interferometer (MZI): An interferometer based on the Twyman-Green interferometer.

Multiple Cavity Transmission (MCT): Thin-film filters are a type of multiple cavity transmission.

Multiplexing (MUX): The combination of several signals onto a common path.

Planar Light-Wave Circuit (PLC): Formed by a fiber-matched, silica-based waveguide on silicon.

Wavelength Cross Connect (WXC): Primarily a device switch connection of input ports to output ports.

Wavelength-Division Multiplexing (WDM): A system that allows the transmission of multiple signals with varying wavelengths over a common path.

INTRODUCTION

A fascinating phenomenon that is now referred to as a *soliton* was discovered for the first time in 1834 by John Scott Russell, who was conducting experiments in the Union Canal near Edinburgh to determine the most efficient design for canal boats. He noticed “a large solitary elevation, a rounded, smooth and well-defined heap of water, which continued its course along the channel apparently without change of form or diminution of speed” (Russell 1844). He named this phenomenon “the wave of translation.” Later, these waves were called “solitary waves” or “solitons.”

The name *soliton* was put forward by Zabusky and Kruskal (1965), who performed a detailed numerical study of the interaction of solitary wave solutions of the Korteweg-de Vries equation. It was shown that nonlinear waves can interact elastically and retain their shape after collision. It is noteworthy that the distinction between a “soliton” and a “solitary wave” is often disregarded in optics literature (Ablowitz, Biondini, and Ostrovsky 2000). The term *soliton* is used in optics to describe a localized pulse that travels without a change in shape. However in a strict mathematical sense, solitons only exist for integrable problems—that is, problems that are solvable by inverse scattering theory (IST)—whereas the solitary waves exist for a much broader class of nonlinear wave equations. According to Ablowitz and Clarkson (1991), “a soliton is a solitary wave which asymptotically preserves its shape and velocity upon nonlinear interaction with other solitary waves, or more generally, with another (arbitrary) localized disturbance.”

Initially, solitons were primarily the subject of fundamental research in various fields, including optics, mathematics, quantum mechanics, particle physics, and molecular biology. Currently, optical solitons are emerging as promising candidates for building future all-optical networks. The development of all-optical signal processing and computing devices becomes increasingly important as data rates and the capacity of optical communication systems continue to increase. Remarkably, from 1980 to 2000, the capacity of fiber-optics

transmission systems increased by a factor of more than 30,000 (Agrawal 2005).

The field of optical solitons is broad and continuously growing. Several excellent books and book chapters are currently available that address the properties and applications of different kinds of solitons, including Akhmediev and Ankiewicz (1997), Trillo and Torruellas (2001), Buryak et al. (2002), Kivshar and Agrawal (2003), and Desyatnikov, Torner, and Kivshar (2005). In this chapter, we focus on those classes of optical solitons that have been demonstrated to have a potential for optical networking applications. In the next section, the theoretical and experimental results demonstrating important properties of the main classes of solitons—including temporal, spatial, spatio-temporal, incoherent, discrete, and Bragg solitons—are summarized. Applications of solitons for optical networking applications are discussed in “Applications of Solitons.” Finally, in the summary, we outline future perspectives for the applications of optical solitons.

Optical Soliton Properties

Light propagation in a nonlinear medium is described by the *nonlinear Schrödinger equation* (NLS) (Ablowitz and Clarkson 1991). The particular form and dimensionality of the NLS depends on the geometry and material properties of the nonlinear medium. In this section, we review the mathematical background and main properties of several types of optical solitons.

Temporal Solitons in Telecommunication Systems

Theoretical Background

Temporal solitons in single-mode optical fibers were predicted by Hasegawa and Tappert (1973). Their propagation is described by the NLS equation in the form

$$i \frac{\partial u}{\partial z} - \frac{s}{2} \frac{\partial^2 u}{\partial \tau^2} \pm |u|^2 u = 0 \quad (1)$$

where the amplitude $u = \frac{A}{\sqrt{P_0}}$ is a normalized slowly varying pulse envelope, $z = Z/L_D$ is a normalized longitudinal coordinate, $\tau = (t - \beta_1 Z)/T_0$ is a time coordinate, β_1 is inversely proportional to the group velocity, and $P_0 = (\gamma L_D)^{-1}$ is the soliton peak power, implying the balance between the dispersion and the nonlinearity. The dispersion length $L_D = T_0^2/|\beta_2|$ describes the characteristic length at which dispersion becomes significant. The parameter $\gamma = \frac{n_2 \omega_0}{c A_{eff}}$ is the nonlinear coefficient, n_2 is the nonlinear refractive index, ω_0 is the carrier frequency, c is the speed of light in a vacuum, and A_{eff} is the effective mode area. The parameter $s = \text{sgn}(\beta_2) = \pm 1$ is the sign of the group velocity dispersion (GVD) parameter β_2 , which can be positive or negative depending on the wavelength. The first two terms in Equation (1) describe linear wave propagation, while the third term is responsible for the nonlinear interaction owing to the intensity-dependent refractive index change. The nonlinear term can be positive (as in optical fibers) or negative (as in semiconductors).

In the absence of the nonlinear term, Equation (1) can be solved using a Fourier transform method. The basic idea of this method is illustrated schematically in Figure 1a for the case of temporal wave-packet propagation. The initial data are transformed from the time domain to the spectral domain using a Fourier transform, propagated in time, and then transformed back to the time domain using an inverse Fourier transform. On the other hand, in the nonlinear case, wave propagation is described by the partial differential Equation (1) and cannot be solved by the Fourier transform method because the system is no longer linear. It was first demonstrated by Zakharov and Shabat that Equation (1) can be solved analytically using the IST (Zakharov and Shabat 1973). The schematic for the inverse scattering method is shown in Figure 1b. Interestingly, one of the papers on inverse scattering method by Ablowitz et al. (1974) was entitled

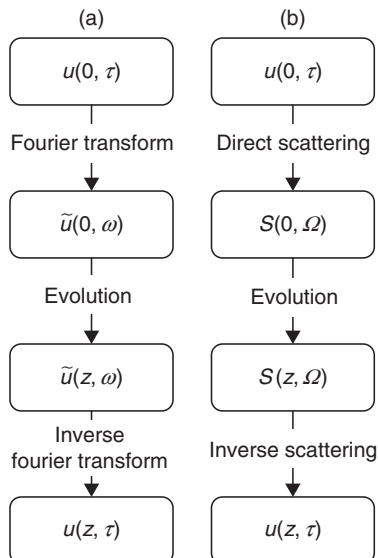

Figure 1: Schematic of (a) Fourier transform method and (b) inverse scattering method

“The Inverse Scattering Transform: Fourier Analysis for Nonlinear Problems.” Although the IST is analogous in many ways to the Fourier transform method for the linear problem, the last step in solving the inverse problem is highly nontrivial. Detailed treatments of the IST are available in the original papers by Zakharov and Shabat (1972, 1973) and in many textbooks (see, for example, Ablowitz and Segur 1981; Akhmanov, Vysloukh, and Chirkin 1992).

In the most general form, the bright soliton solution of Equation (1), which is often called a *fundamental soliton*, can be written as (Agrawal 2001)

$$u(z, \tau) = u_s \sec h[u_s (\tau + \omega_s z - \tau_s)] \exp[i(u_s^2 - \omega_s^2)z/2 - i\omega_s \tau + i\phi_s], \quad (2)$$

where u_s , ω_s , τ_s , and ϕ_s represent the amplitude, frequency, position, and phase of the soliton, respectively. Equation (2) can be simplified, resulting in

$$u(z, \tau) = u_s \sec h(u_s \tau) \exp(iu_s^2 z/2) \quad (3)$$

Equation (3) shows that the soliton width is inversely proportional to the soliton amplitude. This relationship is one of the most important properties of these solitons.

In addition to the bright soliton solution, Equation (1) has a so-called dark soliton solution as shown in Figure 2. The fundamental dark soliton, with zero intensity at its center, is often referred to as a *black* soliton. In addition to the fundamental dark soliton, there is a continuous range of lower-contrast dark solitons, referred to as *gray* solitons.

As shown in Figure 2, a major difference between bright and dark solitons is their symmetry. Fundamental bright solitons are even pulses, with a constant phase across the entire pulse, whereas black solitons are odd pulses, with a π -phase jump at the center (where the intensity is zero). Gray solitons have a similar but smaller phase shift at their center. Like bright solitons, dark solitons are highly robust under perturbation of their width and the shape of the intensity dip (Tomlinson et al. 1989). However, unlike bright solitons (Satsuma and Yajima 1974; Zakharov et al. 1984; Kivshar 1989), dark solitons may be created

Figure 2: (a) Intensity and (b) phase as functions of normalized time for bright and dark solitons. Adapted from Tomlinson et al. (1989)

without a threshold value in the input pulse power (Gredeskul and Kivshar 1989a, 1989b).

Three major factors affect the signal transmission in long-haul telecommunication systems: dispersion, nonlinearity, and loss. In nonsoliton-based systems, all three factors are generally detrimental for system performance. Optical soliton-based transmission systems have attracted significant attention because solitons use two of these factors—fiber nonlinearity and dispersion—to their advantage. Nevertheless, fiber loss remains a problem because, as the energy and the peak power of the soliton decrease, the nonlinear effects weaken and the pulse broadens resulting from GVD.

To describe the bright temporal soliton propagation in realistic optical fibers with loss, Equation (1) can be modified to include fiber loss:

$$i \frac{\partial u}{\partial z} - \frac{s}{2} \frac{\partial^2 u}{\partial t^2} + |u|^2 u = -i \frac{\alpha}{2} u, \quad (4)$$

Fiber loss α is usually compensated using either lumped or distributed amplification schemes. Historically, distributed amplification based on *stimulated Raman scattering* (SRS) was proposed first by Hasegawa (1983, 1984). In distributed amplification, losses are compensated locally at every point along the fiber link, making the fiber effectively loss-free. The main advantage of Raman amplification is that it can operate at any wavelength. However, because it is a nonlinear process, it requires especially high pump powers. The invention of *erbium-doped fiber amplifiers* (EDFAs) enabled an alternative, relatively low pump power solution known as *lumped amplification* (Mear et al. 1987). Typically, amplifier length is a few meters and therefore soliton energy increases almost “instantaneously.” This rapid change in soliton energy is accompanied by a change in the soliton width and can destroy a soliton. For this reason, the amplifier spacing should be kept much smaller than the characteristic length scale over which the soliton is significantly affected by energy losses (the dispersion length or the soliton period). Because the dispersion length and the soliton period are proportional to the pulse width squared, the above requirement is increasingly difficult to satisfy as the soliton width decreases in order to increase the bit rate. Although lumped amplification has the advantage of the lower pump power requirements, the distributed amplification offers a viable solution at higher bit rates requiring short solitons (soliton width less than 10 ps). Currently, the distributed amplification schemes rely on either SRS or “active” erbium-doped fibers.

Another important factor that can limit the total soliton transmission distance is *timing jitter*, which causes deviations in the soliton position from its original bit position. Several physical mechanisms result in timing jitter, including Gordon-Haus jitter, acoustic jitter, polarization mode dispersion, and soliton interactions (Agrawal 1997). In addition, in *wavelength-division multiplexed* (WDM) systems, additional factors—including soliton collisions and collision-induced jitter—should be accounted for. A comprehensive discussion of WDM technique can be found in Agrawal (2005). Briefly, in a WDM system, several soliton trains are superimposed on each other in the time

domain but are launched at different carrier frequencies. WDM has a great potential for using the large spectral bandwidth available in the optical fiber.

Among all of the above-mentioned types of jitter, Gordon-Haus jitter (Gordon and Haus 1986; Elgin 1993) is often considered as a major factor limiting the performance of the transmission system. The origin of Gordon-Haus jitter can be understood as follows. Stimulated emission in EDFAs is always accompanied by a certain amount of spontaneous emission, which adds noise to the signal. In the case of solitons, the added noise produces fluctuations in the pulses' positions and leads to transmission errors at high bit rates or large enough distances. It was predicted by Mecozzi et al. (1992) and Kodama and Hasegawa (1992) that the maximum noise-limited propagation distance of optical solitons can be increased with the addition of optical filters to the transmission system. Such filters remove some of the noise added by the amplifiers. As discussed in the next subsection, a further improvement in transmission distance can be achieved by varying the central frequencies of the filters linearly with distance along the fiber (Mollenauer, Gordon, and Evangelides 1992).

In addition to the loss management described above, modern WDM systems significantly benefit from dispersion management. The concept of dispersion management was first described by Lin, Kogelnik, and Cohen (1980). In one approach, adiabatic dispersion management is utilized. In this approach, the dispersion is changed in proportion to the soliton power in order to reduce dispersive wave radiation and collision-induced frequency shift in WDM systems (Forysiak, Knox, and Doran 1994; Hasegawa, Kumar, and Kodama 1996). An alternative approach uses a nonadiabatic map to cancel out the accumulated dispersion in a transoceanic soliton transmission by periodically inserting dispersion-compensating fibers (Suzuki et al. 1995). In this case, the Gordon-Haus effect, which is proportional to the accumulated dispersion, is successfully reduced. However, when the dispersion is reduced, the corresponding soliton peak power reduces as well, leading to deterioration of the signal-to-noise ratio. This problem was addressed by alternating anomalous dispersion fiber and normal dispersion fiber in a periodic fashion (Smith et al. 1996). The solitons realized in this approach do not actually preserve their shape at every position in the fiber link. However, the parameters repeat from period to period. These solitons are called *dispersion-managed solitons*. Figure 3 shows an example of the evolution of a dispersion-managed soliton over one map period. The design of dispersion-managed soliton systems requires a careful choice of input parameters of the pulse, including the pulse width, energy, and chirp, to ensure that the soliton recovers its input state after each period. The advantages of the dispersion-managed solitons over the standard solitons include a decrease of timing jitter, reduced interaction among neighboring pulses in single-channel systems and of the four-wave mixing as well as significant reduction of the jitter caused by WDM soliton collisions (Mu et al. 1998; Golovchenko, Pilipetskii, and Menyuk 1997).

Several important factors that affect the performance of dispersion-managed soliton-based communication

Figure 3: Numerical simulations of the evolution of the dispersion-managed soliton through one map period of 80 km. The parameters of the system used in numerical simulations are input pulse width 21 ps (full width at half maximum), normal dispersion section length 40 km, GVD $\beta_2 = 4\text{ps}^2/\text{km}$, anomalous dispersion section length approximately 40 km, and $\beta_2 = -4\text{ps}^2/\text{km}$

systems have been addressed in the literature, including the dispersion map configuration, the interaction between the signal and the noise, and nonlinear interaction between signals (Gabitov and Turitsyn 1996; Kodama, Kumar, and Maruta 1997; Shapiro and Turitsyn 1997; Yang and Kath 1997; Ablowitz and Biondini 1998; Kumar et al. 1998; Yu et al. 1999; Hirooka, Nakada, and Hasegawa 2000; Lushnikov 2001; Poutrina and Agrawal 2002; Poutrina and Agrawal 2003; Del Duce, Killey, and Bayvel 2004). From a practical viewpoint, one of the most important advantages of using dispersion-managed soliton systems is that they can utilize already installed fibers with a zero dispersion wavelength of $1.3\text{ }\mu\text{m}$ combined with existing dispersion-compensation techniques such as dispersion-compensating fibers or fiber Bragg gratings. A long-term debate ranging from whether solitons have advantages over other signal modulation formats to whether solitons are not practical at all for long-haul telecommunication applications still has not completely settled down. Still, a large number of important theoretical results, laboratory experiments, and system demonstrations suggest that solitons have significant potential to find their niche in communication technologies (Menyuk et al. 2002).

Experimental Progress

The earliest example of temporal solitons is related to the discovery of the *self-induced transparency* in 1967 (McCall and Hahn 1967). Temporal solitons and their interactions in optical fibers were experimentally observed for the first time in 1980 (Mollenauer, Stolen, and Gordon 1980) and then in 1987 (Mitschke and Mollenauer 1987). Extensive research in the field of temporal solitons has led to the development of soliton-based telecommunication systems (Hasegawa and Kodama 1995; Iannone et al. 1998). The first commercial fiber-optic telecommunications link using solitons, launched in Australia in 2003, was approximately 3000 km long (McEntee 2003).

As discussed above, the maximum transmission distance of soliton-based systems is limited by several factors,

including the losses, the Gordon-Haus timing jitter, and soliton collisions. In early experiments, Raman amplification was used for loss compensation (Mollenauer, Stolen, and Islam 1985). Using this technique, a soliton transmission of more than 4000 km in a fiber loop with periodic loss compensation was demonstrated in an experiment in 1998 (Mollenauer and Smith 1988). Two main drawbacks associated with Raman amplification are gain variations resulting from polarization fluctuations and relatively high pump power requirements. The emergence of the EDFAs provided a practical solution to these challenges. The first long-distance experiment utilizing an EDFA was reported by Mollenauer et al. (1991). In this experiment, error-free soliton transmission at 2.5 Gbit/s over more than 14,000 km was demonstrated. In the same experiment, a new technique of a fixed-frequency guiding filter was implemented for the first time. As a result, a significant increase in maximum transmission distance owing to the use of the guiding filter technique was demonstrated. For comparison, an error-free distance limited to 11,000 km in a system with no guiding filters was increased to 14,000 km by adding the filter, as shown in Figure 4. However, a soliton transmission utilizing fixed-frequency guiding filters requires additional gain to compensate for the filter attenuation. This extra gain leads to the exponential growth of spontaneous emission and dispersive waves at the soliton center frequency that may destroy solitons.

To avoid this problem, sliding-frequency guiding filters were proposed (Mollenauer, Gordon, and Evangelides 1992; Mollenauer et al. 1993) and resulted in the transmission of a 5 Gbit/s signal over 15,000 km. In addition, in the same work, the bit rate was doubled using the WDM technique. Further improvement in the maximum transmission distance was reported by Morton et al. (1995), and an error-free transmission at 10 Gbit/s was achieved over a distance of 27,000 km. A combination of sliding-frequency filters, a WDM technique, and dispersion-tapered fiber spans allowed for soliton transmission in six and seven WDM channels of 10 Gbit/s each, with measured bit error rates $<10^{-9}$ over distances of 11.4 and 9.4 Mm, respectively (Mollenauer, Mamyshev, and Neubelt 1996). A detailed comparative study of dense WDM systems with and without frequency-sliding guiding filters was reported by Evangelides et al. (1996). In these experiments, the adjacent channel spacing was only

Figure 4: Measured bit-error rate as a function of total path with and without fixed-frequency guiding frequency filter in the loop (Mollenauer et al. 1991)

25 GHz, and error-free transmission of 2.5 Gbit/s at 10 Mm for eight channels without the use of filters was demonstrated. The addition of the filters allowed the number of 2.5 Gbit/s channels to be increased to twelve.

Finally, several experimental studies confirmed the advantages of dispersion-managed solitons for fiber transmission systems (Carter et al. 1997; Morita et al. 1998, 1999; Mollenauer et al. 2000; Mu et al. 2000). The use of dispersion management resulted in demonstration of single-channel soliton transmission at 40 Gbit/s over 8600 km (Morita et al. 1998) and then over 10, 200 km (Morita et al. 1999) without any active transmission control in the transmission link. Massive WDM error-free twenty-seven channel transmission at 10 Gbit/s per channel using dispersion-managed solitons was demonstrated over distances greater than 9000km (Mollenauer et al. 2000) without the use of forward-error correction. A thorough comparison of the experiments and the theory describing the detailed dynamics of the dispersion-managed soliton trains propagating in a recirculating fiber-loop was demonstrated by Mu et al. (2000). An excellent agreement between the experiments and the simulations for the temporal and spectral pulse shapes was demonstrated. Figure 5 shows the comparison of the experimentally measured *full width at half maximum* (FWHM) pulse durations and eye diagrams to those from the simulation results.

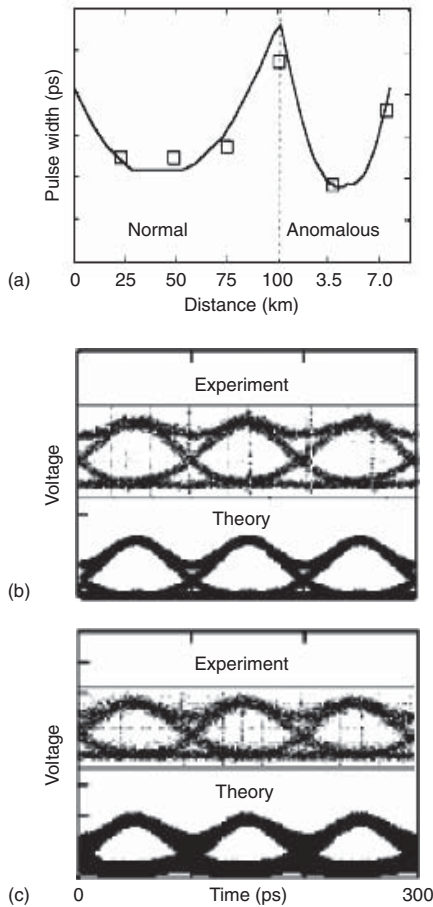

Figure 5: Comparison of the experimentally measured FWHM pulse widths and eye diagrams with those from the simulation results (Mu et al. 1998)

Although theoretical studies predicted that dark solitons may have inherent advantages for long-haul transmission, their implementation was significantly delayed because of relatively difficult generation and detection of dark solitons in comparison with bright solitons. Advantageous properties of dark solitons that have been predicted are reduced Gordon-Haus timing jitter and a longer collision length in comparison to bright solitons (Hamaide, Emplit, and Haelterman 1991; Kivshar et al. 1994). In the initial experiments, a long optical pulse was used as a background for the dark soliton, which appeared as a dip in the center of that pulse (Emplit et al. 1987; Krökel et al. 1988; Weiner et al. 1988). Later, other techniques were implemented, including (1) a spectral filtering approach (Krökel et al. 1988), (2) a continuous train of dark solitons generation using an electro-optic modulator (Zhao and Bourkoff 1990), (3) a quasi-continuous dark soliton train generation by colliding two pulses (Rothenberg 1991; Rothenberg and Heinrich 1992), and (4) beating two continuous wave signals in a dispersion-decreasing fiber (Richardson et al. 1994). The transmission of a pseudo-random 10 Gbit/s data train of dark solitons through 1200 km normal dispersion fiber was demonstrated in a 1995 experiment (Nakazawa and Suzuki 1995). The interactions of dark solitons were observed experimentally in 1996 (Foursa and Emplit 1996) and were shown to be repulsive. Further progress is expected with the development of improved sources for the generation of dark solitons.

Spatial Optical Solitons

Theoretical Background

Spatial optical solitons are self-trapped optical beams that propagate without changing their spatial shape because of the competing effects of diffraction and self-focusing in a nonlinear medium (Chiao, Garmire, and Townes 1964; Kelley 1965; Chiao et al. 1966; Haus 1966; Luther-Davies and Stegeman 2001). In the linear regime, the optical beam experiences a diffraction-induced broadening of its spatial profile. In a nonlinear material with a positive nonlinear index of refraction, light essentially changes the index of refraction of the medium in which it propagates, leading to self-focusing. This self-focusing competes with diffractive effects; at sufficient intensities, it can lead to the formation of a bright soliton owing to the exact balance of diffraction and self-focusing.

Spatial soliton propagation in a bulk medium is described by the generalized NLS:

$$i \frac{\partial u}{\partial z} + \frac{1}{2} \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right) \pm f(|u|^2) u = 0 \quad (5)$$

where $x=X/w_0$ and $y=Y/w_0$ are the dimensionless transverse coordinates, $z=Z/L_{dif}$ is the dimensionless longitudinal coordinate, the parameter w_0 is the soliton width, $L_{dif} = \beta_0 w_0^2$ is the diffraction length, $\beta_0 = 2\pi n_0/\lambda$ is the propagation constant, n_0 is the linear refractive index, and λ is the optical wavelength in a vacuum. The nonlinear term is written in a generalized form. In contrast to temporal soliton propagation in optical fibers, where the GVD is balanced by a weak Kerr nonlinearity, spatial

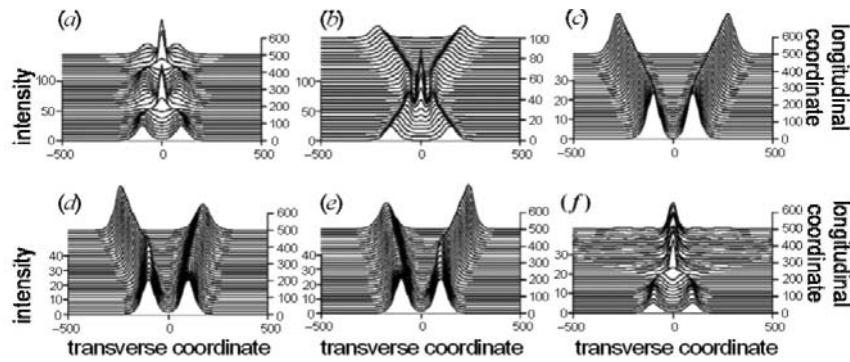

Figure 6: The interactions between two solitons for the following cases: (a) parallel input trajectories, in-phase Kerr solitons; (b) converging input trajectories, in-phase Kerr solitons; (c) parallel input trajectories, out-of-phase Kerr solitons; (d) parallel input trajectories, $\pi/2$ relative phase between Kerr solitons; (e) parallel input trajectories, $3\pi/2$ relative phase between Kerr solitons; and (f) fusion of two solitons input on parallel trajectories in saturating nonlinear media for “small” input separations (Stegeman and Segev 1999)

solitons rely on much larger nonlinearities that counteract the diffraction-induced beam spreading. Such nonlinearities often saturate at high intensities and generally may be not of a Kerr type (Akhmediev and Ankiewicz 1997; Akhmediev 1998; Biswas 2003; Konar and Biswas 2004). Depending on the particular form of the nonlinear (third) term in Equation (5), the solitary wave solutions can possess very different properties, such as the fusion of two solitons in a saturating nonlinear medium.

Stability is one of the most important properties of solitons or solitary waves because only stable or weakly unstable beams can be observed experimentally (Vakhitov and Kolokolov 1973; Kolokolov 1974; Kuznetsov, Rubenchik, and Zakharov 1986; Soto-Crespo et al. 1991; Soto-Crespo, Wright, and Akhmediev 1992; Atai, Chen, and Soto-Crespo 1994; Skryabin and Firth 1998). Self-trapped beams may be unstable in bulk media and may undergo catastrophic self-focusing. However, they are stable when diffraction is limited to one spatial dimension, such as in planar optical waveguides. In such a waveguide, the optical beam forms a one-dimensional spatial soliton in one transverse direction and is confined by the waveguide in another transverse direction. In this case, one of the second-order x or y derivatives in Equation (5) is absent. In the case of Kerr nonlinearity, the spatial soliton is described by the NLS that, from a mathematical standpoint, is identical to Equation (1) for $s = -1$. This observation is known as a *spatio-temporal analogy* (Akhmanov, Vysloukh, and Chirkin 1992), meaning that the propagation coordinate z is treated as the evolution variable and the spatial beam profile along the transverse direction in waveguides is similar to the temporal pulse profile in optical fibers.

Soliton interactions are the most fascinating features of solitons. Different examples of spatial soliton interactions, including in-phase and out-of-phase Kerr soliton collisions and the solitons in a saturating nonlinear medium, are shown in Figure 6. Two examples of more exotic three-dimensional soliton interactions, such as soliton spiraling and soliton fission, are shown in Figure 7 (Buryak and Steblina 1999).

Scalar solitons (or solitons that have only one field component) of an integrable system discussed so far,

Figure 7: (a) Soliton spiraling and (b) soliton fission (Buryak and Steblina 1999)

such as those in Kerr nonlinear media, remain unaltered during collisions with other solitons, except for a phase shift or a lateral displacement in the case of spatial solitons. This phase shift depends only on the soliton power and velocity, which are conserved quantities. This result can be understood by considering a soliton as a guided mode of its own induced waveguide or induced potential (Snyder et al. 1991). For a Kerr soliton, the induced potential is reflectionless, so scalar Kerr solitons colliding at a nonzero angle cannot exchange energy. Therefore, when two scalar soliton collisions occur sequentially, the outcome of the first collision does not affect the second collision. This is an important property of solitons, demonstrating their robustness, which is important for communication systems applications (Hasegawa and Tappert 1973). However, energy transfer between solitons is essential in applications such as optical computing.

Several approaches to enabling such energy-transferring collisions have been discussed in the literature. In one approach, collisions of solitons in nonintegrable systems, such as spatial solitons in saturable nonlinearities (Stegeman and Segev 1999), can be employed. However, it is problematical to define a “state” in such systems because the number of solitons is not always conserved. Therefore, it would be useful to find a way to transfer information between solitons in an integrable system. Vector solitons consisting of more than one field component in the integrable Manakov system

(Manakov 1974) are good candidates for this application. These solitons can be described by a system of two coupled NLS equations:

$$\begin{aligned} i \frac{\partial u}{\partial z} + \frac{1}{2} \frac{\partial^2 u}{\partial x^2} + (|u|^2 + |v|^2) u &= 0 \\ i \frac{\partial v}{\partial z} + \frac{1}{2} \frac{\partial^2 v}{\partial x^2} + (|u|^2 + |v|^2) v &= 0 \end{aligned} \quad (6)$$

Both temporal and spatial Manakov solitons have also been described and demonstrated experimentally (Kang, Stegeman, and Aitchison 1996; Chen et al. 1996; Yang 2002). The field components that compose the vector solitons exchange energy upon collision, and at the same time they retain all other conserved quantities of integrable systems. This energy-exchange effect has been proposed as a mechanism for performing computation through interaction of vector solitons (Radhakrishnan, Lakshmanan, and Hietarinta 1997; Jakubowski, Steiglitz, and Squier 1998).

Experimental Progress

The first demonstration of spatial solitons in an atomic vapor was reported by Bjorkholm and Ashkin (1974). Some ten years later, bright spatial solitons were observed in multimode CS₂ waveguides and single-mode glass waveguides (Barthelemy, Maneuf, and Froehly 1985). However, rapid progress in the field of spatial solitons occurred only since the 1990s, stimulated by the availability of appropriate nonlinear materials. One-dimensional bright solitons were subsequently demonstrated in glass (Snyder and Sheppard 1993), semiconductors (Khitrova et al. 1993), and polymers (Torruellas, Lawrence, and Stegeman 1996).

One of the most important issues for the practical realization of solitons is the optical power requirements. Photorefractive materials provide an ideal environment for the propagation of spatial solitons. In a photorefractive medium, the focusing effect, which is necessary for the soliton formation, is produced by an internal nonlocal space-charge DC field as opposed to the local

intensity-dependent Kerr effect. The degree of self-focusing can be controlled by an applied DC voltage across the photorefractive crystal. Because of an especially strong nonlinearity in photorefractive materials, a self-trapping of an optical beam was observed at microwatt power levels (Duree et al. 1993). Figure 8 shows an example of spatial soliton formation in a strontium barium niobate photorefractive crystal (Shih et al. 1995).

As will be discussed in “Applications of Solitons” below, soliton interactions form a basis for various applications of solitons for information transfer, ultrafast switching and processing, optical computing, and logic operations. The first experimental demonstration of spatial soliton interactions was performed by Aitchison et al. (1991). The experimental observations of the trapping of two spatial solitons of the same wavelength but with slightly different propagation directions and the nonlinear interaction between two fundamental spatial solitons with a $\pi/2$ phase difference in carbon disulfide were demonstrated by Shalaby et al. (Shalaby and Barthelemy 1991; Shalaby et al. 1992). It was shown that by adjustment of the phase shift between the two overlapped solitons, it was possible to switch the major part of the input energy to one soliton or the other.

Manakov solitons were first demonstrated in aluminum gallium arsenide (AlGaAs) waveguides in 1996 (Kang et al. 1996). For electric field vectors polarized parallel to the AlGaAs 110 and 001 crystalline axes, it turns out that the self- and cross-phase modulation terms are approximately equal, thus satisfying the requirement for Manakov solitons.

Spatio-Temporal Solitons

Theoretical Background

Spatio-temporal solitons, which are sometimes called *light bullets* (Silberberg 1990), have attracted a lot of attention in the past several years (Malomed et al. 2005; Mihalache et al. 2005). They represent objects that are localized in all of the transverse dimensions of space, as well as in time. Spatio-temporal solitons result from the simultaneous balance of diffraction and dispersion by self-focusing and

Figure 8: Photograph of (top) a 10- μm -wide spatial soliton propagating in a strontium barium niobate photorefractive crystal and (bottom) the same beam diffracting naturally in the linear regime (Shih et al. 1995)

Figure 9: Schematic of the spatiotemporal soliton formation resulting from the simultaneous balance of diffraction and dispersion by nonlinear self-focusing (Malomed et al. 2005)

nonlinear phase modulation, respectively. The schematic of the spatio-temporal soliton formation is shown in Figure 9. Although it is natural to assume that the conditions necessary for the formation of low-dimensional spatial or temporal solitons can be readily extended to the spatio-temporal case, that was not found to be true.

Spatio-temporal solitons are described by the NLS, taking into account the dispersive and diffractive effects:

$$i \frac{\partial u}{\partial z} + \frac{1}{2} \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right) - \frac{s}{2} \frac{\partial^2 u}{\partial \tau^2} \pm f(|u|^2) u = 0 \quad (7)$$

The stability analysis of spatial and spatio-temporal solitons in the case of Kerr nonlinearity shows that only in a one-dimensional case is the shape-preserving solution stable. In two- and three-dimensional cases, the phenomenon of collapse was theoretically predicted (Silberberg 1990). The spatio-temporal collapse is an instability process in which small fluctuations in soliton parameters grow with propagation length. As a result, when the pulse energy exceeds some critical value, the size of the beam decreases both spatially and temporally and the intensity becomes infinitely large at a finite distance. Although the collapse was predicted for a somewhat idealized system in which the effects such as saturation of the Kerr nonlinearity or nonlinear absorption were neglected, in reality these effects could prevent the collapse. Indeed, as it has been first discussed in the original paper by Silberberg (1990), saturation of Kerr nonlinearity can halt the collapse and lead to formation of the aforementioned light bullets (Edmundson and Enns 1993; Enns and Edmundson 1993; Akhmediev and Soto-Crespo 1993; Hayata and Koshihira 1993; Chen and Atai 1995; Edmundson and Enns 1995).

Experimental Progress

The following conditions should be satisfied simultaneously in order to generate a stable, localized spatio-temporal soliton in a homogeneous medium: (1) self-focusing nonlinearity, (2) anomalous group velocity dispersion, and (3) one or more collapse-preventing mechanisms. Eisenberg et al. (2001) demonstrated stable spatio-temporal focusing in a planar waveguide configuration under conditions of the self-focusing Kerr nonlinearity and anomalous group velocity. However, the spatio-temporal soliton as such was not observed. The same mechanisms that prevented collapse, multiphoton ionization, and Raman scattering in this case, eventually

reduced the intensity and caused the pulse to broaden in space and time. Although it should be mentioned that besides the dissipative collapse-preventing processes, there are several mechanisms that conserve energy, such as nonparaxiality and higher-order dispersion, that may lead to new forms of soliton-like propagation (Fibich, Ilan, and Papanicolaou 2002). Soliton-like propagation and beam self-channeling have been observed under conditions of normal group velocity dispersion (Koprinkov et al. 2000; Gaeta and Wise 2001), although the pulses were not temporal solitons.

Although in cubic nonlinear media the formation of stable solitons may be precluded because of the lack of collapse-preventing mechanisms, stable spatio-temporal solitons have been predicted in quadratic nonlinear media with a saturable self-focusing nonlinearity (Karamzin and Sukhorukov 1976; Kanashov and Rubenchik 1981; Liu, Qian, and Wise 1999; Liu, Beckwitt, and Wise 2000). An important step toward the formation of spatio-temporal solitons in quadratic media has been the demonstration of solitons in one transverse spatial dimension and time (Liu, Qian, and Wise 1999; Liu, Beckwitt, and Wise 2000). These pulses were the first experimentally observed optical spatio-temporal solitons, as well as the first temporal solitons directly observed in quadratic media (lithium iodate and barium metaborate) over several characteristic lengths. In these experiments, the effective third-order nonlinearity was produced by the cascade $\chi^{(2)}:\chi^{(2)}$ process. The angular dispersion was used to create large and negative group velocity dispersion. The input beam (pulse) size was 50 μm (100 fs). For comparison, if the propagation were linear, the beam (pulse) would have broadened to 300 μm (500 fs) because of diffraction (group velocity dispersion).

Spatio-temporal solitons have an enormous potential for a variety of applications. For instance, a spatio-temporal soliton-based ultrafast logic gate with switching speeds of several Terahertz has been predicted (McLeod, Wagner, and Blair 1995). Various alternative approaches for the realization of spatio-temporal solitons are currently under investigation, including the generation of so-called X-waves, which are stationary and slowly decaying Bessel function-like spatio-temporal beams (Jedrkiewicz et al. 2003; Conti et al. 2003; Di Trapani et al. 2003), and spatio-temporal soliton formation in Bragg gratings formed in a quadratic nonlinear crystal (He and Drummond 1997). Recently, fundamentally new features of spatio-temporal soliton formation were investigated numerically in metamaterials having a negative linear index of refraction (Zharova et al. 2005).

Discrete Optical Solitons

Theoretical Background

Discrete optical solitons are collective excitations of coupled, periodic, nonlinear lattices (Stegeman and Segev 1999; Christodoulides 2003; Buljan et al. 2004; Kartashov, Vysloukh, and Torner 2004; Kartashov et al. 2004; Kartashov, Torner, and Vysloukh 2004; Neshev et al. 2004; Yang et al. 2004a, 2004b; Xu, Kartashov, and Torner 2005; Kevrekidis, Susanto, and Chen 2006; Pezer and Buljan 2006). They are self-localized wave packets, the

energy of which resides primarily in distinct waveguide array sites. They are generated through a balance of discrete diffraction and material nonlinearity. Arrays made from materials with intensity-dependent Kerr, quadratic, or photorefractive nonlinearities have been shown to support such discrete localized states (Eisenberg et al. 1998; Pertsch et al. 2002; Fleischer et al. 2003).

Discrete optical solitons possess many properties that are similar to conventional solitons. However, they do not have the translation and rotation invariance typical of their conventional counterparts. As a result, arrays of waveguides support both stable and unstable soliton solutions. The stable states correspond to solitons that are centered on a waveguide and propagate along the waveguide direction. The solitons that are symmetrically centered between two neighboring waveguides are unstable (Morandotti et al. 2003).

Several theoretical approaches have been proposed to study linear and nonlinear propagation in the waveguide arrays. If the waveguides forming the array are sufficiently separated, then a coupled-mode theory or a tight-binding approximation is typically used to study the propagation effects of the soliton within the array (Ashcroft and Mermin 1976). The main assumption of this approach is that the only nearest-neighbor interaction resulting from the evanescently coupled guided modes is taken into account. For ideal, infinite-size, lossless arrays employing the Kerr nonlinearity, the normalized mode amplitude u_n satisfies the discrete nonlinear Schrödinger equation (Christodoulides and Joseph 1988):

$$i \frac{du_n}{dz} + \beta u_n + \kappa (u_{n+1} + u_{n-1}) + |u_n|^2 u_n = 0 \quad (8)$$

where β is the linear propagation constant and κ is the coupling coefficient. No second-order derivatives are included because all dispersive and diffractive effects in each waveguide are usually neglected. It has been shown numerically that at high enough powers, introducing a field distribution to the array such as (Christodoulides and Joseph 1988; Darmanyan et al. 1998)

$$u_n(z) = u_0 \sec h(x_n) \exp(i\beta z + 2ikz) \quad (9)$$

where $x_n = x_n/x_0$ is the normalized transverse coordinate corresponding to the location of the n th waveguide, $x_n = nd$, and X_0 is the characteristic width, results in a localized propagating distribution. Note that even though no diffraction occurs in each individual waveguide, an input beam spreads over the whole array because of the coupling among the waveguides. This phenomenon is called a *discrete diffraction*.

More recently, array waveguides were also analyzed using Floquet-Bloch theory (Russell 1986). Band theory provides a more formal description not only of the individual waveguides' propagation modes but also of the modes that propagate between waveguides. In this approach, linear optical modes are described using Floquet-Bloch theory, with the corresponding diffraction relation [$k_z = k_z(k_x, k_y)$] characterized by bands of allowed propagation constants separated by forbidden gaps.

Figure 10: Linear band structure and diffraction properties of a one-dimensional waveguide array (a) consisting of bands of allowed propagation constants separated by forbidden gaps; (b) modes in convex regions experience normal diffraction; (c) modes in concave regions experience anomalous diffraction (Fleischer et al. 2005)

A typical band structure in k -space for a linear one-dimensional waveguide array is shown in Figure 10a (Fleischer et al. 2005). Each mode of the system is an extended Bloch wave with its own propagation constant and direction. During linear propagation, each mode evolves independently of the others. Any wave packet exciting the array can be decomposed in these Bloch modes; because the modes remain the same but attain different relative phases during propagation, the wave packet may have a significantly different profile at the output of the array. Figures 10b and 10c illustrate how the band geometry influences the dynamics of the wave packet. In regions of convex band curvature, the central mode propagates faster than its neighbors, and the beam experiences normal diffraction analogous to that in homogeneous media. By contrast, a group of modes in concave regions of band curvature will diffract anomalously. It is noteworthy that there is an inflection point in each band, implying that wave packets propagating in this direction experience no (lowest-order) diffraction.

When the waveguide array is also nonlinear, propagation dynamics can be further modified. If the beam is narrow, the light modifies the refractive index locally, thus inducing a defect in the periodic structure of the lattice. Such a defect has localized modes, the propagation constant of which now lies outside of the linear transmission band—that is, in a gap. When these nonlinear modes induce the defect and populate it self-consistently, the wave packet becomes self-localized, and its diffractive broadening is eliminated, forming a discrete soliton (Fleischer et al. 2005).

Finally, although discrete solitons were mostly studied through propagation of coherent light beams in nonlinear photonic lattices, the existence of lattice solitons made of incoherent white light originating from an ordinary incandescent light bulb have recently been predicted (Pezzer and Buljan 2006).

Experimental Progress

Discrete solitons were first observed experimentally in the AlGaAs nonlinear waveguide array of forty-one waveguides (Eisenberg et al. 1998). Light was coupled to the central waveguide. At low power, the propagating field was spread as it coupled to more waveguides. When sufficient power was injected, the field was localized close to the input waveguides as shown in Figure 11. Figure 12 shows a comparison of experimental measurements

Figure 11: Intensity images at the output of a Kerr AlGaAs array with a waveguide spacing of $D = 8\mu\text{m}$ and operated at $1.53\mu\text{m}$ observed at various power levels. At low powers (70 W), the beam discretely diffracts, whereas a discrete soliton forms at 500 W (Eisenberg et al. 1998)

(solid line) with the results of numerical simulations (vertical straight lines) obtained by integrating the discrete NLS equation. It is noteworthy that if an input beam with a phase tilt is launched into several waveguides, the discrete soliton propagates across the waveguides. Also, even without the initial phase tilt, a discrete soliton can be shifted significantly by a small change in the position of the input beam (Morandotti et al. 1999). Several phenomena unique to discrete solitons were demonstrated experimentally. These include power-dependent steering (Eisenberg et al. 1998; Morandotti et al. 1999) and diffraction management (Eisenberg et al. 2000).

The possibility of manipulating discrete soliton motion using engineered structural defects in waveguide arrays was predicted theoretically and demonstrated

Figure 12: The comparison of experimental and theoretical results. Experimental results are represented by a solid curve and numerical results are shown as vertical lines (Eisenberg et al. 1998)

experimentally in arrays of AlGaAs waveguides (Morandotti et al. 2003). It was shown that the dynamics of a discrete soliton are similar to those of a classical particle in the presence of a potential introduced by the defect. An attractive defect, corresponding to a locally higher effective index, is equivalent to an interaction of the soliton with a potential well. In this case, the soliton will be totally transmitted through the defect at high transverse velocities (or input angle) or reflected from it while it excites a linear guided mode at the defect site at low velocities. At intermediate velocities, the soliton may be trapped by the defect, which induces an attractive potential for the soliton. A repulsive defect, corresponding to a local decrease in the effective index, is equivalent to the interaction of the soliton with a potential barrier. At small transverse velocities, the soliton may be totally reflected from the defect site, whereas at high velocities it is totally transmitted. At intermediate velocities, the soliton exhibits an inelastic collision with the defect and is partially transmitted and partially reflected. Trapping of the soliton to the defect site occurs only at a specific velocity. However, it is highly unstable because of the repulsive nature of the potential barrier.

Experimental observation of two-dimensional discrete or *lattice* solitons was first reported by Fleischer et al. (2003). A two-dimensional photonic lattice was created in real time using an optical induction technique, which is based on the interference of two or more plane waves in a photosensitive material. Then a probe beam was launched into the periodic waveguide array, where it experienced discrete diffraction and, at a sufficiently high nonlinearity, formed a lattice soliton.

Recently, the first observation of discrete optical surface solitons at the interface between a nonlinear self-focusing AlGaAs waveguide lattice and a continuous medium was reported by Suntsov et al. (2006). This approach is attractive because the power response is determined by two easily controllable fabrication parameters: the difference between the propagation constants of the channels and the continuous region, and the coupling strength between adjacent waveguides.

Incoherent Spatial Solitons

Theoretical Background

In most cases, an optical pulse or a wave packet forming a soliton is assumed to be coherent. However, solitons can also be launched using incoherent beams such as incandescent light bulbs (Mitchell et al. 1996; Mitchell and Segev 1997). An *incoherent spatial soliton* is a wave packet self-trapped to form a localized nondiffracting beam in a nonlinear medium with noninstantaneous nonlinearity. The three main requirements for an incoherent soliton to form are: (1) a noninstantaneous nonlinearity, which has a response time much longer than the duration of the phase fluctuations across the beam; (2) the multimode beam should be able to induce a multimode waveguide; and (3) self-consistency (i.e., the multimode beam must be able to guide itself in its own induced waveguide).

Several different approaches have been used to investigate incoherent solitons theoretically. The *coherent-density approach*, in which a partially coherent beam is

represented as a superposition of mutually incoherent components, was developed by Christodoulides and co-workers (Christodoulides, Coskun, and Joseph 1997; Christodoulides et al. 1997). In another approach, optical beams in nonlinear media are described in terms of a self-induced multimode waveguide. Stationary soliton propagation is governed by a proper combination of various mutually incoherent linear modes of the self-induced waveguide. This approach has provided both symmetric and asymmetric solutions (Christodoulides et al. 1998; Akhmediev, Królikowski, and Snyder 1998; Carvalho et al. 1999; Litchinitser et al. 1999). An example of a four-mode asymmetric solution is shown in Figure 13.

Until recently, most of the theoretical studies of incoherent solitons use the so-called mean-field approximation (Christodoulides et al. 1997; Mitchell et al. 1997; Shkhunov and Anderson 1998). The mean-field approximation can be justified when the response time of a nonlinear medium is much longer than the correlation time associated with phase fluctuations across the wave front. Within the framework of the mean-field approximation, the nonlinear refractive index of the medium is assumed to depend only on the average intensity of an optical beam. However the mean-field theory does not take into account intensity fluctuations of the source and their effects on generating such solitons. More recently, a general theory of partially coherent optical solitons in slow-responding nonlinear media that takes into account these intensity fluctuations was formulated (Ponomarenko, Litchinitser, and Agrawal 2004). When the source is laser-like with negligible intensity fluctuations, the new theory reduces to the previously reported mean-field theory of partially coherent solitons. However when such fluctuations are significant, the new theory shows that the properties of partially coherent solitons in saturable nonlinear media can be qualitatively different from those predicted by the mean-field theory. Experimental studies verifying the predictions of these two models, however, are not yet available.

Finally, a novel class of incoherent random-phase spatial solitons in fast instantaneous nonlocal nonlinear media has been recently predicted by Cohen et al. (2006). The key mechanism responsible for self-trapping of such

incoherent wave packets is played by the nonlocal rather than the traditional noninstantaneous nature of the nonlinearity.

Experimental Progress

Temporally incoherent solitons were discussed by Hasegawa (1975, 1977, 1980) for both waves in bulk dispersive media and nonlinear pulses in multimode fibers. In optical fibers, the wave packet can propagate as a single stationary pulse when the intermodal dispersion is balanced by the cubic nonlinearity. However, intermodal dispersion typically exceeds intramodal dispersion and, as a result, the generation of incoherent solitons in optical fibers requires unrealistically high pulse energies.

The majority of the experimental studies of incoherent solitons were performed in photorefractive materials (Duree et al. 1993; Shih et al. 1995; Iturbe-Castillo et al. 1994; Mamaev et al. 1996; Zozulya et al. 1996). The first demonstration of the self-trapping of a partially spatially incoherent beam was demonstrated by Mitchell et al. (1996) in a biased photorefractive material. A partially incoherent beam was produced by sending an argon laser beam through a rotating diffuser. The self-trapping effect has also been observed using a white light beam that is both spatially and temporally incoherent (Mitchell et al. 1997).

Dark incoherent soliton formation was also demonstrated using a diffuser followed by a mirror with a $\lambda/4$ step in the beam center that produced a dark intensity dip on a broad, partially coherent background (Chen et al. 1998).

Most of the studies have focused on the fundamental aspects of incoherent solitons, but these solitons have significant potential for various applications. In particular, the ability of trapping light beams from incoherent sources such as light-emitting diodes suggests possible applications such as optical interconnects and steering light from such sources.

Bragg or Gap Solitons

Theoretical Background

Bragg solitons (also called *gap solitons*) can form in a nonlinear medium with a periodically varying linear refractive index (such as Bragg gratings). Bragg soliton

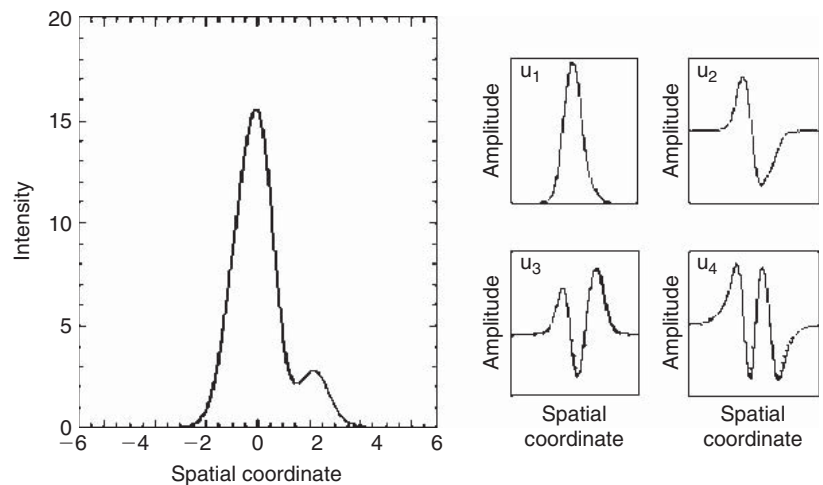

Figure 13: Intensity profile of an asymmetric partially coherent soliton composed of four modes. The inset shows the amplitudes of the constituent modes (Litchinitser et al. 1997)

formation relies on strong GVD of the periodic structure and on a cubic nonlinearity. It is noteworthy that the GVD in fiber Bragg gratings can be as many as six orders of magnitude larger than that in a uniform fiber (Litchinitser, Eggleton, and Patterson 1997). Dispersion is normal on the lower branch of the dispersion relation (ω versus k) and anomalous on the upper branch (Winful 1985; De Sterke and Sipe 1994). A fiber Bragg grating couples forward- and backward-propagating modes and opens up a photonic band gap. While frequencies inside the gap are reflected, those outside the band gap propagate. At low intensities, a transform-limited pulse tuned to a frequency close to the upper edge of the band gap broadens because of the anomalous dispersion introduced by the grating. However in the nonlinear regime, at high intensities *self-phase modulation* (SPM) generates new frequency components that are red-shifted near the leading edge and blue-shifted near the trailing edge. As the upper branch of the dispersion relation exhibits anomalous dispersion, the trailing edge of the pulse travels faster than the leading edge of the pulse. If the incident pulse width is larger than the width of the fundamental soliton, then the pulse undergoes compression initially. In this process, the pulse shape adjusts itself until the SPM and the dispersion compensate each other to maintain a pulse shape, leading to the formation of a Bragg grating soliton.

Bragg solitons were discovered theoretically in the 1980s (Voloshchenko et al. 1981; Winful 1985; Chen 1987a, 1987b; Christodoulides and Joseph 1989; Aceves and Wabnitz 1989) and demonstrated experimentally by Eggleton et al. (1996). Their propagation is described by the *nonlinear coupled mode equations* (NLCMEs). The total optical field inside the grating can be written as the sum of two counterpropagating waves (De Sterke and Sipe 1994):

$$u(z, t) = [u_+(z, t) \exp(ik_B z) + u_-(z, t) \exp(-ik_B z)] \exp(-i\omega_B t) \quad (10)$$

where the slowly varying amplitudes of forward-propagating wave u_+ and backward-propagating wave u_- satisfy the following set of two NLCMEs (De Sterke and Sipe 1994):

$$\begin{aligned} i \frac{\partial u_+}{\partial z} + i \frac{n}{c} \frac{\partial u_+}{\partial t} + \kappa u_- + \Gamma_s |u_+|^2 u_+ + 2\Gamma_\times |u_-|^2 u_+ &= 0, \\ -i \frac{\partial u_-}{\partial z} + i \frac{n}{c} \frac{\partial u_-}{\partial t} + \kappa u_+ + \Gamma_s |u_-|^2 u_- + 2\Gamma_\times |u_+|^2 u_- &= 0. \end{aligned} \quad (11)$$

Here ω_B is Bragg frequency, k_B is the corresponding wave number, n is the average refractive index, c is the speed of light in a vacuum, $\kappa = \pi \Delta n / \lambda_B$ is the coupling coefficient associated with the grating, Δn is linear refractive index modulation depth, λ_B is the Bragg wavelength, and Γ_s and Γ_\times are self- and cross-phase modulation parameters, respectively. These equations are nonintegrable, and therefore Bragg solitons are actually shape-preserving solitary waves. Their interactions are similar in many aspects to those of NSL solitons. In fact, in some

limits, the NLCMEs can be reduced to the NLS equation form (De Sterke 1998). A solution of these equations, corresponding to a two-parameter family of Bragg solitons, was found by Aceves and Wabnitz (1989).

Experimental Progress

Experimental demonstration of Bragg solitons in a fiber Bragg grating was first performed by Eggleton et al. (1996). Figure 14a shows measured intensity profiles at the output of fiber Bragg grating for two cases: (1) the optical pulse has its central frequency far from the edge of the band gap (solid line) and (2) the optical pulse has its central frequency close to the band gap (dashed line). In the first case, the grating is transmitting at 100 percent and the dispersion is negligible. As a result, there is no noticeable reshaping in the transmitted pulses. In the second case, the transmission of the grating is still relatively high but the dispersion is extremely strong, resulting in a significant pulse compression. Detailed numerical studies of the evolution of the envelopes of the electric fields along the length of the Bragg grating confirmed predicted soliton-like pulse propagation with

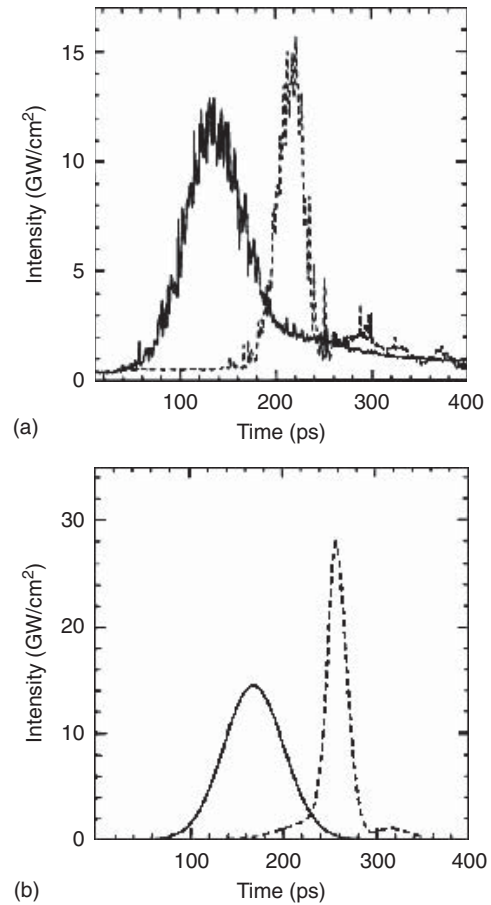

Figure 14: Experimental demonstration and numerical simulations of Bragg solitons. The solid line (broad pulse) corresponds to the launch conditions far from a Bragg resonance when the pulse propagates the fiber without interacting with the grating; the dashed line (narrow pulse) is a Bragg soliton (Eggleton et al. 1996)

an approximately constant shape (Eggleton et al. 1996). Corresponding simulation results are shown in Figure 14b.

High-quality fiber Bragg grating is a mature, relatively inexpensive technology, and its properties—including bandwidth, dispersion, and loss—can be designed and controlled. The peak intensities required for observation of Bragg solitons in silica fiber gratings, however, are typically on the order of 10 GW/cm², which is too high for a majority of practical applications. In addition, from a practical standpoint, soliton formation within the grating band gap is much more challenging to achieve because of the grating's high reflectivity. However, it was recently proposed that stimulated Raman scattering may provide a viable solution: A pump pulse launched far from the stop band can excite a Raman gap soliton that is trapped within the grating (Winful and Perlin 2000). The required peak power can also be reduced by at least two orders of magnitude using highly nonlinear glasses such as chalcogenides (Asobe 1997). Low-power Bragg solitons may have applications in all-optical switching (Taverner et al. 1998) and slow light generation (Mok et al. 2006; Mok, de Sterke, and Eggleton 2006).

APPLICATIONS OF SOLITONS: TOWARD ALL-OPTICAL COMPUTER NETWORKS

As the information transmission speed increases beyond 100 Gbit/s, optical components are likely to replace their electronic counterparts. The ultimate goal of high-speed photonics is a realization of all-optical technology. This section discusses several applications of the unique properties of optical solitons for the realization of all-optical logic elements, interconnects, and soliton-based computing.

Logic Functions

Recent progress in high bit-rate optical communications stimulated the rapid development of all-optical devices for performing routing, switching, multiplexing and demultiplexing, and coding operations without conversion to the electronic domain. Examples of such devices are the nonlinear optical loop mirror (Doran and Wood 1988), the temporal soliton trapping and dragging gates (Islam 1989, 1990; Soccolich et al. 1992), the asymmetric loop mirror (Eiselt 1992; Sokoloff et al. 1993), and the nonlinear directional coupler (Jensen 1982). However, many of these devices do not possess the important properties of a logic gate, such as signal restoration with gain, and as a result require additional amplification stages to use the output of one gate to drive the input to another.

Restoration of the logic level is necessary because of the degradation of the signal level by attenuation or cumulative noise. For an optical gate, logic-level restoration includes power, beam shape and position, pulse duration and timing, wavelength, polarization, and sometimes phase (Blair and Wagner 2000). Large-signal gain implies that the output of the gate is larger than the input necessary to switch the gate. Without large-signal gain, fan-out, in which the output of one gate directly provides the inputs to subsequent gates, is not possible when gates have identical switching thresholds (assuming all gates).

A class of optical logic devices that is based on temporal (Islam 1990) or spatial (Blair, Wagner, and McLeod 1994) optical solitons and satisfies many of the requirements of a logic gate has been proposed. The use of solitons is essential to these optical logic gates because solitons are not affected by dispersion (or diffraction) but use it to their advantage on propagation over distances much longer than the characteristic linear lengths. In one implementation, the trapping-dragging gates use temporal solitons of the same wavelength and orthogonal polarization (Islam 1989). It was shown that orthogonally polarized solitons can trap one another through cross-phase modulation (Islam 1989; Menyuk 1987, 1988). Using soliton trapping in birefringent optical fibers, an ultrafast, all-optical inverter, exclusive-OR, and AND logic gates have been demonstrated (Islam 1989).

These gates are directly cascable if a wave plate is used to rotate the output pump polarization to the correct state for an input signal or if the definitions of the pump and signal polarization are alternated, and the gate's operation relies on a resolvable spectral shift of the pump soliton. An unshifted pump passes through a spectral bandpass filter, but a pump that is shifted in the presence of the signal does not. This operation results in amplitude keyed logic, which is compatible with common high-speed optical detectors. These trapping gates typically require sufficiently large fiber birefringence to produce the necessary difference in group velocity between the pulse propagating down the slow axis and the pulse propagating down the fast axis. This difference in group velocities is compensated by optical trapping and results in a spectrally resolved frequency shift. Another requirement is that the pump and signal pulses must also be of nearly the same amplitude so the spectral shift will not be weighted toward one of them. As a result, this gate cannot provide significant large-signal gain. Similar trapping gates based on the optical pulses of different central frequencies have been proposed by Friberg (1991) and Kodama and Hasegawa (1991). Because of the chromatic dispersion of the optical fiber, two pulses of different wavelengths propagate with different group velocities. Therefore, these gates are cascable only through the use of nonlinear frequency shifters or by alternation of the definitions of pump and signal color at every gate. In addition, an ultrafast, all-optical, three-terminal NOR gate with a gain based on temporal rather than frequency phase shift was demonstrated by Islam (1990).

The temporal soliton dragging logic gate utilizes a dispersive fiber delay line to allow a weak signal soliton to drag a strong pump in time (Islam 1992). Even a small spectral shift of the pump can result in a large time delay. Because the pump is a temporal soliton that does not broaden with propagation distance, a resolvable temporal shift can be achieved by choosing an appropriate length of the delay line. Although operation of the majority of non-soliton-based fiber-switching gates is limited by birefringent walk-off (Morioka, Saruwatari, and Takada 1987), the temporal soliton trapping-dragging gate actually uses birefringent walk-off to induce the switching operation.

The first spatial trapping gate demonstrated experimentally was based on spatial solitons of the same polarization (Shalaby and Barthelemy 1991).

(i.e., phase-dependent but propagating at different angles that were not necessarily resolvable). The solitons were attracted to each other because of cross-focusing, which is the spatial analogy to cross-phase modulation, and under certain conditions formed a trapped pair. The direct spatial analogy to the temporal trapping and dragging gates (Islam 1989, 1990) is the interaction between spatial solitons in the orthogonal eigen-polarization states of a uniaxial crystal (Wagner and McLeod 1993).

A three-terminal angular deflection gate (Blair, Wagner, and McLeod 1996; Blair and Wagner 1999, 2000) is illustrated in Figure 15 based on the spatial-soliton dragging and collision interactions. The basic principle of operation of such devices is as follows. An undeflected pump soliton passes through an aperture at the output of the gate to form the high-output state. A tilted signal wave nonlinearly induces an angle change (a phase shift) in a strong pump soliton that results in deflection outside of a spatial aperture and a low output. Because the undeflected pump is passed on to subsequent gates where it acts as a signal input, it is important that it propagates as a spatial soliton. This stable propagation allows for restoration of the logic level through complete signal regeneration and the ability to realize nontrivial logic functions via multistage circuits. Therefore the pump acts as the power supply in traditional transistor logic, and the signal acts as the gate voltage. The angular-deflection geometry is independent of the physical mechanism underlying soliton formation, and the use of a spatial interaction has the advantages of being compatible with a variety of nonlinear materials, having an additional spatial degree of freedom, and having substantially reduced latency. Optical gates based on the spatial-soliton dragging and collision interactions are shown in Figure 15.

One of the most important design parameters for an angular-deflection gate is the optical energy needed to obtain the phase shift or the energy for each gate operation. A practical optical logic gate should require less than 1 pJ of energy per logic decision (Blair and Wagner 2000) so

Figure 15: A three-terminal angular-deflection gates based on the spatial-soliton dragging and collision interactions (Blair and Wagner 2000)

that high bit-rate operation can occur with low average power. Operating energies can be reduced by many orders of magnitude when more highly nonlinear materials are used. Two of the most promising nonlinear materials for practical realization of low energy logic gates are non-resonant AlGaAs at half of the band gap (Villeneuve et al. 1995) and resonant semiconductor gain media (Manning et al. 1997). Gain media are attractive because inverted resonance is used to obtain extremely large effective nonlinearity with amplification, although the material response time is increased. Measurements have shown that the response time can be of the order of picoseconds (Hall et al. 1994; Manning and Sherlock 1995), which may be short enough for implementation in 100-Gbit/s systems.

Other proposed approaches use the incoherent interactions of spatial solitons in a multilayered structure consisting of layers of different Kerr media, as well as spatio-temporal soliton-based gates with switching speeds of several Terahertz (McLeod, Wagner, and Blair 1995). The angular steering of spatial solitons' light in nematic liquid crystals was demonstrated and investigated for all-optical switching and logic gates applications (Assanto, Peccianti, and Conti 2003; Peccianti et al. 2004). Figure 16 shows the images of the spatial solitons at different bias voltages and the steering angle as a function of biases. Recently, all-optical AND, NOR, XNOR logic gates based on the interaction between spatial solitons and orthogonally propagating beams in azobenzene liquid crystals were demonstrated (Serak et al. 2006). Spatial solitons were excited at microwatt power levels at 632.8 nm, while gating and switching were achieved using milliwatt beams at 409 nm. Deviation and switching of a spatial soliton and the signal it confines at lens-like defects induced by control optical beams via a trans-cis transformation in liquid crystals was demonstrated. For the AND operation, two defects (A and B) play the role of control bits.

Figure 16: (a) The images of the spatial solitons at different bias voltages and (b) the steering angle as a function of biases (Peccianti et al. 2004)

Figure 17: Schematic of the soliton-based AND operation and the experimental realizations that correspond to $(A, B, Y) = (100)$ and $(A, B, Y) = (111)$, respectively (Serak et al. 2006)

The displaced soliton position at the output signifies the logic result. When the soliton is present, the response is 1 (or true), otherwise it is 0 (or false). The corresponding soliton-based scheme is displayed in Figure 17a, with circles representing the isotropic defects induced by external beams onto the liquid crystals. Figure 17b and 17c shows the experimental realizations that correspond to $(A, B, Y) = (100)$ and $(A, B, Y) = (111)$, respectively. The proposed system has a significant potential for realization of complex operations for all-optical computing.

Blocking, Routing, and Time Gating with Discrete Solitons

One of the most important functions of a photonic network is navigating the information from a particular point A to point B. Currently, many of these routing operations also involve opto-electronic conversion. However, opto-electronic conversion will eventually be a limiting factor for the further increase of the speed of information transfer.

The concept of a discrete-soliton optical network was introduced by Christodoulides (Christodoulides and Eugenieva 2001a; Christodoulides and Eugenieva 2001b) and provides a novel platform for all-optical, fast data-processing applications. In such networks, optical beams propagate in a two-dimensional array that behaves as an optical wire. Figure 18 illustrates how discrete

solitons can be routed or blocked at network junctions using vector interactions. Figure 18a shows a Y – 120° intersection involving three array branches. A discrete soliton of the blocking type is positioned at site B at the entrance of the lower branch. A signal soliton travels from left to right, and the two solitons are mutually incoherent. The signal is being routed to the upper branch in an elastic fashion. During this interaction, the blocker always remains in its fixed position. The refractive index around the interaction region is mostly dominated by the high-intensity blocker. The strongly confined discrete soliton blocks the lower pathway and all-optically routes the signal soliton to the upper branch. Without the blocker at the junction, the signal would disintegrate.

Another basic network element is an X junction as shown in Figure 18b. Rerouting at this junction can be accomplished by using two blockers at positions B_1 and B_2 , thus terminating two of the three output pathways. These blockers are coherent with each other and are in anti-phase for stability purposes. This process requires both blockers to be present; otherwise, the signal will disintegrate at the junction. Thus, essentially, the X junction functions as an AND logic gate.

In addition, time-gating functions based on discrete soliton propagation have been proposed. Figure 18c shows a T junction with a blocker B placed at the intersection. A signal S, incoherent with respect to the blocker, travels toward the junction on the vertical branch. At the same time, another signal soliton G, coherent with the blocker, moves toward the junction from left to right. The system is designed such that the G signal reaches the junction before the S. Because of the coherent interaction between the blocker and G, the blocker then moves discretely (Bang and Miller 1996) by one slot leftward just in time to open the gate for the signal soliton.

Recently, reconfigurable two-dimensional soliton networks optically induced by arrays of nondiffracting mutually incoherent Bessel beams in Kerr-type nonlinear

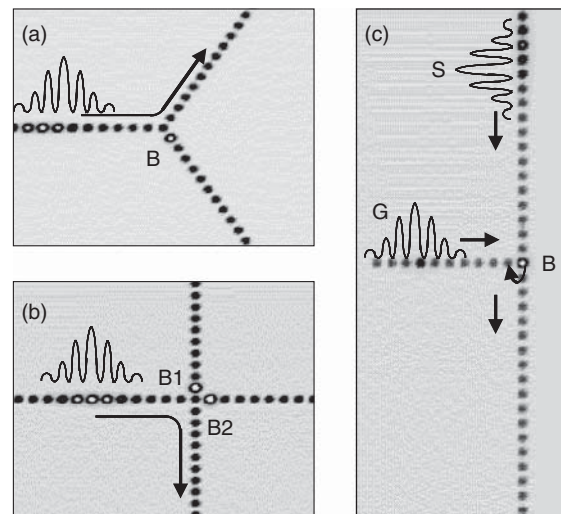

Figure 18: (a) signal router, (b) X junction, and (c) time gating (adapted from Christodoulides and Eugenieva 2001a and Christodoulides and Eugenieva 2001b)

media have been proposed by Xu, Kartashov, and Torner (2005). The dynamics of solitons propagating in such optically induced networks can be used for all-optical manipulation of light similar to that demonstrated in Christodoulides (2001) and Christodoulides and Eugenieva (2001) with additional advantages of the reconfigurability provided by the optical-induction mechanism.

The future success of discrete soliton-based logic schemes relies on the availability of fast-responding highly nonlinear materials. Even though waveguide arrays have thus far been realized in materials that are not ideal in terms their nonlinear properties, research into new materials has the potential to overcome these problems.

Optical Interconnects

Conventionally, when an optical signal reaches a network interconnect, it is converted to an electrical signal, redirected through electrical routers, and then regenerated into an optical signal. Such optical-to-electrical-to-optical conversion often creates significant data traffic jamming. An all-optical interconnect could potentially eliminate this bottleneck by increasing the data-transfer speed, simplifying the network management, and enhancing the interconnection capacity. Both temporal and spatial soliton-based interconnects have been proposed.

Spatial-Soliton Approach

In parallel to rapid progress in the development of temporal soliton-based fiber interconnects, spatial solitons were shown to be promising candidates for the design of dense, reconfigurable, self-induced optical-waveguide interconnects. On one hand, a soliton can effectively induce its own waveguide and guide another beam of a different wavelength or polarization through the effect of induced cross-phase modulation. Such waveguides have several advantages over conventional “fixed” waveguides. They are readily self-reconfigurable, forming a basis for the realization of virtual circuitry. On the other hand, soliton-induced waveguides or waveguide-based circuits can be written in photosensitive materials in which one light-written structure can be erased and replaced by another. The advantage

of using solitons for building optical interconnects is their nondiffracting nature and hence high-packing density for all-optical interconnects. Friedrich et al. (1998) experimentally demonstrated spatial soliton deflection in AlGaAs slab waveguides by an electronically induced prism. It was also shown that a weak signal beam can be guided and steered by a soliton, thus demonstrating the feasibility of a dynamically reconfigurable optical interconnect.

Temporal Soliton-Based Approach

In this approach, a so-called fiber-optic ribbon approach, N parallel bits are sent through corresponding N parallel fibers in a ribbon format, as shown in Figure 19a. This scheme is often called the *space-division-multiplexing* (SDM) scheme. The main drawback of the SDM scheme is that it is extremely difficult to maintain the time alignment of the parallel pulses. This is mainly because, in practice, it is not easy to fabricate identical uniform fibers. An alternative approach based on *bit-parallel-wavelength* (BPW) single-fiber optical links was proposed (Bergman, Mendez, and Lome 1996; Bergman, Morookian, and Yeh 1998; Ostrovskaya et al. 2002). In a BPW scheme, all N bits are wavelength multiplexed and transmitted by the time-aligned solitons through one single-mode optical fiber, as shown in Figure 19b. For bit-parallel optical fiber transmission, the most important issue is maintaining the alignment of pulses corresponding to parallel bits of the same word. The pulse alignment is controlled by employing the pulse-shepherding effect (Yeh and Bergman 1996), which originates from the interaction of co-propagating pulses through the nonlinear *cross-phase modulation* (XPM) effect. In bit-parallel transmission, a strong shepherding pulse traps and constrains a sequence of co-propagating weak pulses to their time slot. It is noteworthy that the XPM effect strongly degrades the pulses in the conventional WDM transmission systems, as discussed previously, and thus should be avoided by all possible means. Ostrovskaya et al. (2002) have shown that because of the XPM interaction of pulses transmitted through the same fiber, they can be treated as fundamental modes of different colors trapped and guided

Figure 19: Schematics of the parallel bits transmission through (a) a fiber ribbon link and (b) a bit-parallel single fiber link (Ostrovskaya et al. 2002)

Figure 20: A schematic of a soliton computing device based on the interactions of spatial solitons in a nonlinear medium (Rand, Steiglitz, and Prucnal 2005)

by an effective waveguide induced by the strong shepherd pulse. As a result, the shepherding pulse and all other (weaker) pulses form a new entity: a multicomponent soliton pulse. The BPW soliton propagates in the fiber, preserving the time alignment of its constituents, and therefore enables multichannel bit-parallel transmission.

Optical Computing

A schematic for a soliton computing device is shown in Figure 20 (Rand, Steiglitz, and Prucnal 2005). Input solitons enter on the left and exit on the right. The computation occurs through collisions, and the configuration of input beams determines the operation performed. Unlike typical existing computer architectures in which the data travel between logical elements that are fixed spatially through fabrication on a silicon wafer, the “dynamic” computer architecture in Figure 20 operates without any fixed gates or wires. This scheme is referred to as *nonlithographic* because there is no architecture imprinted on the medium.

To use soliton interactions for all-optical computations, the appropriate soliton parameters responsible for carrying and transferring the information need to be defined. Recall that, for scalar solitons, the only appropriate parameters that are affected by collisions are the carrier phase and position. Unfortunately, the changes in these parameters do not affect the results of subsequent collisions and therefore cannot be used for transferring the information (Jakubowski, Steiglitz, and Squier 2002). On the other hand, Manakov solitons (Manakov 1974) possess extremely rich collisional properties (Radhakrishnan, Lakshmanan, and Hietarinta 1997) and are capable of transferring information via changes in a complex-valued polarization state (Jakubowski, Steiglitz, and Squier 1998). Energy-exchanging interactions between vector solitons were demonstrated experimentally. It was shown that in a sequence of two collisions the outcome of the first collision directly affects the outcome of the second.

Manakov solitons were proposed and realized in various materials, including photorefractive crystals (Chen et al. 1996; Christodoulides et al. 1996; Shih and Segev 1996; Anastassiou et al. 1999, 2001), semiconductor waveguides (Kang, Stegeman, and Aitchison 1996), quadratic media (Stebina et al. 2000), and optical fibers (Menyuk 1989).

CONCLUSION

We have reviewed the basic properties, experimental realizations, and potential applications of several classes of solitons, including: temporal solitons in uniform optical fibers and fiber Bragg gratings; spatial solitons, including coherent and incoherent ones; spatio-temporal solitons; and discrete solitons in waveguide arrays. Although several potential applications of solitons for time gating and various logic functions, optical interconnects, and optical computing have been already demonstrated in laboratory experiments, several practical issues need to be solved before their full potential can be utilized in real-world applications. Further rapid progress is expected in developing new materials with superior properties for the optimization of soliton-based applications.

Finally, although not described in details in this review, yet other kinds of self-trapped beams, optical vortices, and vortex solitons have been recently proposed as promising candidates for such applications as optical storage, distribution, and processing (Desyatnikov, Torner, and Kivshar 2005). Optical vortices have been suggested for designing novel interconnects (Scheuer and Orenstein 1999), free-space communication links (Gibson et al. 2004; Bouchal 2004), and self-induced waveguides (Truscott et al. 1999; Law, Zhang, and Swartzlander 2000; Carlsson et al. 2000; Salguero et al. 2004).

In summary, optical solitons are an exciting physical phenomenon that offers significant potential for information transfer and optical computing that is likely to be realized in the coming years.

GLOSSARY

Dispersion: The phenomenon that takes place when different components of the signal travel at different velocities in the medium.

Dispersion Management: A technique to cope with the dispersion introduced by the optical fiber.

Erbium-Doped Fiber Amplifier (EDFA): An optical fiber doped with the rare earth element erbium, which can amplify light at 1530 nm to 1610 nm when pumped by an external light source.

Fiber Bragg Grating: A small section of fiber that has been modified to create periodic changes in the index of refraction. Depending on the period (spacing between the index changes), a certain wavelength of light (the Bragg resonance wavelength) is reflected back while all other wavelengths pass through.

Interconnect: An electrical or optical link (or cable) connecting two devices.

Jitter: The deviation in optical pulse parameters, including amplitude, phase timing, and width.

Light Bullet: An optical wave packet confined in three spatial dimensions owing to the combination of self-focusing, diffraction, and dispersion.

Logic Gate: A digital circuit that results in an output whose state (0 or 1) depends on the specific combination of the states of input signals.

Network: A system of cables or other connections that links many terminals or devices, all of which can communicate with each other through the system.

Nonlinear optics: A branch of optics that studies the interaction of intense light with matter. Nonlinear optical phenomena occur when the response of a system to an applied optical field is a nonlinear function of the strength of the optical field.

Optical Computing: The technology that uses optical instead of electronic signals to perform computations.

Optical Demultiplexer: A device that separates two or more optical wavelengths from a single input or fiber into multiple fibers or detectors.

Optical Fiber: A glass or plastic cylindrical waveguide that guides light along its axis.

Optical Multiplexer: A device that combines two or more optical wavelengths into a single output or fiber.

Optical Switch: An optical device that routes an incoming wavelength to a variety of physical output ports.

Raman Amplifier: A fiber that transfers energy from a strong pump beam to amplify a weaker signal at a longer wavelength using stimulated Raman scattering.

Soliton: A solitary wave that asymptotically preserves its shape and velocity upon nonlinear interaction with other solitary waves or, more generally, with another (arbitrary) localized disturbance.

Spatio-Temporal Collapse: An instability process in which small fluctuations in soliton parameters grow with propagation length.

Wavelength-Division Multiplexing (WDM): A fiber-optic transmission technique that increases the capacity of a single fiber by sending independent bit streams at multiple wavelengths.

INTRODUCTION

The roots of optical code division multiple access are found in spread spectrum communication, which was developed in the mid-1950s, mainly as a form of transmission that could overcome grid restrictions in radio bandwidth allocation (Dixon 1975, 1994; Scholtz 1977; Viterbi 1995; Verdú 1998). It is based on the idea of spreading a narrow band message over a much wider frequency spectrum by means of digital codes (Viterbi 1995; Verdú 1998; Pickholtz, Schilling, and Milstein 1982). Because of the spreading, the transmitted signal arrives at the receiver as a noise-like signal, so message recovery is impossible unless the original code is known. The authorized receiver correlates the received signal using a local code that is a replica of the transmission code. Despreading and signal recovery in the presence of interference from other users can be accomplished. As a result, spread spectrum communications is particularly useful for military applications: Signals can be transmitted in an extremely noisy environment with the highest levels of security. Furthermore, with the emergence of satellite and mobile communications, spread spectrum became the basis of a new multiple access technique: code division multiple access (Sust 1994).

In photonic transport systems, *optical time division multiplexing* (OTDM) and *wavelength division multiplexing* (WDM) are the two primary techniques for multiplexing data onto a single transmission fiber. *Optical code division multiplexing* (OCDM) is an alternate technique. The first work on OCDM began in the late 1970s in the area of fiber delay lines for signal processing (Marom 1978). Since then, many research groups have actively researched OCDM.

In OCDM systems, each channel is optically encoded with the specified code. Only the intended user—the one with the correct code—can recover the encoded information. A careful assignment of optical codes enables signals from all network nodes to be carried without interference between signals. Therefore, simultaneous multiple access can be achieved without using a complex

network protocol. As a result, multiple users can share the same transmission bandwidth.

OCDM is generally classified into coherent and incoherent schemes on the basis of the degree of coherence of the signal source. Carrier phase-shifted optical sequences are used for coherent OCDM (Vannucci 1989); intensity-modulated code sequences are used for incoherent OCDM (Salehi 1989). In the coherent case, a phase-shifted bipolar optical chip pulse sequence represents a binary code. Incoherent OCDM uses a unipolar code in which on-off keying modulation is used. The most significant advantage of the coherent scheme is the higher signal-to-interference-noise ratio, which is directly attributed to the superior orthogonality between the codes, which in turn yields higher processing gains. An optical code set is designed so that each *code division multiplexings* (CDM) code has an autocorrelation peak that is as large as possible so that the codes in the set can be easily distinguished. Most of the work in the 1980s focused on incoherent optical codes, but their use results in limited system performance. With the recent advances in optical device technology, most of the difficulties with optical phase encoding have been overcome, so the focus has shifted to coherent optical codes.

There are two types of encoding schemes: encoding in the frequency domain and in the time domain. Encoding in the frequency domain is analogous to the spread spectrum technique (Karafolas and Uttamchandani 1995). In time-domain encoding, time-resolved chip pulses are generated within a one-bit time frame (Kitayama, Sotobayashi, and Wada 1999). The phase of each chip pulse represents an optical code sequence. Matched filtering in the optical domain is one type of despreading. The matched-filtering detection technique maximizes the signal-to-noise ratio for Gaussian noise. The impulse response of the matched filter on the decoder side is the complex conjugate of an optical encoder. The output of the decoder is expressed by the convolution of the matched filter. If the optical codes between the encoder and decoder match, then the decoded time-despread signal reconstructs the original short pulse. On the other

hand, unmatched codes remain randomly spread over a one-bit time frame of T after the decoding.

In coherent OCDM systems, interference noise is a severe problem. The processing gain is expressed as the ratio of one-bit time duration to the gate-time window. Time gating should be used to achieve the highest processing gain. The time gating opens a time window to extract the autocorrelation peak. This operation is equivalent to narrowband filtering in wireless CDM. Placing the optical time gate before the photodetector has a substantial advantage because the requirement for the detector bandwidth is significantly relaxed to the bit rate.

The characteristics of OCDM systems in comparison with those of wireless CDM systems are summarized in Figure 1. OCDM inherits several features from its wireless counterpart: accommodation of a number of channels on a single carrier frequency, tell-and-go access capability, freedom from network-wide timing synchronization, soft capacity on demand, and security (Sotobayashi, Chujo, and Kitayama 2003). Therefore, the potential applications include point-to-point transmission (Sotobayashi, Chujo, and Kitayama 2001; Sotobayashi, Chujo, and Kitayama 2002, "1.6-b/s/Hz"), multiple access (Sotobayashi and Kitayama 1999, "10 Gb/s OCDM/WDM"; Kitayama and Murata 2001), optical path networking (Kitayama 1998; Sotobayashi, Chujo, and Kitayama 2002, "Transparent"), optical secure communications, and label-switching routing (Sotobayashi and Kitayama 2000; Kitayama, Wada, and Sotobayashi 2000).

As shown in Figure 1, a typical OCDM system in the frequency domain (Salehi, Weiner, and Heritage 1990; Sardesai, Chang, and Weiner 1998) uses parallel modulation in the frequency domain to reshape a short pulse into a low-intensity pseudonoise burst. The optical encoder consists of a suitably configured grating and lens apparatus. The first grating spatially decompresses the spectral component of the incident ultrashort light pulse. A phase mask is located at the focal points of the lens, where the optical spectral components experience maximal separation. The mask phase shifts the different

spectral components of the initial short pulse, thereby encoding its spectrum. The encoded spectral components are reassembled by the second lens and the second grating. The shape of the encoded pulse resembles a pseudonoise signal. At the receiver, the original signal is recovered by spectral correlation. The matched optical encoder is a complex conjugate of the encoder that restores the original short pulse. If the encoding and decoding phase masks do not match, then the output pulse remains a low-intensity pseudonoise burst. A 30-MHz, 275-fs pulse was encoded using a 63-chip *binary phase shift keying* (BPSK) code. A proof-of-concept experiment using 10-km transmission demonstrated the viability of this concept.

A group at Nippon Telephone and Telegraph used the same spreading-despreading approach to encode and decode femtosecond pulses (Tsuda et al. 1999, "Photonic," "Spectral"). An *arrayed waveguide grating* (AWG) with phase shifters was used for coherent OCDM. The input pulses were spectrally decomposed into their frequency components in the grating. Each phase was binary shifted by an encoding filter. The frequency resolution was 12.6 GHz. Transmission of more than 40 km at 10 Gbit/s using 810-fs pulses was demonstrated.

A group at Southampton University demonstrated both BPSK and *quaternary phase shift keying* (QPSK) encoding in the time domain using superstructure fiber Bragg gratings (Teh et al. 2001, 2002). Such gratings have a rapidly varying refractive modulation of uniform amplitude and pitch onto which an additional slowly varying amplitude or phase CDM code is imposed along its length. The shape of the impulse response directly follows the shape of this special superstructure. Short pulses reflected from gratings are reshaped into coded pulse sequences. Pattern recognition can be achieved by matched filtering of the coded signal using a decoder grating with a conjugate impulse response. The group demonstrated up to 255-chip QPSK optical coding and 2-WDM, 2-OCDM transmission at 1.25 Gbit/s.

Some recent proof of concept demonstrations are reviewed in Prucnal (2005) and "Optical Code in Optical Communications and Networks" (2007).

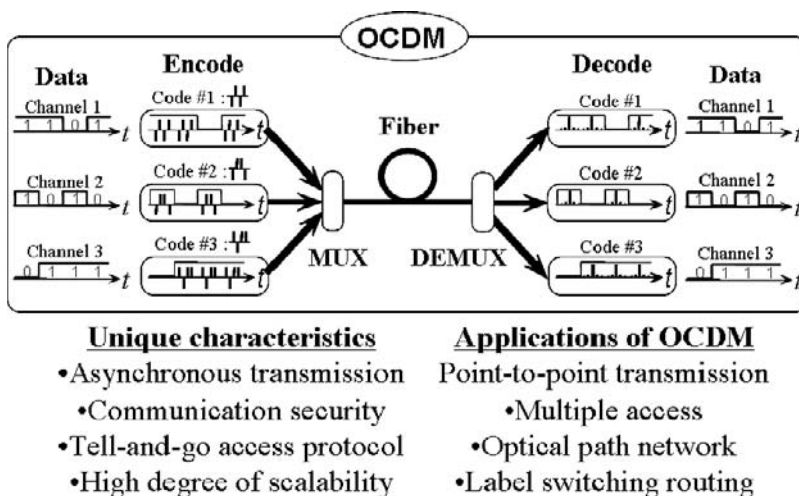

Figure 1: Optical code division multiplexing

APPLICATION OF SYNCHRONOUS OCDM TO HIGH SPECTRAL EFFICIENCY TRANSPORT SYSTEM

The rapidly increasing demand for more bandwidth by end users is driving the development of flexible network infrastructures with Petabit/s (Pbit/s) capacity. Because of their low transmission loss, optical fibers are ideal for high-capacity signal transmission. However, optical amplifiers have limited gain bandwidths. More than 10-Terabit/s (Tb/s) WDM transmission has been reported by fully utilizing the present amplifier wavelength bands—that is, the S-, C-, and L-band wavelength regions (Fukuchi et al. 2002; Bigo et al. 2002). To achieve Pbit/s capacity, the spectral efficiency must be increased to enable full utilization of the limited wavelength resources. Two approaches to increasing spectrum efficiency are *duo binary encoding* (0.6-bit/s/Hz spectral efficiency) (Ono et al. 1998) and *vestigial sideband filtering* with polarization multiplexing (1.28 bit/s/Hz) (Bigo et al. 2002). The use of OCDM may enable achievement of the ultimate spectral efficiency.

The feasibility of over-Tbit/s BPSK-OCDM/WDM transmission with 0.4-bit/s/Hz spectral efficiency was demonstrated by simultaneous multiwavelength optical encoding of a single *supercontinuum* (SC) source (Sotobayashi, Chujo, and Kitayama 2001). To increase the spectral efficiency, in addition to polarization multiplexing, QPSK optical encoding and decoding was applied at 40 Gbit/s accompanied by ultrafast optical time gating and optical hard thresholding for suppressing interference noise. As a result, 6.4-Tbit/s OCDM/WDM (4 OCDM \times 40 WDM \times 40 Gbit/s) transmission using only the C-band wavelength region was experimentally demonstrated with 1.6-bit/s/Hz spectral efficiency (Sotobayashi, Chujo, and Kitayama 2002, "1.6-b/s/Hz").

Suppose an optical short pulse, having a much higher frequency spectrum than the data bandwidth, is spread over a one-bit time frame of length T by optical time domain encoding. The sequence of the phases of the N chip

pulses in one bit represents an optical code sequence. Matched filtering in the optical domain is the basis of the despreading. The impulse response of the matched filter on the decoder side, $h_d(t)$, along with its Fourier spectrum, $H_d(\omega)$, is the complex conjugate of the optical encoder; it is given by

$$H_d(\omega) = H_e(\omega)^* e^{-j\omega t_0} \quad (1)$$

$$h_d(t) = h_e(t_0 - t) \quad (2)$$

where the impulse response of the optical encoder is $h_e(t)$ and its Fourier spectrum is $H_e(\omega)$. The output of the matched filter is expressed by the convolution of the impulse responses of the encoder and decoder as

$$\begin{aligned} \text{Output} &= \int_{-\infty}^{\infty} H_e(\omega) H_d(\omega) e^{j\omega t} d\omega \\ &= \int_{-\infty}^{\infty} |H_e(\omega)|^2 e^{j\omega(t-t_0)} d\omega \\ &= \int_{-\infty}^{\infty} h_e(t') h_e(t' - t + t_0) dt' \\ &= \Psi(t - t_0) \end{aligned} \quad (3)$$

where $\Psi(t)$ represents the autocorrelation function of the input optical code, $h_e(t)$. The matched filtering response can be achieved by time reversing the input and output of the optical encoder. When the optical codes between the encoder and decoder match, the decoded time-despread signal reconstructs the original short pulse as an autocorrelation waveform. On the other hand, unmatched codes remain spread over the one-bit time frame of length T after the decoding as a cross-correlation waveform.

Figure 2 shows the operating principle of the QPSK-code OCDM system with optical time gating and optical hard thresholding. Time-spread QPSK pulses are used as optical codes, and optical transversal filters are used as optical encoders and decoders. Each filter consists of tunable taps, 5-ps delay lines, programmable quaternary optical phase shifters, and a combiner. An optical code sequence of three-chip QPSK pulses with a chip interval of

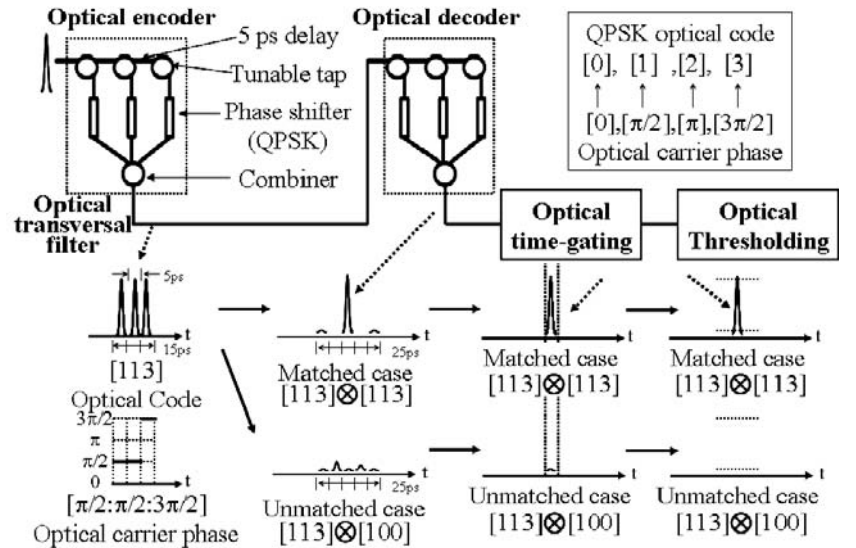

Figure 2: Operating principle of QPSK-code OCDM system with optical time gating and optical hard thresholding

5 ps is generated. The QPSK-encoded signal is despread by the decoder on the receiver side. The QPSK-decoded output shows the correlation waveform with a five-pulse sequence in the time domain. If the receiver's optical code matches the transmitter's optical code, then an autocorrelation waveform, characterized by a sharp central peak, is observed. If they do not match, then a cross-correlation waveform is formed. One bit of the despread signal occupies a 25-ps time frame. Therefore, 40-Gbit/s QPSK optical encoding and decoding is possible. The impulse response of the optical encoding has a frequency periodicity of 200 GHz because of the 5-ps chip interval of the code (Sotobayashi, Chujo, and Kitayama 2001). As a result, simultaneous multiwavelength encoding with 200-GHz WDM channel spacing can be achieved using a single optical encoder when a broadband coherent optical pulse, such as a SC pulse, is used as a chip pulse (Sotobayashi, Chujo, and Kitayama 2001).

In coherent OCDM systems, interference noise is a severe problem. Although optical matched filtering is ideal for beat-noise limited reception, it is only ideal in the absence of intersymbol interference. Introducing optical time gating eliminates interference noise outside the time-gate window. Time gating can realize the exact processing gain in OCDM systems. Looking at Figure 2 again, suppose the time gate opens a time window of $\Delta\tau$ at a repetition rate of $1/T$ to extract only the main lobe of the autocorrelation waveform. The time gate samples only the data-bearing portion of each bit, thereby rejecting the autocorrelation side lobes and the interference codes that fall outside the gate interval. This operation is equivalent to the narrow-bandpass filtering in frequency domain CDM. Placing the optical time gate before the photodetector has a substantial advantage because the requirement for the detector bandwidth is significantly relaxed to the bit rate of $1/T$. If an electrical time gate is placed after the photodetector, then the detector bandwidth needs a chip rate of $1/\Delta\tau$.

When the signal powers of the channels are equal, the signal-to-interference power (SNR) at the receiver is given by

$$SNR = \frac{S}{(K-1)S + \sigma^2} = \frac{1}{(K-1) + \sigma^2/S} \quad (4)$$

$$\frac{E_b}{N_0} = \frac{ST}{(K-1)S\Delta\tau + \sigma^2\Delta\tau} = \frac{T/\Delta\tau}{(K-1) + \sigma^2} \quad (5)$$

where K is the number of channels, S is the signal power, and σ^2 is the variance of the additive noise power including the amplified spontaneous emission noise of the optical amplifier, shot noise, and thermal noise. The bit energy-to-interference density ratio, E_b/N_0 , (Sotobayashi and Kitayama 1999) after time gating is obtained by multiplying S in the numerator by T and by multiplying the noise by time window $\Delta\tau$.

Compared with the results of Equation 4, the bit energy-to-interference density ratio is enhanced by $T/\Delta\tau$. Therefore, a process gain of $T/\Delta\tau$ can be achieved by introducing optical time gating. For ultrafast operation, a 100-m-long *nonlinear dispersion-shifted fiber* (HNL-DSF)-based *nonlinear optical loop mirror* (NOLM) was used. The control signal consisted of a pulse train with 1.5-ps pulses

at a repetition rate of 10 GHz, so the optical time-gating window ranged from 1.5 to 1.8 ps for all WDM channels.

Even after optical time gating, it is likely that interference noise remains in the time-gate window. As shown in Figure 2, this interference noise is reduced by introducing optical hard thresholding. Optical hard thresholding is achieved by using the nonlinear transmission response of a second NOLM, an optical self-switching device that acts as a pulse shaper by setting an appropriate threshold level. It reflects lower-intensity signals and transmits only the higher intensity signals by limiting its intensity to an appropriate level. Adjusting the power of the input signal suppresses interference noise inside the autocorrelation main lobe after optical time gating of both the 0 and 1 bits. This reduces the power variations in the eye diagrams of the received signal, which improves the *bit-error-rate* (BER) characteristics.

For ultrahigh-speed, wideband operation, the device length, hence the group delay, must be reduced. For this purpose, a 50-m HNL-DSF is used as a hard thresholding NOLM. The group delay for the WDM wavelength range (15,533–1564 nm) is less than 200 fs, resulting in ultra-high-speed operation as well as wideband operation.

Figure 3 shows the experimental setup used for testing 6.4-Tbit/s OCDM/WDM (4 OCDM \times 40 WDM \times 40 Gbit/s) transmission (Sotobayashi, Chujo, and Kitayama 2002, "1.6-b/s/Hz"). A 10-GHz, 1.5-ps pulse train transmitted from a *mode-locked laser diode* (MLLD) at 1532 nm was modulated with a 10-Gbit/s data and optically multiplexed to 40 Gbit/s. After being amplified to an average power of 0.48 W, it was launched into a *SC fiber* (SCF) (Sotobayashi and Kitayama 1998). The generated 40-Gbit/s SC signal was linearly polarized and split into eight, and each signal served as the light source for simultaneous multiwavelength optical encoding using a QPSK optical encoder. Two groups of four different optically encoded signals were generated. One group was changed to orthogonally polarized, and both groups of four OCDM signals were multiplexed to orthogonally polarized multiwavelength 2×4 OCDM \times 40-Gbit/s signals using a polarization beam splitter. Each group had WDM channel spacing of 200 GHz, which corresponds to 1.6-bit/s/Hz spectral efficiency. The transmission line was composed of two spans of a reversed dispersion fiber and single-mode dispersion fiber pair. Each span was 40 km long, so the total length was 80 km. The average zero dispersion wavelength was 1546.59 nm. After the 80-km transmission, signals were split into two, and each beam was demultiplexed using a 20-channel AWG with a channel spacing of 200 GHz. The pass band wavelengths of the two AWGs were separated by 100 GHz (WDM channel 1 = 1532.68 nm; channel 40 = 1563.86 nm). After the demultiplexing, frequency chirping was compensated for and the polarization was demultiplexed. Then the received signals were decoded by an optical decoder. Optical time gating was performed at 10 GHz; it both rejected the interference noise outside the time-gating window and demultiplexed a 40-Gbit/s OTDM signal to a 10 Gbit/s signal.

Optical time gating was performed at 10 GHz using a 100-m HNL-DSF based nonlinear optical loop mirror (Sotobayashi et al. 2002). Optical time gating rejected the interference noise outside the main lobe of the

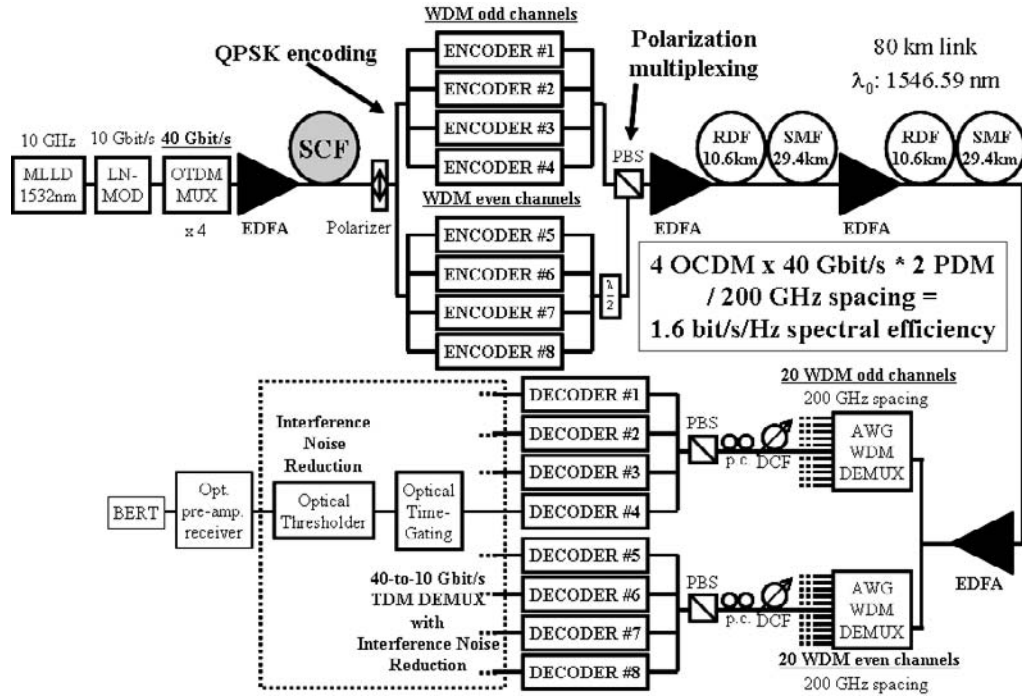

Figure 3: Experimental setup for 6.4-Tbit/s (4 OCDM × 40 WDM × 40 Gbit/s) transmission with 1.6-bit/s/Hz spectral efficiency

autocorrelation waveform. For ultrafast operation, a short HNL-DSF was used. The control pulse used for the time gating was a 1.5-ps pulse from an MLLD at 1562.5 nm for gating of WDM channels 1 to 22 (1533–1549 nm) and at 1542.2 nm for gating of WDM channels 23 to 40 (1550–1564 nm). The walk-off between signal and control pulses was less than 300 fs, resulting in ultrahigh-speed operation. The optical time-gating window ranged from 1.5 to 1.8 ps for all WDM channels. Optical hard thresholding was achieved by using the nonlinear transmission response of the second NOLM. The NOLM acts as a pulse shaper by setting the proper threshold level in the sense that it reflects lower-intensity signals and transmits

a higher-intensity signal by limiting its intensity to an appropriate level. Adjusting the input signal power suppressed the interference noise inside the autocorrelation main lobe after optical time gating, and both the signal 0 and 1 level power variations were greatly reduced. For ultrahigh-speed operation, the device length and group delay must be shortened. Using a short HNL-DSF (50 m) as a hard thresholding NOLM reduced the group delay in all WDM channels (15533–1564 nm) to less than 200 fs, resulting in ultrahigh-speed operation. The BERs were measured using an optical preamplified receiver.

Figure 4 shows the optical spectrum of the SC signal at the output of the SCF, the optical spectra of the

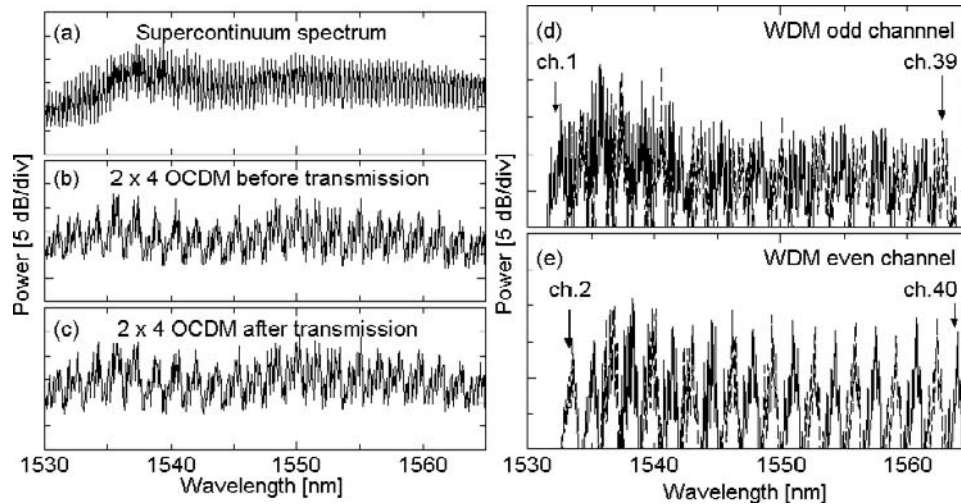

Figure 4: (a) 40-Gbit/s SC spectrum; spectra of 2×4 OCDM (b) before and (c) after transmission; spectra of (d) odd and (e) even WDM channels after WDM and polarization DEMUX

Figure 5: Eye diagrams of optically decoded signals of WDM channels 1, 2, 39, and 40 (a) after optical decoding, (b) after optical time gating, and (c) after optical hard thresholding

multiwavelength 2×4 OCDM signals before and after transmission, and the spectra in the odd and even WDM channels after WDM and polarization demultiplexing.

Figure 5a shows the eye diagrams for WDM channels 1, 2, 39, and 40 after optical decoding. The interference noise of the three unmatched codes severely distorted the signal-to-noise ratio. As shown in Figure 5b, the optical time gating of the main lobe of the matched correlation waveforms greatly reduced the interference noise outside the time-gate window. As shown in Figure 5c, the optical hard thresholding greatly reduced the interference noise inside the time-gate window for both the signal 0 and 1 levels, resulting in clear eye openings. The measured BERs of $4\text{-OCDM} \times 40\text{-WDM}$ data signals were less than 1×10^{-9} .

APPLICATION OF SYNCHRONOUS OCDM TO PHOTONIC ACCESS NODES

In this section, the application of OCDM to photonic access nodes and an experimental demonstration of 10-Gbit/s packet add-drop multiplexing based on optical code correlation will be explained (Kitayama and Murata 2001; Kitayama et al. 2001).

Wavelength add-drop multiplexers enable each wavelength to either add-drop and electronically process packets at the node or optically bypass the node altogether. However, wavelength *add-drop multiplexing* (ADM) has wavelength granularity; moreover, it is limited in that it can only handle traffic on an optical channel and cannot handle traffic on a packet-by-packet basis. This can waste wavelength resources and limit the usage of optical

channels. In contrast, conventional synchronous optical network ADM has a finer granularity for handling traffic and thus can handle traffic on a packet-by-packet basis. It picks up low-speed streams from a high-speed stream and likewise adds low-speed streams to a high-speed stream. However, the speed of the electrical processing eventually becomes a bottleneck because of the limits on overall processing capability. Therefore, there is a growing demand for high-speed multifunctional ADM.

The photonic ADM at each node drops the arriving packets to the node, bypasses the node, or adds packets. It handles traffic on a single wavelength on a packet-by-packet basis. Figure 6a shows the basic architecture of *photonic ADM* (PADM). The fundamental functions are

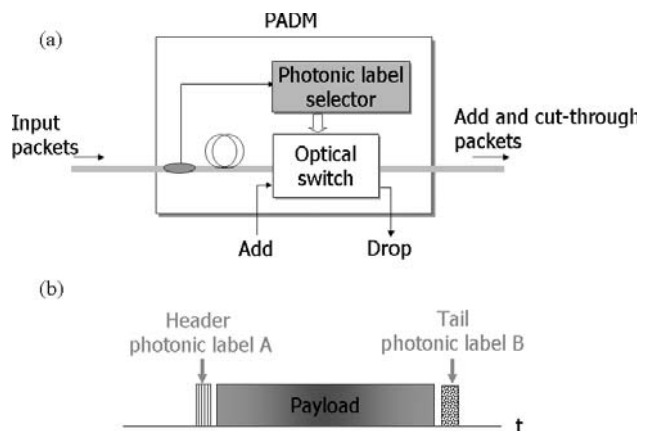

Figure 6: (a) Basic architecture of photonic label-based add-drop multiplexer and (b) optical packet structure

photonic label processing and optical switching. The input and output ports are connected to WDM links of a single wavelength. The photonic label of an arriving packet is processed, and, on the basis of the label, the optical switch is driven by the control signal to direct the packet to the outgoing port either for dropping or bypassing. Figure 6b shows the structure of an optical packet. The label is simply a relatively short fixed-length identifier that bears the information of the destination and source. A flag is attached at the end of the packet to indicate the end. Therefore, two photonic labels—a header label and a tail label—are attached. These two labels enable the handling of variable-length packets. Optical codes (8-chip BPSK) are used for the photonic labels, and optical transversal filters are used as optical encoders and decoders. The decoding is based on matched filtering in the time domain.

As shown in Figure 7, the photonic label selector compares the photonic label of an arriving packet with a local label by optically correlating the optical code of arriving packet with the assigned code of the node. If the incoming label matches the local one, then a control signal is generated that instructs the optical switch to drop the packet. The switch is reset to the bar state by the tail label. If the incoming label does not match the local label, then the switch remains in the bar state, causing the packet to bypass the node. The add multiplexing is performed in the same manner.

Figure 8 shows the experimental setup for testing PADM. Two kinds of optical packets were generated at 10 Gbit/s using two different optical codes. Labels were attached at the head and tail of each packet. After 50-km transmission, the labels were detected using an optical decoder. The generated correlation waveform controlled the optical switch. The measured waveforms of a dropped packet at port 1 and a bypassed packet at port 2 are shown in Figure 9. The dropping and bypassing functions worked well at BERs of less than 10^{-9} on the basis of optical correlation.

Figure 9: Experimental results for dropping and bypassing functions of PADM

APPLICATION OF SYNCHRONOUS OCDM TO OPTICAL PATH NETWORKS

OCDM is applicable not only to multiple access networks but also to optical path networks. The *optical code path*, which is defined as the logical path determined by the *optical code* (OC), has been proposed within the concept of OCDM networks (Kitayama 1998; Sotobayashi, Chujo, and Kitayama 2002, "Transparent"). OCDM can be effectively overlaid onto existing WDM path networks. The introduction of OCs provides soft capacity networks and saves network resources. In future hybrid OCDM-WDM networks, flexible OC and wavelength conversions will be key technologies for establishing optical paths. As a node technology, simultaneous optical code and wavelength conversion in the 8.05-Terahertz (THz) bandwidth by supercontinuum generation has been experimentally demonstrated (Sotobayashi, Chujo, and Kitayama 2002, "Transparent"). Furthermore, all-optical 3R regeneration has been used to create a transparent network. Finally, an optical code and wavelength-convertible virtual optical code, a virtual optical code path, and virtual wavelength path (VOCP-VWP) network has been experimentally demonstrated that has a total link length of 180 km with four network nodes.

Figure 10 shows the experimental setup used for testing the VOCP-VWP network. For simplicity, data were transported from node A to node C along optical path 1 and

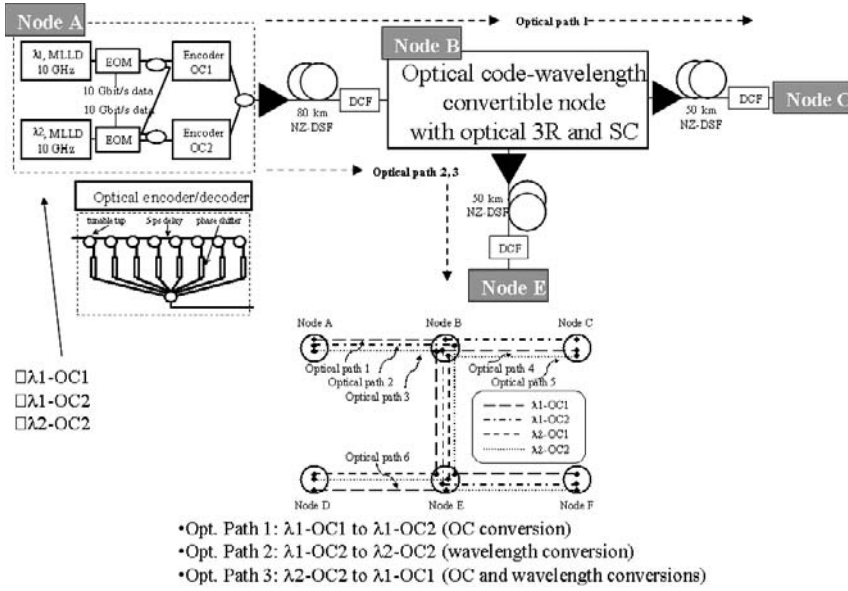

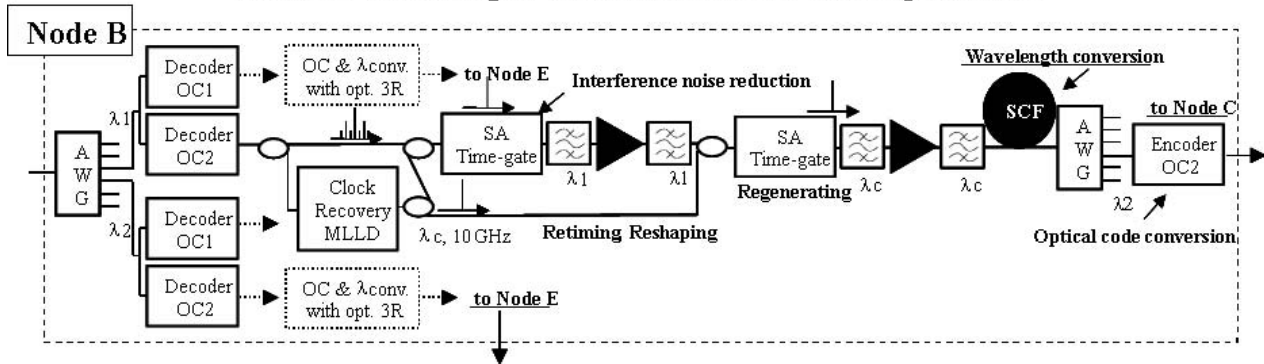

Figure 10: Experimental setup for testing VOCP-VWP network

OC and wavelength convertible node with optical 3R

Receiving end

Figure 11: Architectures of (a) node B and (b) nodes C and E

from node A to node E along optical paths 2 and 3. Three types of OC and wavelength conversions were performed at node B: λ1-OC1 to λ1-OC2 (OC conversion), λ1-OC2 to λ2-OC2 (wavelength conversion), and λ2-OC2 to λ1-OC1 (OC and wavelength conversions) for optical paths 1, 2, and 3, respectively. Each network node was linked to several transmission fibers tens of km long.

At node A, λ1-OC1, λ1-OC2, and λ2-OC2 were generated and multiplexed; 10-GHz, 1.5-ps pulse trains from

the mode-locked laser diodes at λ1 and λ2 were 10-Gbit/s modulated. Optical transversal filters were used as 8-chip BPSK optical encoders and decoders. As shown in Figure 11a, at node B, the received signals were decoded, 3R regenerated, wavelength converted by SC generation, and OC converted. First, they were wavelength demultiplexed and decoded by optical decoders. The decoded signals were divided into two. One was fed into the injection-locked MLLD for 10-GHz clock recovery. The

clock pulses recovered using the first signals were divided, and half were used as pump pulses for the first semiconductor *saturable absorber* (SA) time gate. After time gating, the decoded signals were, in turn, used as pump pulses for the second SA time gate to gate the clock pulse train. By controlling the optical time gate ON/OFF using decoded signals, the network could transfer the data coding to newly generated, clear optical pulses. Thus, all-optical 3R regeneration was obtained. For wavelength conversion, an SC was produced by pumping using 3R regenerated signals. After spectrum slicing using an AWG at the wavelength to be converted, they were optical encoded with the OC to be converted. Consequently, simultaneous OC and wavelength conversion with optical 3R regeneration was obtained. As shown in Figure 11b, after a subsequent 50-km transmission, OC and wavelength converted signals were detected at node C or E. As was done at node B, after wavelength demultiplexing and decoding, optical time gating was done using the recovered 10-GHz optical clock to reduce interference noise.

The measured eye diagram of the decoded $\lambda 1$ -OC2 signal at node B after 80-km transmission is shown in Figure 12a, and that of the recovered clock-produced optical time-gated signal is shown in Figure 12b. The side lobe and interference noise were greatly reduced in the latter. Figure 12c shows the optical 3R regenerated decoded signal at λc . As obviously shown by comparison

Figure 12: Eye diagrams (a) of decoded 1-OC2 with interference noise and (b) after optical time-gating to reduce interference noise at $\lambda 1$ and (c) of decoded signal at λc after optical 3R regeneration

with Figure 12b, the signal-to-noise ratio was higher and the timing jitter was lower.

Figure 13 shows the optical spectrum for a 24-channel WDM spectrum-sliced SC pumped by an optical 3R decoded signal; it ranges from 1524.9 to 1590.0 nm, which corresponds to an 8.05-THz bandwidth. Figure 14 shows the measured BERs back to back after 80-km transmission, after OC and wavelength conversions with optical 3R regeneration at node B, and at node C or E after subsequent 50-km transmission. Comparison of the BERs for after 80-km transmission with those for after OC and wavelength conversions shows that almost power penalty-free OC and wavelength conversions were achieved by using optical time-gating detection followed by optical 3R regeneration. OC and wavelength-convertible signal transport was also achieved in a VOCP-VWP path network with a total link length of 180 km and four network nodes.

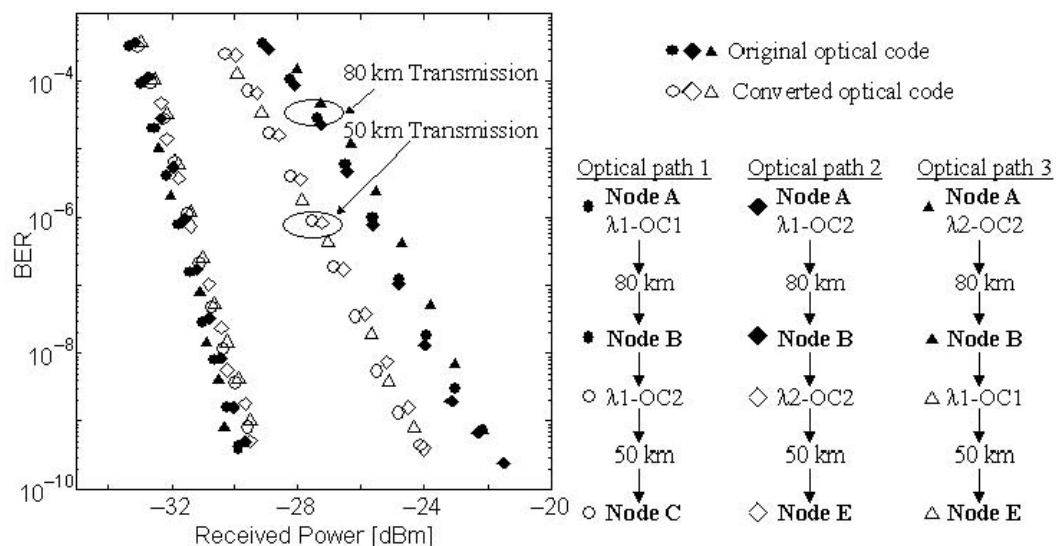

Figure 14: Measured BERs—back-to-back, after 80-km transmission, after optical and wavelength conversion with optical 3R regeneration, and after subsequent 50-km transmission

APPLICATION OF SYNCHRONOUS OCDM TO PHOTONIC ROUTING

A proposed photonic label-switching router (Sotobayashi and Kitayama 2000; Kitayama, Wada, and Sotobayashi 2000) processes labels on the basis of optical code correlation. The use of this scheme is a potential way to overcome the bottlenecks created by electronic routers in Internet protocol over WDM networks. Architectures for a photonic label-switching router, including the photonic label processing, the photonic label swapping, the optical switching, and their optical implementations, are currently being investigated. The results of proof-of-concept experiments for photonic label processing and photonic label swapping should confirm their feasibility.

Figure 15a shows an Internet protocol (IP) over photonic network in which photonic IP routers are used at the nodes instead of electronic routers. Label switching is used to forward the IP packets. A packet is forwarded to its destination via designated intermediate nodes.

The node configuration in an IP over photonic network is shown in Figure 15b. It consists of *photonic label switching routers* (PLSRs) and wavelength multiplexers

and demultiplexers. The PLSRs differ from their electronic counterparts in that the processing of IP packets is mainly performed in the optical domain without optical-to-electrical conversion.

Figure 16 shows the PLSR architecture. Each label is mapped onto a single optical code, and an IP packet is encapsulated in an optical frame. The main building blocks are the photonic label processor, the photonic label swapper, and an optical switch. Exact matching for the table lookup uses optical correlation, which identifies a photonic label only when all of the bits of the label coincide with those of the label entry in the lookup table. The optical payload is gated for routing to the desired port in the switch fabric. The label is swapped at the LSR output in accordance with the entries in the address bank.

Figure 17 shows the principle of the label processing. An input photonic label is optically duplicated by optical amplification and power splitting into as many copies as there are label entries in the table. This enables all of the optical correlations between the copies and the label entries to be performed in parallel. An autocorrelation peak appears in the bit time duration only when the codes match. Unique to the photonic label processing is that no

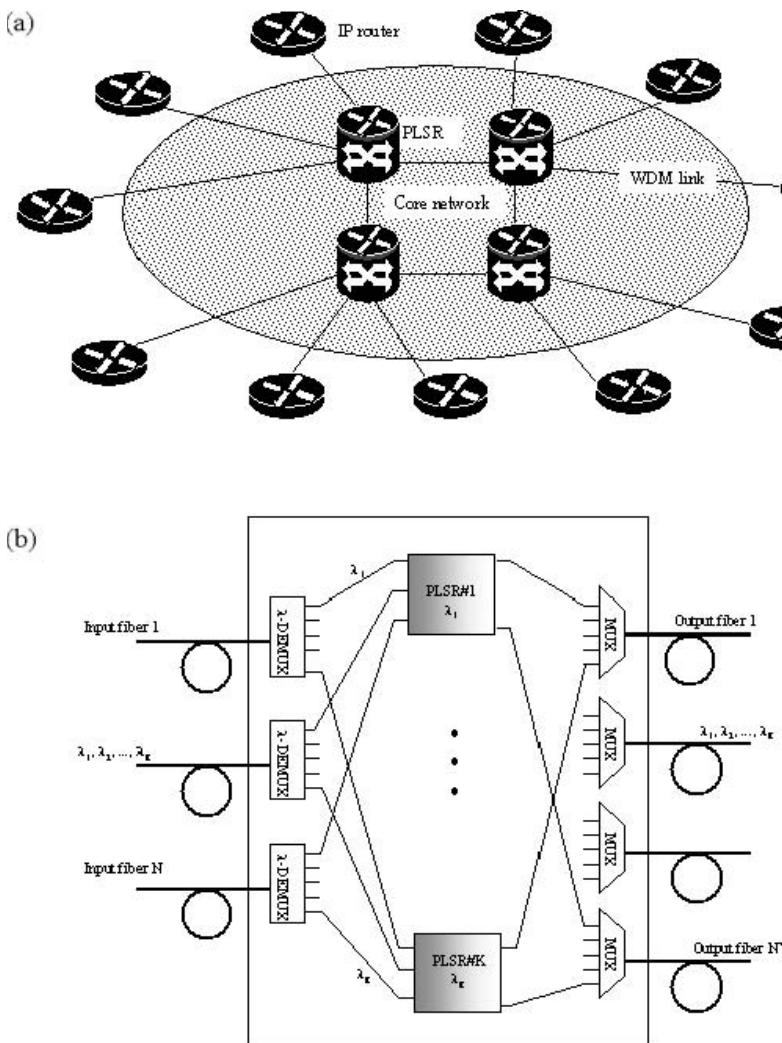

Figure 15: (a) IP over photonic network with PLSRs; (b) node configuration of IP over photonic network

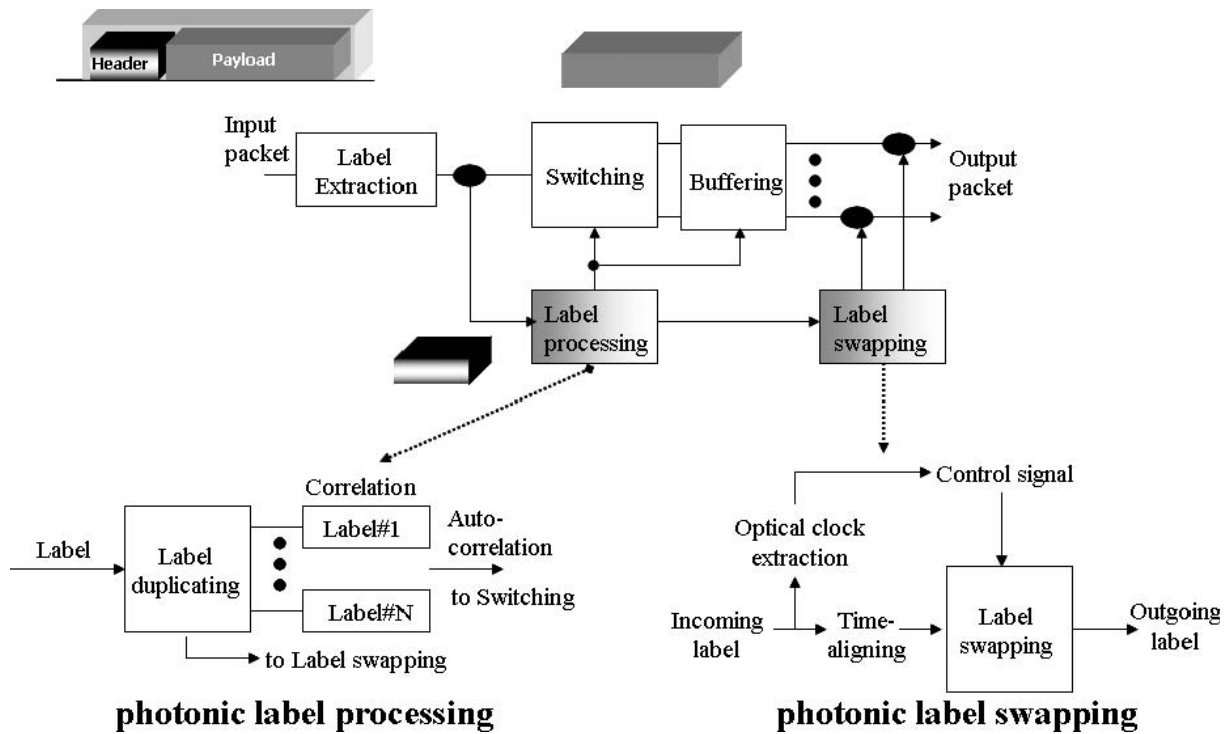

Figure 16: Architecture of PLSR

Figure 17: Parallel optical correlation for photonic label processing

optical logic operation is involved—only optical correlation is used. The processing can thus be performed using simple passive optical devices.

Figure 18 shows the experimental setup used for testing the photonic label processing. In the optical transmitter, a photonic label of 8-chip BPSK optical code was generated and a 64-bit-long burst payload data signal was attached. The optical packet was sent to the photonic label processor. The output signal of the autocorrelation peak was detected when the input label matched the label of the correlator. As a result, only the autocorrelation output signal could drive the opening of the optical gate switch

and thereby guide the packet to the target output port. Otherwise, the gate switch remained closed.

Figure 19a shows streak camera traces of a 64-bit-long packet generated with photonic label 1, and Figures 19b and 19c show the auto- and cross-correlation outputs of the packet decoded using label 1 (matched) and label 2 (unmatched). Figures 19d and 19e show the payload data observed at port 1 and port 2 for the two different input packets for which the labels were matched using correlator 1 and correlator 2. These figures clearly show that the address processor alternatively switched the two optical gates as the input optical code switched between labels 1

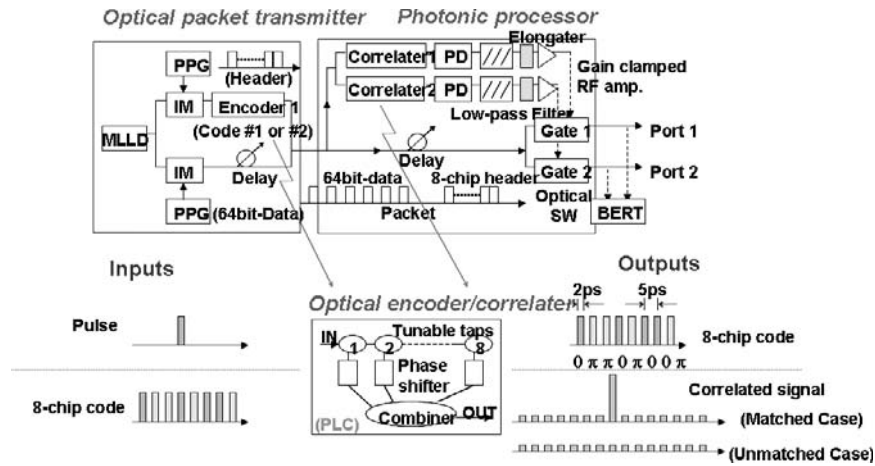

Figure 18: Experimental setup for testing 1×2 photonic label processing

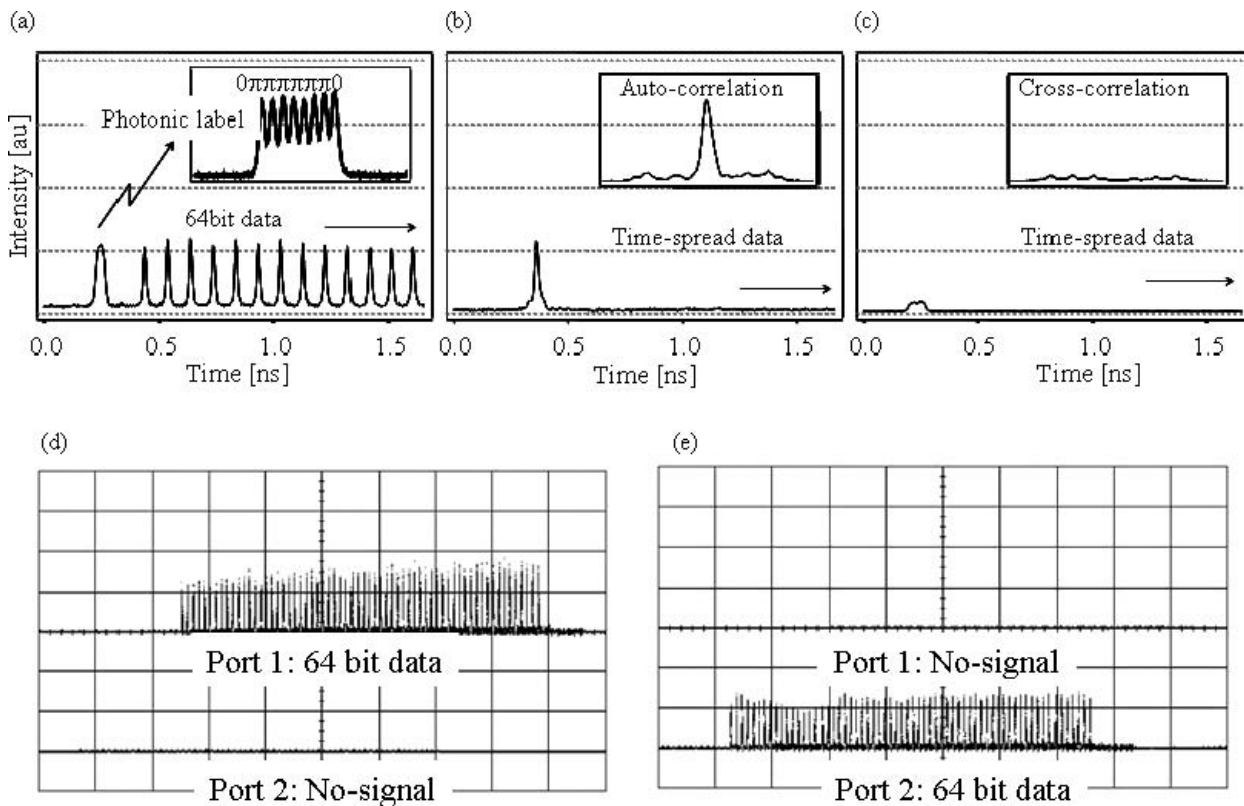

Figure 19: Streak camera traces of (a) generated 64-bit packet with photonic label 1, (b) autocorrelation output of packet decoded with label 1 (matched label), and (c) cross-correlation output decoded with label 2 (unmatched label). Observed payload data at ports 1 and 2 for two input labels: (d) matched with correlator 1 and (e) matched with correlator 2

and 2. This means that the label processor can distinguish eight-chip-long optical codes in packet labels and thereby control the optical switch.

The operation principle of photonic label swapping is shown in Figure 20a. Input photonic labels are swapped to the desired label in the optical domain. Suppose that the label to be swapped propagates along with the control optical pulses in an optical fiber. The use of cross-phase modulation enables the phase to be shifted by π . As a result, label swapping can be obtained by photonic processing.

Figure 20b shows the experimental setup used for testing photonic label swapping. Optical encoders 2 and 3 generated four-chip long BPSK optical code and a control pulse, respectively. Label swapping was performed by cross-phase modulation in a dispersion-shifted fiber. The output swapped label was inspected by correlator 3.

Figure 21a shows the output of correlator 3 without the control pulse. The signal code of [0000] and the setup of the correlator were the same, resulting in an autocorrelation trace. Figures 21b and 21c, respectively, show the

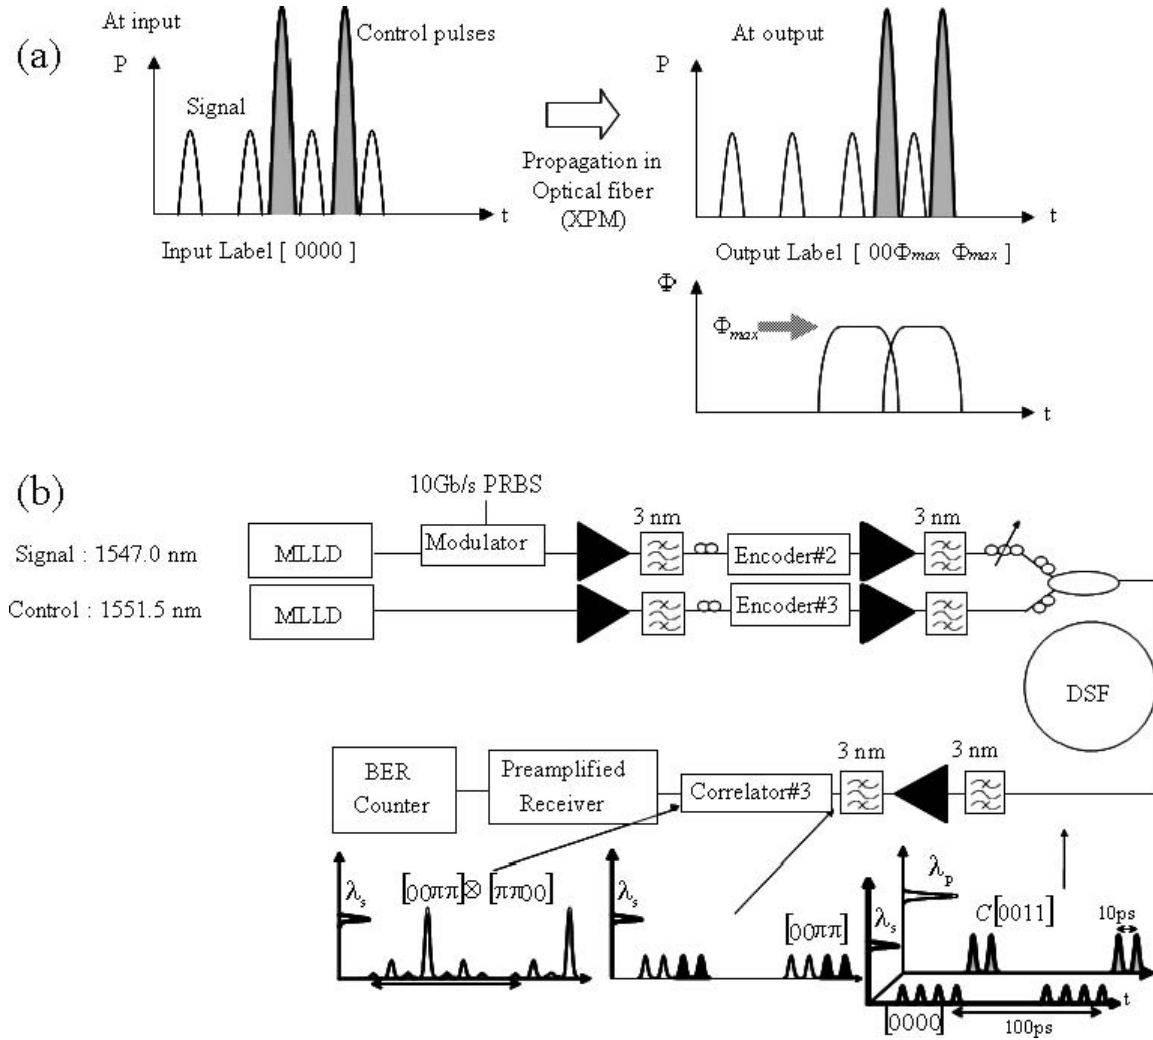

Figure 20: (a) Principle of photonic label swapping using cross-phase modulation; (b) experimental setup for photonic label swapping

Figure 21: Output of correlator 3: (a) without control pulse, (b) swapped with control pulse (0011), representing cross-correlation decoded with code sequence [0000], and (c) swapped with control pulse (0011), representing cross-correlation decoded with code sequence [0011]

outputs with the control pulse for correlator 3 setups of [0000] and [00 $\pi\pi$]. The resultant cross- and autocorrelation waveforms clearly show that label swapping was achieved by optical means. A photonic label-switching router in which the photonic label processing is based on optical code correlation has been investigated. The architectures of PLSRs with photonic label processing, photonic label swapping, and optical switching and their optical implementations have been experimentally demonstrated.

The target performance of a photonic label-switching router is estimated to be multi-Terabit/s. If a 32-chip-long optical code is used for IP routing, then the processing time of the optical correlation is 155 ps. Therefore, the processing speed of the photonic routing is 6.5G packets per second. For a 1000-bit-long packet, the transmission capacity per wavelength is 6.5 Tbit/s.

CONCLUSION

Ultrafast photonic network systems based on the synchronous OCDM have been reviewed. The potential applications of synchronous OCDM include high spectral efficiency transport systems, photonic access nodes, optical path networks, and photonic routers. The synchronous OCDM is thus a promising technique for future photonic networks.

GLOSSARY

Bandwidth: The highest capacity that can be transmitted in information-carrying systems.

Bit error rate (BER): The number of bits that are incorrect as compared with the number transmitted.

Demultiplexer: A device that separates a multiplexed signal into its original channels.

Eye diagram: A simultaneously overlaid display of the rise and fall of a 1 and 0. This generally results in a pattern in the shape of an eye that indicates the bit error rate.

Gigabit per second (Gbit/s): One billion bits per second.

Internet protocol (IP): Standard format for transmitting data on the Internet that uses packet switching.

Optical amplifier: A device that amplifies an optical signal without converting it into an electrical signal.

Point-to-point transmission: Carrying a signal between two points without splitting to other points.

Router: A device that determines the available route to send a packet and instructs the switches accordingly.

Terabit per second (Tbit/s): One trillion bits per second.

Time division multiplexing: Digital multiplexing by taking one pulse at a time from separate signals and combining them into a single stream.

Virtual path: A unidirectional logic connection between two signal destinations.

Wavelength division multiplexing (WDM): Placing multiple simultaneous telecom wavelengths in a single fiber.

INTRODUCTION

Free-space optics (FSO) is a technology that uses modulated laser beams to communicate without a special transmission medium such as fiber optics. FSO is not without its problems—most notably, its inability to transmit long distances through thick fog. FSO is still in its infancy, with a significant amount of research left to conduct in solutions to its key problems, but it already has become a principle contender in the market for last-mile access.

HISTORY OF FREE-SPACE OPTICS

Heliographs

The recorded history of using light signals for communication goes back to a recounting of Greek history by Xenophon in 405 B.C., who wrote that polished shields were used to make signals from the battlefield. The heliograph was invented in the mid-1800s by Sir Henry Christopher Mance and used extensively by the military; it was one the first devices to provide digital communications over long distances. The telegraph, a wired communication technology, was already in widespread

use at that time; however, the heliograph met the need for long distance, portable, wireless communications. Heliographs only operated in direct sunlight because there was no light source powerful enough to be seen at the link distances. Heliograph operators used Morse code, which was already familiar to telegraph operators of the day.

Two primary transmission technologies were used. The original Mance heliograph simply tilted a mirror, which moved the rays of the sunlight away from the receiver to signal letters. A later design improvement added a mechanical shutter to block the light so that the aiming of the mirror was not affected. Heliographs were in wide military use until the mid-1920s when they were superseded by radio communications. The longest recorded heliograph link was 183 miles between Mt. Uncompahgre in Colorado, and Mt. Ellen in Utah. One interesting fact about this link is that the sites were actually obscured by the curvature of the Earth, but in the mornings, an atmospheric effect carried the beam over the horizon allowing the two groups to signal each other (Giddings 1895). Figure 1 shows the use of the heliograph to communicate during the surveying of the U.S.–Canadian boundary in 1910.

Figure 1: Use of heliograph in 1910 (photo courtesy of the National Oceanic and Atmospheric Administration)

Alexander Graham Bell's Photophone

In 1880, Alexander Graham Bell improved on the heliograph by modulating the light signal, similarly to how the telephone modulates a telegraph signal (Korevaar, Kim, and McArthur, undated). Bell used an extremely thin mirror coupled to a microphone to change the intensity of the reflected sunlight. The receiver used selenium, a material whose resistance changes based on the intensity of light received.

The photophone has many of the characteristics of a free-space optics link. Figure 2, from the patent application for Bell's photophone, shows the transmitter side.

Figure 2: Diagram of Bell's photophone

Sunlight came in through a focusing lens (e), bounced off a thin mirror (a), and was collimated by the output lens (e). The signal was modulated by the audio-induced movement of the thin mirror by the microphone (d). The vibration of the microphone changed the shape of the thin mirror and focused more or less of the incoming sunlight on the target photophone.

Laser

The heliograph and photophone shared one fatal flaw: They required direct sunlight to operate properly. The invention of an electric, high-powered spotlight made communications at nighttime and during cloudy conditions possible. The invention of the laser opened up a new realm of optical communications. Lasers have some features that make them especially useful for long-distance communications. Most digital optical communications today use on-off keying, which turns the transmitter on and off at predetermined intervals to indicate a binary 0 or 1 value. Ordinary electric lights rely on the heat of the filament to provide light, causing a significant ramp-up and ramp-down time, but lasers have nearly instant-on and instant-off capability, providing communication rates in excess of gigabits per second. Another characteristic is *coherence*: All of the light transmitted from a laser is at the same phase. Although this is currently not used to improve FSO communication, significant research has been conducted using coherence as a mechanism for filtering out atmospheric distortion. Lasers also transmit at a single light wavelength. This property allows multiple lasers to be used simultaneously over the same link, a technique called *wavelength division multiplexing* (WDM) (Acampora 2002).

Dispersion in Space

As part of the U.S. manned Apollo missions, corner cube reflectors were installed on the surface of the moon. These reflectors have the property that the light is returned parallel to the incident light. In experiments using these

Figure 3: Laser retroreflector (photo courtesy of NASA)

reflectors, laser light from the Earth was aimed at the reflectors, which then directed the beam back toward the experiment site. The beam from the Earth was shown to disperse to approximately 7 km before reaching the surface of the moon (approximately 385,000 km). The photographs in Figures 3 and 4 show a retroreflector and the McDonald Laser Ranging Station, respectively.

Although the lasers used in this experiment are more powerful and more precise than those typically used for communications, the narrowness of the beam means that much of its energy arrives at the destination, where *radio frequency* (RF) energy spreads more, with less arriving at the destination. Scientists quickly discovered that the dispersion of RF will render the signals too weak to use for deep-space communications, leaving FSO as the principal approach.

A TYPICAL FSO SYSTEM

A simple FSO transceiver is depicted in Figure 5. The transmit laser is located at the bottom of the transceiver. Many FSO systems add forward error correction and link status information to the transmitted beam to reduce errors and provide network status information to the network operator. The incoming beam passes through a lens and is focused onto a *charge-coupled device* (CCD) sensor. The CCD sensor converts the incoming laser signal into electrical impulses that are decoded and transmitted to the rest of the network. Most FSO systems today have made significant improvements to this simple design to optimize the maximum bandwidth and maximum distance while still meeting the constraints of eye safety and reliability.

CHALLENGES FOR FREE-SPACE OPTICS

Eye Safety

Although the *infrared* (IR) frequencies used in FSO are invisible to the human eye, FSO laser transmitters can still potentially cause damage to humans if they are of significant power. FSO systems are engineered to provide protection from any eye injury during installation or while the link is active. Because the eye-safety measurement is defined as the power making it outside the FSO transmitter, some tricks can be used to provide more signal energy. For example, multiple eye-safe beams can be used simultaneously, provided they do not overlap in an unsafe manner. Also, a beam that is not safe can be passed through a spreading lens, allowed to expand for a short distance, and then passed through a collimating lens to make the beam parallel. The result is a dispersion of the laser energy over a larger area, which reduces the intensity and thus the possibility of retinal damage.

Weather

Although the attenuation of a laser beam in air under near-ideal conditions is on par with current single-mode fiber technology (on the order of 0.1 dB/km), weather conditions such as haze and fog can quickly reduce visibility, or the maximum range where the laser signaling can be detected. The reliability of FSO systems is primarily dependent on the visibility afforded by weather conditions, especially dense fog, where the laser beam is quickly absorbed (Ketprom et al. 2003; Leitgeb et al. 2002; Ragulsky and Sidorovich 2001). Currently, the only solutions to overcome dense fog are to increase the power of the beam (which is limited by eye safety), and shorten the link distance. Sometimes a series of shorter link segments can be used to create a long link. FSO systems that provide link statistics through a feedback mechanism can raise the power of the beam to overcome weather effects and lower the beam power when visibility improves. The lower beam power allows the system to provide longer service life for the laser transmitter and lower continuous power requirements.

Because link reliability is primarily dependent on weather conditions, FSO vendors rate the reliability of a given FSO link based on the percentage of time the link is available. This is somewhat inconsistent with reliability ratings of other systems, such as fiber. A 99.999 percent reliability of a fiber-based system means that there is a

0.001 percent chance that the link will be down (Kim and Korevaar 2001). The link failure, however, is thought to be dependent on equipment failure. For both FSO and fiber, these measurements do not classify the type of loss. The thought behind 99.999 percent reliability is that the total link downtime in a year averages to approximately 8.5 hours. For fiber, this represents the reliability of the equipment used to establish and maintain the connection but not necessarily the reliability of the medium. For FSO, what is being predicted is primarily the existence of environmental conditions that are conducive to maintaining the link; however, it does not typically account for equipment failure. The reliability prediction for fiber cannot really account for the business risk of catastrophic events such as a fiber cable being cut by construction equipment.

Obstructions and Line of Sight

Although the FSO beam typically disperses to at least 1 meter over typical distances, the beam can still be obstructed by helicopters, large birds, and other objects. Because typical Internet protocol-based communications is resilient to momentary interruptions, brief link loss will not be perceptible to the end user, except for certain time-critical services such as streaming media. One way to overcome obstruction by smaller objects such as dirt or dust on a window is to use multiple transmitting lasers. Larger obstructions are temporary in nature and would be nearly undetectable in most networks, although the affect on streaming media would generally be perceptible. Other line-of-sight problems that cannot be solved by relocating the transmitters are solved by adding multiple hops or by switching to a non-line-of-sight technology.

Scintillation

Scintillation is an optical effect caused by the uneven distribution of heat in the atmosphere. Pockets of hot air have a slightly different index of refraction, which creates small lenses that interrupt the laser beam. Because the pockets are small, the aggregate effect is to reduce the intensity of the incoming beam, which limits the distance the beam can travel (Korevaar, Kim, and McArthur, undated). Scintillation is most significant during the afternoon, when the intensity of the sun is greatest. For humans, scintillation appears as a “shimmering,” which is what causes stars to “twinkle.” Scintillation can often be overcome by increasing the transmission power. Using multiple transmitters is also effective in overcoming scintillation because the distortion caused by scintillation is highly localized (Willebrand and Ghuman 2001).

Building Movement

Anyone who has been in a skyscraper during a heavy wind will attest to the fact that buildings have significant movement. Movement of the transmitter and receiver is a problem for FSO systems because laser beams are typically extremely narrow and require pinpoint accuracy. Most of the commercial FSO systems available today use some sort of active tracking mechanism to manage the movement of buildings. To overcome

higher-frequency artifacts, FSO systems purposefully spread the transmitted beam (Willebrand and Ghuman 2001). Although beam spreading increases resilience to higher-frequency building movement, beam divergence decreases the range of the link and its ability to overcome poor weather conditions.

FREE-SPACE OPTICS DEVICES

Choice of Infrared Laser Wavelength

Two primary laser wavelengths are used for FSO systems: 780–850 nm and 1550 nm. The shorter wavelengths are much easier to produce, and transmitters are approximately 1 percent of the cost of longer-wavelength transmitters. Both wavelengths have similar propagation characteristics through normal weather conditions (Korevaar, Kim, and McArthur, undated). In fact, the only significant reason for choosing the more expensive 1550-nm transmitter is eye safety. The 1550-nm transmitter can have approximately fifty times greater intensity because the majority of the energy in the beam is absorbed by the cornea without being able to focus on the retina (Kim and Korevaar 2001). The increased transmission intensity can be used to increase the availability or link distance.

Active and Passive FSO Devices

Regardless of the physical connection to the existing network, most FSO devices today use internal lasers to actively generate the transmission beam. The manufacturer can then exert more stringent control over the transmission and reception characteristics, which are critical for performance. Having a laser in the FSO device, however, adds latency by introducing, at a minimum, an electrical-to-optical conversion. With optical LAN, an additional conversion is required from optical to electrical. When a manufacturer chooses to generate the transmission beam within the FSO device, extra information can be coded in the transmission path, including forward error correction, beam steering information, and link statistics. The receiving FSO device can use the extra information to improve reliability and other performance characteristics (Li and Uysal 2003).

Passive FSO devices, on the other hand, use only an *erbium-doped fiber amplifier* (EDFA) to amplify the incoming fiber signal in-route, and thus no latency is added. Although this provides complete transparency to the controlling network equipment, the typical wavelengths used in fiber-based optical networking are not specially designed for transmission through the atmosphere, so the link lengths must be reduced to maintain the same reliability characteristics. The FSO system also does not benefit from the beam steering, error correction, and link statistics that are available to active FSO devices.

Active Tracking and Beam Steering

Most commercial systems in use today provide for beam steering to accommodate building movement and some atmospheric problems. The typical solution is to use a

large photosensor, which is divided into regions. The intensity of the beam is measured in the different regions, and if the beam is found to be off-center, that information is fed back to the transmitter. The transmitter then adjusts a mirror to point the beam toward the center of the receiver. Different vendors provide different mirror technology, including steerable mirrors and *micro-electromechanical systems* (MEMS) mirrors.

Semiconductor Laser Technology

Recent advances in semiconductor lasers are expected to provide benefits for FSO. The most significant of these appears to be *vertical-cavity surface-emitting lasers* (VCSELs). VCSELs are almost exclusively used in high-speed data communications today and are finding more widespread use as sensors. VCSELs offer many advantages over traditional “edge-emitting” semiconductor lasers. VCSELs emit light that is perpendicular to the surface of the wafer. This allows the devices to be tested on-wafer, saving manufacturing cost. VCSELs are brighter and more energy-efficient than edge emitters, allowing more applications. VCSELs output light in a circular Gaussian pattern, with less divergence than edge emitters, which reduces the complexity of coupling optics. VCSELs can also be modulated at much higher speeds than edge emitters, allowing for increased network bandwidth (Guenther et al. 2001; O'Brien et al. 2005).

ALTERNATIVES TO FREE-SPACE OPTICS

Fiber

Although fiber has quickly been established as the medium of choice for service-grade networking, digging fiber trenches in dense cities causes significant problems. Because of resulting traffic congestion and other problems caused by trenching, cities have become more concerned about the disruptions involved in developing fiber-optic networking. Some cities encourage carriers to lay fiber whenever trenches are dug for sewer, water, or even competing fiber lines. Others have outlawed fiber trenching entirely. Some cities and companies have actually run fiber cables through existing sewer lines to avoid the problems associated with trenching. This reaction to fiber trenching is creating a unique opportunity for FSO vendors to build metropolitan mesh networks as an alternative to fiber.

Radio Frequency Links

802.11

Radio frequency links are a significant competitor to FSO. The two primary RF links tend to be 802.11a and b/g. These operate at 5 GHz and 2.4 GHz, respectively, which do not require FCC licenses, and are thus subject to significant interference from other nearby wireless networks. The current 802.11 standards do not allow data rates higher than 54 Mbps, making it suitable only for small company local area network (LAN) traffic over short distances. Some commercial offerings use 802.11 as a slow-speed backup connection for FSO links.

Millimeter-Wave RF Systems

Millimeter-wave (MMW) RF systems carry network traffic at speeds comparable to FSO. However, MMW systems are more affected by weather than 802.11, especially by heavy rain. Because FSO is typically unaffected by heavy rain, MMW-FSO combination systems have made significant inroads because they are capable of sustaining 99.999 percent reliability under most weather conditions.

802.16

The 802.16 standard is designed primarily as a metropolitan area network technology that can supply broadband connectivity to the last mile. The standard is designed to be operated in licensed spectrum near the 2.4-GHz band. An 802.16 cell can support approximately 70 Mbps of shared bandwidth, and new cells can be added as the demand for bandwidth grows. Its operation in licensed spectrum provides protection from interference.

T1 and T3

For lower-bandwidth connections, a T1-T3 link, which is typically routed over copper lines, provides a low-cost, high-reliability link.

ADVANTAGES OF FREE-SPACE OPTICS

Setup Cost

Compared to fiber-optic cable, FSO systems are significantly cheaper to install. The labor involved includes site planning, site preparation (routing cables and power to the transceiver locations), mounting the transceivers, aligning the transceivers, and performing diagnostics (Willebrand and Ghuman 2001).

Security

FSO provides security capabilities on par with fiber optics. The beam dispersion is on the order of 3 meters per kilometer for a typical system. This allows an interceptor to be easily detected. Because the beam often does spread beyond the size of the receiver in building-to-building links, the receivers should be placed against a solid wall to prevent any stray beam from being intercepted.

Freedom from Interference

Because photons do not tend to interfere with each other, FSO systems can be installed in close proximity without risk of interacting with other systems. There is some risk of interference between identical systems mounted in close proximity, but this is easily solved by good site planning.

Because of the scarcity of unlicensed RF bands, low-frequency (2.4 GHz and 5 GHz) point-to-point systems can be greatly affected by interference caused by other devices operating in the same spectrum. Interference is less common with MMW systems because the signal is more directional.

Free Licensing

Because light-based systems are interference-free, the FCC has always allowed free licensing for transmission in the visible, ultraviolet (UV), and IR spectra. This is fortunate because, otherwise, people might not be allowed to wear certain clothes, get UV suntans, or even cook dinners on their stoves.

Because of interference on RF bands, the only enterprise-level option may be to license spectrum for a point-to-point system. This greatly increases the cost of an RF system, although it does guarantee that other nearby systems will not suffer interference.

Line-of-Sight Requirements

One issue in setting up an RF-based point-to-point link is that the signals transmitted between the two towers spread out over the distance of the link. This is caused by the diffraction of the signal in the atmosphere between the transmitting and receiving antennas. The pattern of diffraction is called the *Fresnel zone* and is modeled by an ellipsoid. Any obstructions in the Fresnel zone will affect the transmission, either by attenuating the signal or creating multiple paths. For a 2.4-GHz signal over 1 km, the radius of the Fresnel zone at the midpoint is more than 5 m, whereas at 60 GHz it is only 1 m. Although IR light does have a Fresnel zone, the zone is only 0.1 m.

Bandwidth

Higher bandwidth in an FSO link is usually provided by decreasing the per-symbol time, which reduces the range and reliability of the system. Through some of the technological improvements available today, FSO systems can provide Gigabit speeds. With technologies such as wavelength division multiplexing, which uses multiple light frequencies to transmit more information, FSO can support much higher bandwidth than any other free-space networking technology.

THE GROWTH OF FSO

Mesh Topologies

Mesh topologies allow a long link to be broken into many smaller links. This has allowed network service providers to link multiple clients together by creating multiple-hop optical networks. An additional advantage of mesh networking is that the network can be designed to provide fault tolerance by providing more than one path from a customer site to the service provider (Acampora 2002). For cities where buildings can obstruct each other, a customer with no line of sight to the service provider can be linked through another building with line of sight to both the customer and the network operator. The weather advantages are significant as well. Figure 6 represents an example mesh topology. The node at the top left cannot be reached by a conventional FSO link, so a network has been built, based on existing nodes, to link the farthest node to the fiber end point on the far right. The mesh network depicted also has at least two paths to each node, which provides for failover capability if a link or node fails.

Figure 6: Mesh network topology

Emergency Linking

Although fiber links are extremely reliable, they can be susceptible to excavation problems, seismic activity, and other major failures. Because fiber generally takes months to install, FSO is often used as a disaster-recovery mechanism. Some FSO vendors are even selling so-called disaster kits that include everything needed to set up a temporary link in the case of a severe network outage. For extreme reliability, FSO systems can be installed as a hot standby to another network technology when there is a greater risk of a cable cut or other failure.

Linking in Large Cities

With the rise in mesh networking, FSO has become an enterprise-grade networking system in larger cities where fiber installation is cost-prohibitive (Willebrand and Ghuman 2001). Older buildings were not built with today's networks in mind and lack the bandwidth capability needed for medium to large businesses. FSO becomes an extremely cost-competitive solution with speeds equivalent to fiber, installation time on the order of days, and low system costs compared to fiber. FSO links can even be set up through windows so that roof access is not necessary. Many corporations are using FSO to bridge offices with line of sight without having to lease dedicated bandwidth from a network provider.

The Last Mile

Studies show that 90 percent of businesses with 100 or more employees (Acampora 2002) and 95 percent of buildings (Willebrand and Ghuman 2001) are located within one mile of a fiber backbone. With technologies such as *dense WDM* (DWDM), the backbone supports an almost unlimited bandwidth by today's standards, yet the pipe to most smaller businesses is a T1 or T3 line. FSO provides the unique capability of providing a low-cost optical link to the last mile without the bandwidth limitations of an RF-based system and without the cost of running fiber underground.

THE FUTURE OF COMMERCIAL FSO WDM and DWDM

Although the propagation characteristics of IR provide a significant advantage in typical weather, multiple wavelengths can be used simultaneously over shorter distances to provide for more bandwidth. This technology in the fiber realm has enabled a single fiber to carry data rates in the Terabits per second range. This can be used to create higher-bandwidth networks over short distances or provide dedicated, wavelength-separated networks.

Passive Optical Networks

The rise of passive optical devices for networking has created the dream of a passive optical network in which backbone traffic could be routed solely by wavelength. This has been made possible by the invention of the EDFA, a device that amplifies laser signals without a loss of its coherent properties. Thus, long-haul networks can be achieved without the latency added by conversion between electronic and optical. Pure optical switches (think of a programmable prism) can reduce the dependence on store-and-forward routing. FSO fits in well with an all-optical solution by providing the capability to expand the network or connect nearby sites without fiber.

Communication to Space

The propagation characteristics of RF preclude its use for deep-space communications. Lasers are being researched extensively because they provide the only viable mechanism for deep-space communications. The two main obstacles for space communications are tracking and atmospheric effects. Eye safety is not as critical because the downlink and uplink stations can be located in restricted areas where human contact and airplane flight paths would not be a concern.

Although the maximum range of a typical eye-safe laser is on the order of 5 km, space agencies have their choice of location (e.g., Antarctica) and can potentially deal with eye safety by restricting the airspace around future satellite and mission ground stations.

The high bandwidth of FSO communications also makes satellite communications via laser a possibility. Recent patents (e.g., 6,912,075) suggest that WDM FSO between satellites could be used to carry a significant amount of data, which would then be communicated to the Earth through RF links.

Quantum Cryptography

A fascinating phenomenon first proposed by Einstein as a proof against quantum mechanics is that two photons can have a relationship that is unaffected by distance. For coupled photons, the relationship is polarization: Two photons can be created simultaneously that will have equal and opposite polarizations. If the polarization of one photon is changed, then the polarization of the other is changed as well. This effect, called *entanglement*, holds until the photon is measured, which destroys the relationship.

This phenomenon is important because, first of all, interception of the photons can be detected easily by comparing the polarizations of the photons at both ends (they should never be equal). In addition, the key, which is distributed over the optical link, means nothing without the information transmitted over a secondary channel. The receiver needs to know both the spin of the photon received and how that photon was changed by the transmitter in order to know the key.

FSO plays an important role because it can be a medium for the secure quantum channel. RF channels do not share the properties of entanglement.

Combined FSO and RF Links

Although FSO cannot meet the enterprise reliability requirements alone, FSO systems can be backed up by RF transmitters to provide continuous coverage in all weather conditions (Kukshya et al. 2002). These combinations generally appear as either a high-data-rate FSO link with a low-cost, low-data-rate RF solution such as 802.11 as a backup during dense fog. Another approach is to use MMW systems of comparable bandwidth that can be load balanced during typical weather conditions and switched over to the surviving system when an outage occurs (Hashmi and Mouftah 2004). A five-year study conducted in Seattle, Washington, tracking hourly visibility and rainfall rates showed that heavy rain, which disrupts MMW systems, and dense fog, which disrupts FSO systems, do not occur simultaneously (Korevaar and Kim 2001). As the bandwidth of FSO solutions increases, even MMW systems, which enjoy Gigabit rates, will become a low-data-rate backup.

RF backup systems guarantee at least some network connectivity in the most adverse weather conditions, although the network performance may not be optimal.

FSO RESEARCH

Multiple Quantum Well Retroreflectors

In discussing dispersion in space, the concept of a retroreflector was covered. Retroreflectors can also be used as a passive, transmit-only node in a FSO network.

The concept is similar to the later modulation scheme used by a heliograph in which a shutter was placed in the line of the beam of light. The difference is that the shutter is placed in front of a passive mirror. The result is a low-power device that can communicate on an FSO network. *Multiple quantum well* (MQW) devices have extremely fast switching times (on the order of 10 GHz), which can enable extremely high-bandwidth communications (O'Brien et al. 2005).

MQW retroreflectors find applications where there is no need for bidirectional communications. A beam of light can be used to query the status of the devices, and modulation schemes could potentially allow multiple devices to communicate simultaneously.

Much of the research in MQW retroreflectors is in the military domain. Because of the small size and low power consumption of these devices, they could be attached to sensors, carried on unmanned aerial vehicles, or even provide status information from soldiers. Low-flying planes or other air vehicles could read the status from the sensors.

Another area of research is wire replacement in space. Copper wiring in space can add significant weight to payloads and is susceptible to vibration during launch and reentry. A communicating node could use a combination of a high-dispersion light source to avoid alignment issues, and a retroreflector to transmit and receive important data.

Reconfigurable FSO Networks

Current commercial implementations of FSO rely on two fixed communications nodes. The mounts are extremely rigid, and the transceivers can only accommodate minimal movement. Although this is acceptable for commercial networking, many potential uses of FSO require communication between nodes at multiple speeds and under multiple conditions. Nodes might be soldiers, helicopters, automobiles, low- and high-flying airplanes, and even satellites.

Indoor FSO Networking

Although the primary market for FSO devices is in outdoor point-to-point networking, FSO research is also finding applications for indoor wire replacement. Although non-line-of-sight systems provide similar performance to 802.11b, higher-performance networking is required to replace the current networking infrastructure. Researchers are proposing a cell-based system so that each transceiver will have a line-of-sight path to one or more base stations. Prototype systems of this type have been demonstrated at bandwidths of 155 Mbps (O'Brien et al. 2005).

CONCLUSION

Free-space optics has developed from a highly intermittent communication technology to one that can provide high-data-rate communications reliably over short distances. FSO provides more significant benefits with increased numbers of customers in close proximity with mesh topologies that can create multiple highly reliable links instead of relying on a single intermittent link.

An FSO's high bandwidth and short setup time give it a unique edge in the network market today. Currently, FSO links are only used where reliability is not as critical or in combination with other technologies because of the possibility of outage.

GLOSSARY

Dense Wavelength Division Multiplexing (DWDM):

This technique uses optical properties to transmit multiple simultaneous streams of information on a single optical link. The invention of a few significant devices allows the building of networks based on wavelength. These devices are the *erbium-doped fiber amplifier* (EDFA), which can amplify the entire spectrum of light in a fiber without losing its characteristics; the optical switch; and optical drop-add devices, which can route or add a single wavelength of light into or out of an optical link.

Laser: A device whose name is an acronym for *light amplification by the stimulated emission of radiation*. It produces highly directional and intense light beams by energizing electrons to a specific excitation state. When these electrons return to their rest state, they emit photons at a highly specific wavelength based on the difference in energy between the two states. Different materials emit different wavelengths based on their molecular properties.

Mesh Networking: Networks that are created using multiple links. Mesh networks can also be designed to be more reliable by creating multiple paths to each node on the network. If one link fails, then smart routers in the network can move traffic from the failed link to the remaining link.

Micro-Electromechanical Systems (MEMS): These are microscopic machines created through processing of silicon and other materials at a nanometer level. As an example, MEMS mirrors act like a single bit of RAM but can quickly and accurately switch between two positions. Some projectors use this technology because they support extremely high contrast.

Millimeter Wave (MMW): This refers to radio frequency communications using frequencies in the 60-GHz range. The wavelength of these systems is approximately 1 millimeter. These systems operate within the oxygen absorption band, which means that the maximum link distance is significantly limited. The limiting characteristics of oxygen absorption also increase the security of the MMW links.

Passive Optical Network (PON): A network created by routing of optical signals without requiring conversion to or from electrical impulses. Each wavelength can be routed independently, usually requiring significant setup time and planning, but the advantage is that no latency is added in the optical switches, where electrical switching can add significant latency.

INTRODUCTION

Optical transmission and switching technologies based on *wavelength division multiplexing* (WDM) have been increasingly deployed over the last decade to satisfy the tremendous demand for bandwidth. WDM transmission technology has been efficiently established, while the development of optical switching technologies has continued to progress rapidly. The result of such efforts has led to the creation of optical networks in which the optical signal undergoes optical-electrical-optical conversion at each intermediate node. Two tendencies have emerged for the design and deployment of WDM networks. The first trend attempts to increase network transparency in order to remove electronic bottlenecks and manage a large set of heterogeneous signals regardless of protocol formats, modulation, and bit rates. The second trend looks for network reconfigurability such that bandwidth can be assigned efficiently to end users in order to accommodate dynamically changing traffic demands. Both trends reflect the vision for future networks in which optical switching technologies play a fundamental role and bandwidth is promptly available to end users.

The migration of switching functions from electronics to optics is a critical issue. It is progressively done through several phases. The first phase is ongoing. It deploys wavelength routing, which offers circuit-switching services at the granularity level of wavelengths. Because of the circuit nature, wavelength-routed networks can be built with commercially available optical switching technologies such as the optomechanical, micro-electromechanical system switches, electro-optic switches, and thermo-optic

switches (Papadimitriou, Papazoglou, and Pomportsis 2003; Yano, Yamagishi, and Tsuda 2005); unfortunately, these are still relatively slow. Although wavelength routing represents an important step toward transparent configurable optical networking, optical circuits tend to be inefficient for traffics that have not been multiplexed. In addition, circuit-switching models do not fit well with Internet protocol (IP) packet switching. The second phase undertakes the move toward *optical burst switching* (OBS) (Qiao and Yoo 1999; Baldine et al. 2002) and attempts to minimize the header management at the internal nodes. OBS is generally considered as an attractive technique for supporting improved switching granularity. Because the unit of transmission and switching is a burst, OBS is more efficient than circuit switching when the carried traffic does not utilize full wavelength. In the longer term, *optical packet switching* (OPS) (Yao et al. 2001; Sivalingam and Subramaniam 2005) promises finer switching granularity, providing bandwidth efficiency, flexibility, and data management. The achievement of this third phase, however, faces major difficulties because OPS will necessitate the development of several component and system technologies that are still in their experimental stage (Sivalingam and Subramaniam 2005).

One major issue in optical switching is the provision of differentiated service to support various *quality-of-service* (QoS) requirements. *Multiprotocol label switching* (MPLS) (Rosen, Viswanathan, and Callon 2001) is a recent technology that has been proposed for IP networks to increase node throughput and provide multiclass routing to multiple services. Throughput increase

is achieved by packet forwarding at lower layers, whereas QoS differentiation is based on the assignment of a unique label to all of the packets of each flow. To provide more efficiency to MPLS in terms of traffic forwarding and QoS, a technology called *optical label switching* (OLS) has emerged based on the idea of adapting the traditional label-switching technology to WDM networks, which may provide QoS support over WDM networks and resolve some shortcomings. Two approaches are considered: *multiprotocol lambda switching* (MP λ S) (Awduche et al. 2002) and photonic label switching. Considering that there are many technologies underlying the data-link and physical layers, the *generalized multiprotocol label switching* (GMPLS) (Mannin 2001; Banerjee et al. 2001) is proposed to extend MPLS to encompass time division, wavelength, and spatial (or fiber) switching. It provides a common control plan that is used to simplify network operation and management by automating end-to-end provisioning of connections and managing network resources.

Signaling is one key issue of interest in the development of optical networks to support switching. It monitors the establishment of several objects and activities such as lightpaths. Specifically, to set up a lightpath, a signaling protocol is required to exchange control information among nodes and reserve resources. Signaling schemes can also be used to manage contention-based optical buffering, wavelength conversion, or deflection methods (Yao et al. 2003). Different signaling protocols have been proposed to implement the aforementioned optical switching techniques. Among these protocols are the signaling protocols proposed for static and dynamic lightpath establishment over *wavelength routing* (WR) networks (Zang, Jue, and Mukherjee 2000) and the *just-enough-time* (JET) (Yoo and Qiao 1997; Myers and Bayvel 2001) and the *just-in-time* (JIT) (Wei and McFarland 2000) signaling protocols in OBS networks. Other examples are the signaling protocol that is similar to the *asynchronous transfer mode* (ATM) proposed in Lazzez et al. 2006 for the transmission of packet flows over an optical network in an ATM-like manner, and the MPLS and GMPLS protocols (Rosen, Viswanathan, and Callon 2001; Banerjee et al. 2001; Yao et al. 2003; Ashwood-Smith and Berger 2003; Berger 2003) for the implementation of label-switching technologies over WDM networks.

In this chapter, we discuss the major switching techniques proposed for the development of WDM networks. More precisely, we address the following issues: (1) the description of the architecture of WR networks and related schemes for link and path protection and restoration; (2) the burst switching technology and the issues in designing and implementing OBS networks such as burst assembly, contention resolution, and QoS support; (3) the architecture of an OPS network and the major concerns and difficulties in designing optical packet switching; (4) the label-switching technology and its contribution in terms of traffic forwarding efficiency and QoS support; (5) the MPLS paradigm over WDM optical networks; (6) the most important signaling schemes proposed for WDM; and (7) the advanced issues in network evolution toward an all-optical network.

WAVELENGTH ROUTING NETWORKS

Lightpath Management in WR Network Architecture

In WR networks (Jue and Xiao 2000), an all-optical wavelength path called the *lightpath* can be established between edges of the network. A lightpath is created by dedicating a wavelength channel on every link along the chosen path. After data transfer, the lightpath is released. A WR network is formed by *optical cross-connect* (OXC) devices connected by point-to-point optical fiber links. The OXC devices are capable of differentiating data streams based on their input ports and the wavelengths they use (Elmirghani and Mouftah 2000). The data transmitted in a WR network require no electronic-to-optical conversion, no buffering, and no processing at the intermediate nodes. An OXC device switches optically an incoming wavelength λ_i on an input fiber to the outgoing wavelength λ_i of an output fiber. If the OXC is equipped with wavelength converters, then it can also switch λ_i to different outgoing wavelengths λ_j of the output fiber. This happens when the wavelength λ_i of the output fiber is in use. An OXC can also be used as an optical add-drop multiplexer. Thus, it can terminate the optical signal of a number of incoming wavelengths and insert new optical signals on the same output wavelengths.

Lightpath Establishment

Establishing a lightpath is done in a WR network in two steps: path selection and channel assignment. *Path selection* refers to the selection of a path from source to destination based on certain criteria. *Channel assignment* allocates a wavelength channel on every link in the selected path. Path selection can be carried out in several ways. If every source-destination pair has one preselected path, then the selection is referred to as a *fixed-path approach*. If a path is selected depending on the network status from a preselected set of candidate paths, then it is referred to as *dynamic path selection*. With this selection, the set of candidate paths remains the same all of the time and does not change. If the candidate paths are chosen based on the network status, then the path selection process is called *exhaustive routing*.

Traffic Grooming

As shown previously, a lightpath in a WR network occupies an entire wavelength on each hop of the source-destination path. The wavelength can be the same throughout the optical network or differ from one link to another if converters are available at the optical nodes. Nevertheless, many traffic flows do not require the bandwidth of an entire wavelength. In fact, a traffic flow may need only a small portion of a wavelength bandwidth. This results in inefficient network resources utilization because a great part of a lightpath's bandwidth may be unused and unavailable for use by other traffic streams. To solve this problem, the bandwidth of a lightpath is divided into lower subrate units so that it can carry traffic flows transmitted at lower rates. A traffic stream can use one or many subrate units. This allows the unused

bandwidth to be available to other traffic streams. Such a technique is referred to as *traffic grooming*, whereby lower-rate traffic streams are multiplexed onto (and demultiplexed from) higher-capacity WDM wavelengths in order to improve wavelength utilization and meet network design goals such as cost minimization (Dutta and Rouskas 2002; Naoya and Kubota 2005; Takahashi 2004; Lazzez et al. 2006).

Quality of Service in WR Networks

A major concern in WR networks is how to provide differentiated services to support various QoS requirements. We present here the general framework proposed in Kaheel et al. (2002) for providing differentiated service in WR networks. This framework extends the previously proposed *differentiated optical services* (DOS) model (Golmie, Ndousse, and Su 2000) and considers other QoS schemes for WR networks. The DOS model considers the unique optical characteristics of lightpaths. A lightpath is identified by a set of optical parameters such as bit error rate, delay, jitter, and behaviors such as protection, monitoring, and security capacities. These parameters and behaviors provide the basis for measuring the quality of optical service available over a given path. The DOS framework is composed of the following six items.

1. **Service class:** A service class is determined by a set of parameters that characterizes the quality and impairments of the optical signal carried over a lightpath. These parameters are either specified in *quantitative terms* such as delay, average bit error rate, jitter, and bandwidth; or based on *functional abilities* such as protection, security, and monitoring.
2. **Routing and wavelength assignment (RWA) algorithm:** In order to provide QoS support over a WR network, it is obligatory to use an RWA algorithm that manages the QoS characteristics on the wavelength channels. An example for RWA algorithms is presented in Jukan (2001), where the primary idea aims at using adaptive weight functions that characterize the properties of the wavelength channels.
3. **Lightpath groups:** Lightpaths are classified into groups that reflect the distinctive qualities of the optical transmission. Each lightpath group corresponds to a specific service class.
4. **Traffic classifier:** Traffic flows are classified at the network ingress into one of the supported service classes. A traffic flow of a given traffic class is transmitted on a lightpath, which is able to provide the required QoS (lightpath groups).
5. **Lightpath allocation algorithm:** Several algorithms have been proposed in the literature for allocating lightpaths to different service classes.
6. **Admission control:** An optical resource allocator is used to conduct dynamic provisioning of lightpaths in a WR network. The optical resource allocator keeps track of the resource usage and evaluates the lightpath characteristics and functional capabilities (monitoring, protection, and security). The resource

allocator is also responsible for initiating an end-to-end call setup along the sequence of optical resource allocators representing the different domains traversed by the lightpath.

QoS-Based Lightpath Allocation Algorithms

Lightpath allocation can be static, static with borrowing, or dynamic. In *static* allocation, a fixed subset of lightpaths is assigned to each service class. The number of lightpaths in each group depends on the service class—that is, higher service classes are allocated more lightpaths. When *borrowing* is allowed, different priority classes can borrow lightpaths from each other according to certain criteria. An example of this approach is to permit lower-priority traffic to borrow lightpaths from higher-priority traffic. However, borrowing in the reverse direction is not assigned because lightpaths originally assigned to lower-priority traffic may not satisfy the QoS requirements of higher classes (Kaheel et al. 2002).

Using a *dynamic* lightpaths allocation algorithm, the network begins with no reserved lightpaths. The available set of lightpaths can then be assigned dynamically to any class under the assumption that all lightpaths have similar characteristics and functional capabilities. One approach for dynamic lightpath allocation is to use *proportional differentiation*, which quantitatively adjusts the service differentiation of a particular QoS parameter to be proportional to differentiation factors that a network service provider sets beforehand. More precisely, if P_i is the QoS metric of interest and S_i is the differentiation factor for class i , then the proportional differentiation model shows that $P_i/P_j = S_i/S_j$ for all pairs (i, j) . For example, assume that P_i is the packet-loss probability for class i . If $S_1/S_2 = 2$, then the number of lightpaths assigned to Class 1 must be twice the number assigned to Class 2.

OPTICAL BURST-SWITCHING NETWORKS

Optical burst switching has been proposed as a new switching paradigm for optical networks and has emerged as a candidate for the optical transport layer of the next-generation Internet. OBS combines the advantages of optical circuit switching and optical packet switching while overcoming the weaknesses of the circuit switching and the complexity of OPS. OBS is a fast circuit-switching technique that provides a granularity between wavelengths and packets but mandates neither the use of optical header processing nor optical buffering. Two key characteristics differentiate the OBS technology: (1) a hybrid approach in which control information is signaled out of band and processed electronically while data stay in the optical domain all of the time, and (2) the one-pass reservation whereby the transmission of a burst is not delayed until an acknowledgment of successful end-to-end path setup is received but is instead initiated as soon as the burst has been pulled together (COST 266, undated).

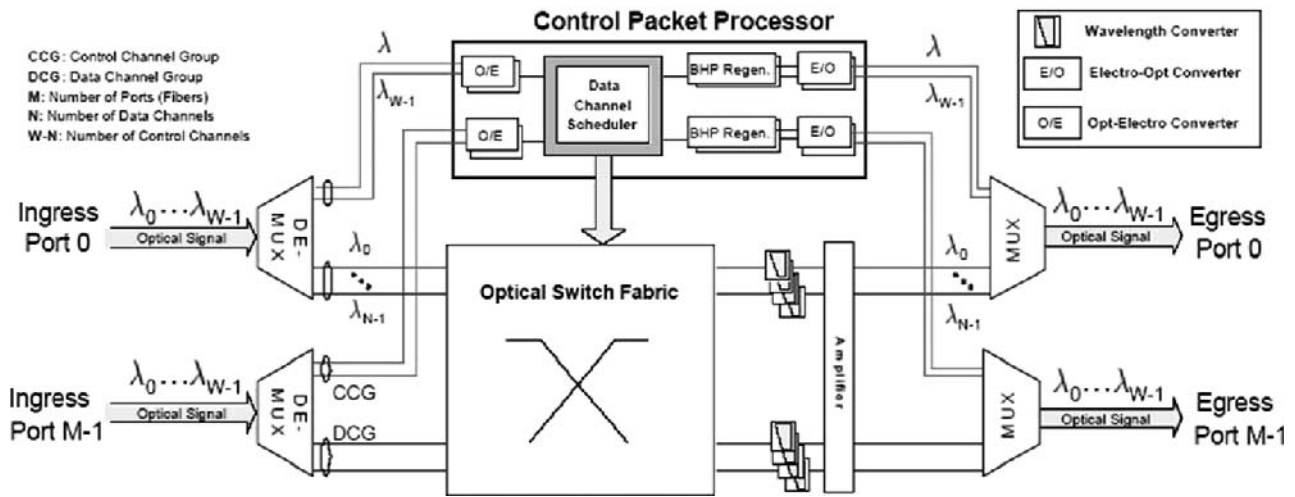

Figure 1: Architecture of an OBS core node

OBS Network Architecture

In an OBS network, data bursts that consist of multiple packets are switched through the network all-optically. Each burst is preceded by a control message—the *burst header packet* (BHP)—to configure the switches along the burst's path. The burst follows the header without waiting for an acknowledgment that resources have been reserved and switches have been configured along the path. An OBS network is composed of edge and core nodes interconnected via WDM fiber links. An optical burst switch transfers a data burst coming on an input port to its destination via an output port. The fiber links carry multiple wavelengths; each wavelength can be seen as a channel. Control traffic may be transmitted in-band over the same channel as data traffic or on a separate control channel. The source edge node (or ingress node) assembles the electronic input packets into an optical data burst, which is sent over the OBS core. The assembled bursts are transmitted all-optically over OBS core routers, without any storage at intermediate nodes to the destination edge node (or egress node). Upon receiving the burst, the egress node disassembles the bursts into packets and forwards the packets to the destination client terminals. In Vokkarane (2004), a basic architecture has been proposed for core and edge nodes in an OBS network.

Core Node Architecture

As depicted in Figure 1, an OBS core node is mainly composed of an *optical switch fabric* (OSF) and a *control packet processor* (CPP) (Vokkarane 2004). The CPP creates and maintains a forwarding table and is responsible for configuring the OSF. When the CPP receives a control packet (the burst header packet), it identifies the intended destination and consults the router signaling processor to find the appropriate output port. If the output port is available when the data burst arrives, then the CPP configures the OSF to let the data burst pass through. If the port is not available, then the OSF is configured depending on the contention-resolution mechanism implemented in the network. Typically, the SCU is responsible for BHP

interpretation, scheduling, contention detection and resolution, forwarding table lookup, wavelength conversion control, BHP rewriting, and OSF control. In the case of a data burst entering the OSF before its control packet, the burst is simply dropped (Vokkarane 2004).

Edge Node Architecture

Edge nodes carry out electrical-optical-electrical conversion and burst assembly and disassembly. Figure 2 depicts the architecture of an OBS edge node, which includes a *routing module* (RM) (Vokkarane 2004), and a *burst assembler* (BA) for each output wavelength channel. The RM selects the appropriate output channel for each packet and sends each packet to the corresponding BA module. The BA assembles bursts from the received packets. Each BA module is composed of a classifier, a separate packet queue for each traffic class, and a scheduler. The scheduler creates a burst based on the adopted burst assembly technique and sends the burst to the output port. At the egress node, a burst disassembly module disassembles the bursts into packets.

Figure 2: Architecture of an OBS edge node

Burst Assembly

Burst assembly is the procedure of aggregating and assembling input packets from various sources into bursts at the ingress edge nodes of the OBS network. The trigger condition for a burst creation is a key factor in an OBS network because it permits the control of the burst arrival into the OBS core. Different types of burst assembly techniques are developed in the OBS literature. The most frequent burst assembly techniques are timer-based and threshold-based (Vokkarane 2004; Yu, Chen, and Qiao 2002). In timer-based approaches, a timer starts at the beginning of each new assembly cycle. After a fixed time τ , all the packets that arrived during period τ are assembled into a burst. A *timer-based* scheme is used to provide uniform separation between successive bursts from the same ingress node. In *threshold-based* approaches, a limit is placed on the number of packets in each burst. A burst is generated when a new packet arrives, making the total number of current buffered packets exceed the threshold. A threshold-based scheme will generate fixed-length bursts at nonperiodic time intervals.

The time-out value for timer-based approaches must be set properly. If the value is too large, then the packet delay at the edge might be intolerable. If it is extremely small, then too many small bursts will be created, resulting in a higher control overhead. Although timer-based techniques may lead to undesirable burst lengths, threshold-based assembly schemes do not grant any guarantee on the assembly delay that packets will experience. To address the deficiency connected to each type of the aforementioned assembly algorithms, mixed assembly algorithms were proposed in Yu, Chen, and Qiao (2002) in which a burst is sent out when either the timer expires or the burst length exceeds the fixed threshold. A more significant case occurs when packets arriving to an ingress node are of different classes. The choice of a single burst assembly mechanism for all classes of traffic may be inappropriate. To overcome this, a composite burst assembly mechanism was proposed in Vokkarane (2004) whereby packets of different classes may be assembled into a single burst. It has been confirmed that composite burst assembly techniques can provide different levels of service for packets of different classes within the same burst if suitable contention-resolution mechanisms are implemented within the optical core (Vokkarane 2004).

Contention Resolution

Using one-way reservation protocols, an ingress node sends out bursts without having reservation acknowledgments or benefit from global coordination. Thus, it is possible that bursts contend with one another at the intermediate nodes. Contention occurs if multiple data bursts from different input ports are destined for the same output port at the same time. Contention problems can be addressed using techniques such as optical buffering, wavelength conversion, and deflection routing. A combination of contention-resolution techniques may be used to provide high throughput, low delay, and low packet-loss probability (Lazzez et al. 2006).

Optical Buffering

In electronic packet-switched networks, contention is typically handled using *random access memory* (RAM) buffers; however, because of technological constraints, optical RAM-like buffering is not yet available today. In optical networks, *fiber delay lines* (FDLs) can be utilized to delay packets for a fixed amount of time. Using multiple delay lines implemented in stages or in parallel, an optical buffer that can hold a burst for a variable amount of time can be created. Also, different FDL buffer architectures have been proposed in the literature (Chlamtac et al. 1996; Chia et al. 2001). Optical buffers are either *single-step*, meaning that they have only one block of delay lines, or *multistep*—that is, they have several blocks of delay lines. Optical buffers can be also classified into feed-forward, feedback, and hybrid architectures. According to the position of the FDL buffers in the switch, an optical switch is essentially classified into one of three major configurations: input buffering, output buffering, or shared buffering. In input buffering, for example, a set of buffers is dedicated for each input port (Vokkarane 2004).

Wavelength Conversion

Based on the WDM technology, several wavelengths run on a fiber link that connects two OBS nodes. The wavelengths can be operated to minimize contentions. Let us consider that two bursts are destined to the same output port at the same time. Both bursts can still be transmitted but on two different wavelengths. Wavelength conversion is the process of converting the wavelength of an incoming channel to another wavelength at the outgoing channel, thus minimizing burst contentions. Wavelength conversion can be full, limited, fixed, or spare.

Deflection Routing

Using the deflection routing scheme, a contending burst is routed to an output port other than the intended output port and consequently on a different route toward its destination (Vokkarane 2004). Although deflection routing is often not preferred in traditional packet-switched networks because of possible looping and out-of-sequence packet delivery, it may be significant to implement deflection in all-optical burst-switched networks in which buffer capacity is extremely limited to ensure an acceptable level of traffic loss. To further reduce packet loss resulting from contention, another approach called *burst segmentation* has been also proposed (Vokkarane, Jue, and Sitaraman 2002). It aims to drop only those segments of a burst that overlap other bursts.

QoS in OBS Networks

Quality-of-service support is another important issue in OBS networks. Different schemes have been proposed for offering QoS differentiation in OBS networks and providing loss or delay differentiation.

QoS Models

Three models for QoS can be used: relative, proportional, and absolute (Chen, Hamdi, and Tsang 2001; Zhang et al.

2004). In the *relative* QoS model, the performance of each class is defined relatively in comparison to other classes. For example, a high-priority class is guaranteed to experience lower loss probability than a low-priority class. However, the loss probability of the high-priority class depends on the traffic load of the low-priority class; hence, no upper bound on the loss probability is guaranteed for the high-priority class. In the *proportional* differentiation model, the service differentiation of a particular QoS metric is quantitatively adjusted to be proportional to the factors that a network service provider sets. If p_i is a QoS metric and s_i is the differentiation factor for class i , then using the proportional differentiation model, we should have $p_i/p_j = s_i/s_j$, for all (i, j) . The achievement of these models requires that each core node maintains traffic statistics. The *absolute* QoS model provides, for the guaranteed traffic, an upper-bound guarantee for any of the supported QoS metrics. This kind of strict QoS guarantee is essential to support applications with delay and bandwidth constraints such as videoconferencing and voice-over-IP applications. Efficient admission-control and resource-provisioning mechanisms are required for the realization of the absolute QoS model over an OBS network.

Relative QoS Differentiation

Several schemes have been proposed to support the relative QoS model. In Yoo, Qiao, and Dixit (2000), an extra offset-based scheme that provides relative loss differentiation was proposed. Using this scheme, higher-priority class bursts are given a larger offset time than the lower-priority class bursts. By providing a larger offset time, the probability of reserving the resources for the higher priority class bursts is increased, and consequently the loss probability experienced by higher-priority class bursts is reduced. The limitations of the extra offset-based scheme are unfavorable end-to-end delay, irregular loss probability differentiation, and a burst-selecting effect (Chen, Hamdi, and Tsang 2001).

Contention-resolution schemes may be used to provide relative QoS differentiation in an OBS network. In Lazzez et al. (2006), a QoS-based contention resolution has been suggested. The proposed scheme combines optical buffering and wavelength conversion techniques. It is based on a differentiated QoS provision in the sense that the selection of the traffic unit to convert or delay in case of contention is done according to the priority of the contending units. Therefore, lower loss probability and lower blocking delay are made to ensure proper operation for the high-priority traffic class. A relative QoS differentiation can be also provided based on the assembling scheme. For example, by using a timer-based single burst assembly mechanism with a specific timeout for each traffic class, we can provide a relative packet delay differentiation.

Proportional QoS over an OBS Network

Different schemes have been proposed to provide proportional QoS differentiation over an optical burst-switched network. In Chen, Hamdi, and Tsang (2001), an intentional burst-dropping scheme has been made available to provide proportionally differentiated loss

probability. This will give longer free time periods on the output link capacity, which induces more opportunity for high-priority bursts to be admitted. A limitation of the scheme is that it can result in unnecessary dropping of low-priority bursts. In Loi and Yang Liao (2002), proportional loss probability differentiation is provided by maintaining the number of wavelengths occupied by each class of burst. Every incoming burst is planned based on a usage profile maintained at every node.

To provide a proportional packet delay differentiation over an OBS network, an appropriate assembling scheme has been proposed in Chen, Hamdi, and Tsang (2001). It expands the waited-time-priority scheduler proposed to provide a proportional packet delay over a packet-switched network (Chen, Hamdi, and Tsang 2001), where a queue is kept for each class of packets. A burst will be assembled and transmitted into the OBS backbone when a token is generated at time t . The priority for each queue is given by $p_i(t) = w_i(t)/s_i$, where $w_i(t)$ is the waiting time of the packet at the head of queue i and s_i is the proportional factor for class i . The queue with the largest $p_i(t)$ will be chosen. Therefore, a proportional packet-delay differentiation is provided.

Absolute QoS over an OBS Network

Relative QoS differentiation schemes cannot provide an upper-bound guarantee for the supported QoS metrics; therefore, absolute QoS differentiation schemes are required. An intuitive approach to provide absolute QoS differentiation is to design a hybrid optical backbone network consisting of wavelength-routed lightpaths to carry the guaranteed traffic and a traditional OBS network for nonguaranteed traffic transmission. This approach leads to inefficient bandwidth utilization over the wavelength-routed part of the network. To guarantee efficient bandwidth use, efficient absolute QoS differentiation schemes, in which all wavelengths in the network are available for statistical multiplexing and dynamic bandwidth allocation, are needed.

In Zhang et al. (2004), an absolute QoS model that provides an upper-bound loss probability for guaranteed traffic has been proposed. Two mechanisms have been proposed for providing loss guarantees at OBS core nodes: early dropping and wavelength grouping. The *early dropping* mechanism probabilistically drops the bursts of lower priority class to guarantee the loss probability of higher-priority class traffic. The *wavelength grouping* mechanism provides wavelengths for the guaranteed traffic and schedules the bursts based on provisioning. The integration of the two mechanisms gives a successful solution for providing absolute loss guarantee while significantly reducing the loss probability experienced by the nonguaranteed traffic. In addition, Phung et al. (2004) present a novel signaling and reservation scheme that has been developed to provide an absolute QoS provision for an optical burst-switched network.

OPTICAL PACKET-SWITCHING NETWORKS

Optical packet switching has emerged as a promising solution for the next-generation all-optical networks.

By enabling packet switching in the optical domain, OPS networks can provide cost-efficient and transparent transport services to higher layers. Nevertheless, commercial deployment of OPS requires a careful investigation of several challenges because they are fundamentally different from traditional networks.

OPS Technology

In an OPS network, packets are processed and forwarded hop by hop until they reach their destination node. An OPS network should be able to process and forward packets in the optical domain, which makes the network truly transparent. On the other hand, as optical processing is still in the experimental stage, electronic processing of the packet header is operated until optical processing becomes mature. Therefore, when a packet arrives to a node, the packet header is extracted and converted to the electronic domain in order to be processed, whereas the packet payload is switched to an input FDL to be buffered during packet header processing. OPS benefits from statistical multiplexing, which guarantees better network resource utilization compared to WR and OBS networks. An OPS network can be either synchronous or asynchronous. In *asynchronous* OPS, packets arrive at a switch at nonsynchronized instants. In *synchronous* OPS, time is slotted, and packets arrive at an optical core switch in synchronized and equally spaced time slots. The impact of contention is often less severe in slotted OPS compared to asynchronous OPS. However, slotted OPS requires synchronization at each switch input, which increases the switch cost and complexity. In both slotted and unslotted OPS networks, the packets may be of variable size (Øverby 2005). In slotted OPS with variable-sized packets, a packet is a multiple of time slots, whereas in slotted OPS with fixed-size packets, a packet is contained in a single time slot. Both fixed-size and variable-sized architectures require packet aggregation at the OPS ingress node. This is also required for asynchronous OPS with fixed-size packets. However, packet aggregation can be avoided in asynchronous OPS with variable-sized packets (Øverby 2005).

Figure 3 depicts the functional architecture of a generic OPS node as it is presented in Rouskas and Xu (2004).

The architecture is composed of a set of multiplexers and demultiplexers, an input interface, a switch fabric unit with FDL buffers and wavelength converters, an output interface, and a switch control unit. Packets arriving on an input fiber are first demultiplexed into individual wavelengths and are then sent to the input interface. Each packet has a payload and an optical header that is used for packet routing in the optical domain. The input interface is typically responsible for extracting the optical packet header and forwarding it to the switch control unit for processing. The SCU processes the header information, determines an appropriate output wavelength channel, and configures the switch fabric unit to route the packet accordingly. In case of output port contention, the switch may need to buffer the packet or transfer it to a new wavelength. When the packet arrives at the output interface, the header and the associated data payload are attached and the packet is forwarded on the outgoing wavelength channel to the next switching node. OPS node architectures can be classified using several dimensions, depending on how the switching functions are implemented (Rouskas and Xu 2004).

Synchronous versus Asynchronous Switch Operation

In a synchronous OPS network, time is slotted, and the switch fabric unit at each individual OPS node can only be reconfigured at the beginning of a time slot. As packets enter a node from different links, they may arrive out of phase with one another. Therefore, it is the responsibility of the input interface (which is depicted in Figure 3) to align packets with the switching time slots. In an unslotted network, switch operations may take place at any point in time, and there is no requirement to align arriving packets at the input of a switching node.

Contention-Resolution Strategies

When two packets from different input port-wavelength pairs must be switched to the same output port-wavelength pair at the same time, contention arises and the switch controller and the switch fabric unit have to employ some strategy to resolve the contention—using, for example, wavelength converters, optical buffers, or deflection routing. Contention-resolution strategies are discussed and compared shortly below.

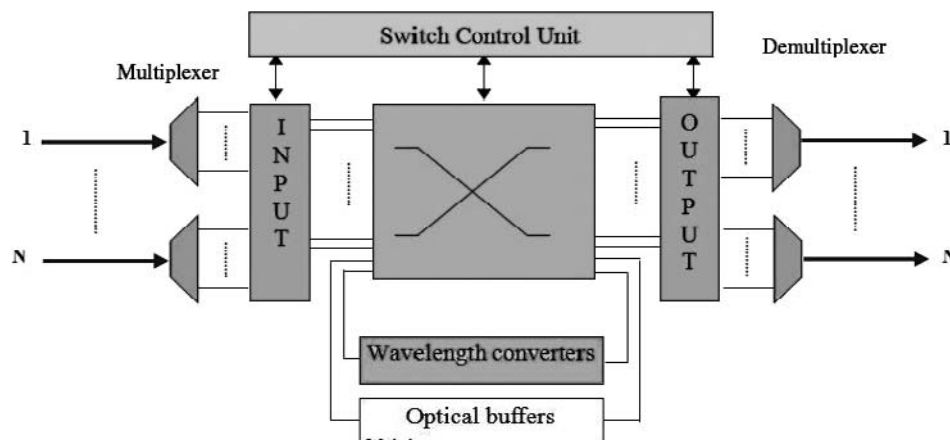

Figure 3: OPS node architecture

Figure 4: Optical synchronization stage

Packet Delineation and Synchronization

Packet delineation is required for both synchronous and asynchronous networks. The purpose of delineation is to determine the beginning and the end of the arriving packet (Yao 2001). During packet delineation, the incoming bits are locked in phase with the clock in order for the node to read the header information.

In addition to packet delineation, OPS nodes in slotted networks must also synchronize incoming fixed-size packets to the local switching slots. Figure 4 shows a typical synchronization stage that consists of a series of switches and delay lines (Yao 2001). When the header processor recognizes the bit pattern in the header and performs packet delineation, it identifies the packet start time and the control unit can compute the necessary delay and configure the correct path through the switched delay lines. This scheme introduces losses and cross talk, resulting in a significant power loss over long paths. A different strategy takes advantage of the fact that the propagation delay in a highly dispersive fiber depends on the signal wavelength. Each incoming packet is first converted to the appropriate wavelength to achieve the desired delay on such a fiber (Rouskas and Xu 2004).

Contention Resolution

A contention can be resolved using three different approaches: (1) the wavelength-based approach by the use of wavelength converters, (2) the time-based approach by the use of FDL buffers, and (3) the space-based approach by the use of deflection routing. With *wavelength conversion*, one or more tunable wavelength converters are used to convert the input wavelength in the case where two or more packets are intended, at the same time, to the same output fiber and the same output wavelength. *Optical buffering* is implemented by the use of fiber delay lines. The FDLs are made of an optical fiber with fixed length and can store a packet for a time that is proportional to the length of the fiber. When contention occurs, one of the contending packets is sent to the intended output port while the others are deviated to FDLs. Using *deflection routing*, a contended packet is routed to a different fiber to take another way to its destination. Deflected packets often experience a longer delay through the network and risk to arrive out of order to their destination. The most effective combination of contention resolution methods is to use wavelength conversion, FDL buffering, and space deflection together. In Yao et al. (2003), wavelength conversion is proven to be the most effective contention-resolution scheme because neither extra delays nor use of extra network resources are experienced.

QoS in OPS Networks

Generally, QoS techniques in OPS networks aim to provide service differentiation when contention occurs

by using wavelengths and FDL assignment algorithms. In Callegati, Corazza, and Raffaelli (2002), two mechanisms have been proposed to provide service differentiation over an OPS network. An overview of these algorithms is given as follows (Kaheel et al. 2002).

Wavelength Allocation

Using *wavelength allocation* (WA), available wavelengths are divided into different groups. Each group is assigned to a different priority level such that higher priority levels get a larger part of the available wavelengths. Wavelength allocation algorithms are similar to those used to provide QoS differentiation over a WR network. Based on the wavelength domain, WA techniques may provide a QoS differentiation over an all-optical OPS network without the need for FDL buffers.

Integrated Wavelength Allocation and Threshold Dropping

In addition to wavelength allocation, integrated *wavelength allocation and threshold dropping* (WATD) uses threshold dropping to ensure a QoS differentiation. If the FDL's buffer occupancy is over a certain limit, lower-priority packets are dropped. By using a different dropping threshold for each priority level, various classes can be supported. Even though it may provide a better differentiation than the bufferless WA, WATD generates a more computational overhead.

The implementation of the aforementioned differentiation techniques over an OPS network can be complex because of the required synchronization between the packet header and packet payload. This process requires the packet payload to be delayed in the FDL buffer until the header is fully processed and the packet is classified. This is done on a packet-by-packet basis, which limits the switching speed. In addition, new techniques will be required to permit an individual access to variable-sized packets stored in fiber delay lines.

OPTICAL LABEL-SWITCHING NETWORKS

IP-over-WDM has been envisioned as the most promising solution for next-generation Internet architectures. IP-over-WDM networking adopts wavelength routing, mainly based on OXCs and a GMPLS control plane (Ashwood-Smith and Berger 2003; Berger 2003). In such an architecture, the minimum granularity of all-optical connections is often a single wavelength, which may lead to an inefficient utilization of resources. OPS technology has emerged as a promising solution for the next-generation IP-over-WDM architecture. OPS would avoid the electronic switching bottleneck and offer a packet-based optical switching solution that matches WDM transmission capabilities. Nevertheless, the achievement

of such a task faces significant difficulties because OPS requires the development of component and system technologies that are still not available because of technological constraints. Considering the efficiency of MPLS in terms of signaling, traffic engineering, and QoS requirements, optical label-switching technology, which aims to implement MPLS over WDM networks, seems to be a promising solution. The common label-switching concept implies a natural compatibility of OLS networking with the MPLS architecture and its extensions defined by MP λ S and GMPLS.

Forms of MPLS

This subsection discusses the concept of optical label-switching networks in light of interoperability and faultless network upgrades in the context of MPLS, MP λ S, and GMPLS.

Multiprotocol Label Switching

MPLS is a switching approach that has been proposed for IP networks with two main objectives: (1) provide a more efficient packet-forwarding mechanism than traditional routing and (2) provide tools for signaling, QoS, and traffic engineering. The principle of MPLS is that every packet is assigned a label, and packets are forwarded along a path where each router makes forwarding decisions based only on the label content. Figure 5 illustrates the principle of the MPLS technology. At each hop, the router substitutes the existing label for a new label, which tells the next hop how to forward the packet. Simple forwarding increases the speed of the forwarding process inside the MPLS network, which may improve the provided QoS in terms of delay and variation of delay (jitter). An IP router that supports MPLS technology is called a *label-switching router* (LSR).

The ingress LSR is the node through which an IP packet enters the MPLS domain. It assigns a label and adds an MPLS header to the packet. If the packet is integrated with a QoS operation, then the ingress LSR will condition the traffic accordingly (e.g., Diffserv). The egress LSR is the router from which the packet leaves

the MPLS domain. It removes the MPLS header that was added by the ingress node and switches the packet to its destination network. Both ingress LSRs and egress LSRs are edge nodes that connect the MPLS network to other networks (e.g., IP networks). The core LSR, also called the *interior LSR*, uses the MPLS header to make forwarding decisions and perform label swapping.

A *label* is a small identifier generated by the ingress LSR and placed in the MPLS header. The implementation of the MPLS technology requires each node to maintain a label-swapping table known as the *label information base* (LIB). By looking up the input port and label in the LIB, the output interface and label are determined. Then the LSR replaces the input label by the output label and forwards the packet. The labels are locally significant only, which means that the label is only useful and pertinent on a single link between adjacent LSRs. The adjacent LSR label tables, however, should form a path through the MPLS network—a virtual connection called a *label-switching path* (LSP). The major advantage of MPLS is its capability to perform traffic engineering. Using MPLS, the LSP is established between two points on a pure packet-switched network. MPLS uses the LSPs in a manner similar to connection-oriented networks (e.g. ATM) while keeping the fundamental efficiency and operation of a packet-switched network. Others benefits of MPLS are in virtual private network applications, multicast, and QoS provision. Although MPLS has added a set of important ATM-like features to IP without accompanying its signaling complexity, MPLS is strictly a data networking protocol that is completely insensible to the abilities of WDM optical networking.

Multiprotocol Lambda Switching

MP λ S was proposed to adopt MPLS traffic engineering as the control plane for optical cross-connects. The main idea behind the design of MP λ S is to facilitate the provisioning and reconfiguration of lightpaths in OXCs using MPLS traffic-engineering functions. MP λ S utilizes the following components of MPLS traffic engineering control plane: resource discovery, state information dissemination,

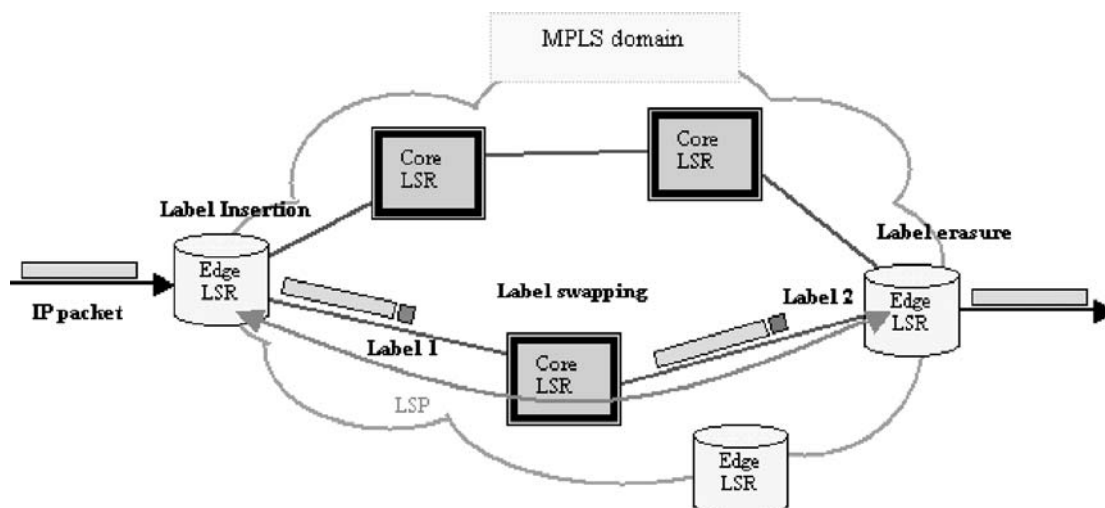

Figure 5: MPLS technology

path selection, and path management (Yoo 2003). MP λ S stands for OLS, and the technology concerns routing individual wavelengths—that is, lambdas (λ 's). Rather than swap labels on a per-packet basis at each hop, λ 's are swapped between the input and output port of OXCs. MP λ S may be the key to unify the control plane for all optical elements, and this can help in provisioning services and optical paths while enabling IP network fast reestablishment and traffic engineering. Although MP λ S was successful in combining MPLS with WDM, the integration between data networking and optical networking was insufficient. OLS will look for a perfect integration between data and optical networking by means of optical labels (Yoo 2003).

Generalized Multiprotocol Label Switching

GMPLS (Mannie 2001; Banerjee et al. 2001; Yoo 2003) is a multiplatform control plane technology that is designed to control not only packet-switching devices but also devices that perform switching in the time, space, and wavelength domains. Like MPLS, GMPLS ensures the separation between the control and data plane, which may be useful when transparent optical network elements are utilized. Although MPLS is limited to a logical separation between the control and data plane, GMPLS allows the control plane to be physically different from the associated data plane. For example, a packet-switching label path LSP1 may be nested in the subordinate time division multiplexing label-switching path LSP2 (e.g., OC-48), which in turn is enveloped in a lambda-switched label-switching patch denoted by LSP3 (e.g., OC-192). Therefore, the end-to-end LSP can be set up across physically diverse hierarchical LSPs (Yoo 2003). GMPLS allows signaling across the IP, MPLS, and MP λ S domains. It basically accommodates any network elements that perform switching in the time, space, and wavelength domains. Interoperability of OLS networks with other networks is achieved via the GMPLS extension known as GMPLS II (Yoo 2003).

Optical Label Switching

The OLS networks utilize a short optical label attached to the data payload, which allows the optical label switching routers (OLSRs) to make decisions about data payloads forwarding. Provided that the optical label is used, the data payload can be of any protocol, format, and length. Therefore, OLS-based circuit switching, burst switching, and packet switching are possible in the optical layer (Yoo 2003). Coming from different networks, the packets are encapsulated, provided with the optical label, and sent through the optical network. To make forwarding decisions, OLSRs only need to look at the optical label. The OLS core network is capable of supporting multiple transport modes with full interoperability between circuit, burst, and packet switching, thus providing a multiservice platform to interface with various client networks.

Figure 6 depicts the structure of an OLS node as it is presented by the National Communications System (2002). When the OLS node receives a packet, both the payload and the header are on the same wavelength; however, the header is on a different subcarrier (1). The optical signal is then split and received by a subcarrier receiver (3) and a fiber delay line (2). The FDL delays the optical signal, whereas the subcarrier receiver forwards the optical label to the optical header processor, which processes the optical label and sets up the switch fabric before the packet arrives from the fiber delay lines (4). Finally, the OLS node receives the packet, deletes the old header information, appends a new optical header, and forwards the packet across the predetermined switched path (5).

OLS provides a means of transmitting the optical header in band and on the same wavelength as the payload; this means that there is no need for the control plane to be separated from the data plane (Yuan and Jue 2004). The data payload is transmitted in the optical domain through an OLS network and therefore requires no electronic processing. However, because of current technological constraints, the optical header must be processed electronically.

Figure 6: Optical label switching

Contention Resolution in OLS Routers

A contention problem occurs when multiple traffic units contend, at the same time, for the same output fiber and the same output wavelength. In case of contention, the OLSR can use one or a combination among the following three mechanisms: wavelength conversion, FDL buffering, and deflection routing (Yoo 2003). The wavelength dimension available in optical routers provides new capabilities far beyond traditional routers, which use electronic buffering as the main approach for switching conflict resolution.

Wavelength Conversion

Wavelength conversion is done when a contending packet is converted to one of the available wavelengths of the intended output fiber. The alternative wavelength routing may achieve the same propagation delay and number of hops; it avoids the difficulties in sequencing multiple packets. From this point of view, wavelength conversion is attractive compared to FDL buffering and deflection routing.

FDL Buffering

In case of contention, one of the contending packets is sent to the intended output channel while the rest are sent to the appropriate fiber delay lines. A delayed packet will be re-sent later to the same OLSR. The choice of the length of the delay line can be arbitrary; however, there will be a trade-off between the contention-resolution efficiency and the maximum latency. A limited number of delay buffer lines can be included in the optical router, and multiple wavelengths are housed in each optical delay line. The OLSR includes both wavelength conversion and buffering so that packet wavelength can be converted to another wavelength if the buffer is using the original wavelength.

Deflection Routing

In this case, a packet may be deflected to an adjacent OLS node from which it can be forwarded toward its destination. Attention must be taken to prevent a packet from being repeatedly deflected, thus leading to signal degradation and resource wasting. This can be avoided based on *optical time-to-live* (OTTTL) control information, which indicates, in a real-time manner, the expected lifetime of the packet. Unlike the traditional time to live (TTL), OTTTL does not require rewriting the label.

SIGNALING IN WDM OPTICAL NETWORKS

Signaling protocols are used to set up and remove connections. Different signaling protocols have been proposed for the implementation of the above-presented optical switching techniques. Among these protocols we can mention lightpath establishment schemes, JET, JIT, and *resource reservation protocol-traffic engineering* (RSVP-TE) in MPLS networks and its extensions for GMPLS.

Signaling in WR Networks

As mentioned in the second section of this chapter, a WR network is an optical circuit-switched network in which the transfer of each data flow is preceded by the establishment of an all-optical lightpath between edges of the network.

Lightpaths

Lightpath establishment in a WR network is done in two steps: path selection and channel assignment. *Path selection* involves selecting a path from source to destination based on certain criteria. *Channel assignment* refers to assigning a wavelength channel on every link of the chosen path. Path selection can be carried out in several ways. If a source-destination pair has one pre-selected path, then it is referred to as a *fixed-path approach*. If a path is selected depending on the network status from a preselected set of candidate paths, then it is called *dynamic path selection*. With this selection, the set of candidate paths remains the same all of the time and does not change. If the candidate paths are chosen based on the network status, then the path-selection process is referred to as *exhaustive routing*. Channel assignment process ensures the allocation of the appropriate transmission channel on every link of a selected path. This results in (1) a fiber, wavelength, and time slot assignment in the case of a WDM grooming networks, and (2) a fiber and wavelength assignment in a WR WDM network.

When establishing a lightpath over a WR network, the same wavelength is used on every link along the selected path. If the required wavelength is not available at the outgoing fiber of an OXC, then the establishment of the lightpath is blocked. To decrease the probability that a lightpath is blocked, the OXC can be equipped with wavelength converters. Figure 7 shows an example

Figure 7: Example of lightpaths

of different lightpaths. The physical topology of a WR network consists of edge nodes, OXCs, and the fibers that connect them. The lightpaths are set up between edge nodes over this physical topology and constitute a logical topology. Each lightpath is assigned a path through the network and a wavelength on that path. Finding routes for the lightpaths through the physical topology and assigning wavelengths to these lightpaths is called the *routing and wavelength assignment problem* (Zang, Jue, and Mukherjee 2000).

Protection and Restoration Schemes

In a wavelength-routed WDM network as well as in other optical networks, the failure of a network element may cause the failure of several optical channels, thereby leading to large data and revenue losses. Therefore, it is imperative to implement appropriate protection and restoration schemes to prevent or reduce data loss. In protection schemes, backup resources are precomputed and reserved for each connection before a failure occurs. In restoration schemes, an alternate path is discovered dynamically for each interrupted connection after a failure occurs. Compared to restoration schemes, protection schemes have faster recovery time and provide guaranteed recovery ability but require more network resources (Yuan and Jue 2004).

Protection Schemes. Protection schemes can be classified as link protection and path protection. In *link protection*, separate backup resources are allocated for each individual link on the working path. In *path protection*, a working path and a disjoint protection path are established for each connection. Path protection usually has lower resource requirements and lower end-to-end propagation delay for the recovered route. Protection schemes can be also divided into dedicated and shared protection schemes. *Dedicated* protection schemes need more network resources, but they are easier to implement. *Shared* protection schemes provide a more efficient resources utilization, but they require more complex signaling (Yuan and Jue 2004).

Dedicated Path Protection. A dedicated link-disjoint backup lightpath is established in advance for each connection that needs to be protected. In 1+1 path protection, the same traffic is transmitted simultaneously on the primary and backup paths. Upon detecting a failure on the primary path, the receiver will switch to continue to receive information from the backup path. This scheme is fast, but there may be a traffic disruption because of the delay difference between the primary and backup paths. In 1:1 path protection scheme, the protected traffic is only transmitted over the primary path; when the primary path fails, the protected traffic is switched to the backup path. Both the sender and the receiver must use signaling to detect the fault and initiate the switchover.

Dedicated Link Protection. Using this dedicated link protection, a backup path and a wavelength are reserved around each link of the primary path during connection setup and are dedicated to that connection. In general, it may not be possible to allocate a dedicated backup path around each link of the primary path.

Shared Path Protection. With the shared path protection scheme, the resources along a backup path may be shared with other backup paths. As a result, backup channels are shared among different failure scenarios that are not expected to occur at the same time; thus, shared path protection provides more efficient resources utilization when compared to dedicated path protection.

Shared Link Protection. Similar to shared path protection, shared link protection reserves backup resources along the backup path and may be shared with other backup paths. Thus, backup channels are shared among different failures scenarios that are not expected to occur simultaneously.

Restoration Schemes

Restoration schemes can be divided into path restoration and link restoration based on the level of network resources involved in the restoration. In link restoration schemes, all of the connections that are concerned with a failed link are rerouted around that link. Source and destination nodes of connections traversing the link are ignorant of the link failure. The end nodes of the link dynamically discover a route around the link for each wavelength that traverses it. They may participate in a distributed procedure to look for new paths for each active wavelength. When a new route is discovered for a wavelength channel, the end nodes of the failed link reconfigure their OXCs to reroute that channel onto the new lightpath. If no new routes are discovered for a wavelength channel, then the connection that utilizes that wavelength is blocked. With path restoration, when a link fails, the source node of each connection that traverses the failed link is informed about the failure. The source node discovers a backup route on an end-to-end basis. When a new route and wavelength channel are discovered for a connection, network elements such as wavelength OXCs are reconfigured appropriately, and the connection switches to the new path. If no new routes are discovered for a failed connection, then that connection is blocked.

Signaling in OBS Networks

Signaling and reservation are important criteria on which OBS can be differentiated from other optical switching technologies. As shown in Figure 8, OBS adopts a signaling approach in which the burst header packet is sent ahead of the associated data burst by an offset time in order to allocate resources and configure optical switches at each node (Vokkarane 2004). In the following subsection, we will look at different design parameters that affect the performance of an OBS signaling technique and also describe the most important signaling protocols proposed for the implementation of an OBS network.

Connection Setup

The connection set up over an OBS network can be either one-way (i.e., tell and go) or two-way (i.e., tell and wait) (Vokkarane 2004). In a one-way connection setup (Figure 9a), the source sends out a control packet requesting the intermediate nodes to allocate the necessary resources for the burst. No control message is sent

Figure 8: OBS signaling

Figure 9: (a) One-way connection setup and (b) two-way connection setup

back to inform the source about the success or failure of the resource reservation. The main objective of the one-way signaling techniques is to reduce the end-to-end data transmission delay. However, this may lead to high data loss because of switching conflict at intermediate nodes. Two-way signaling schemes (Figure 9b) are acknowledgment-based, whereby the data burst is transmitted only after a connection is established successfully. The main objective of the two-way signaling approach is to minimize packet loss; however, it may lead to high data transfer delay because of the round-trip delay during connection establishment.

Resource Reservation and Release

Based on the adopted resources reservation mechanism, OBS signaling techniques can be classified as immediate reservation or delayed reservation (Vokkarane 2004). With the immediate reservation approach, the channel is reserved immediately from the instant that the burst

header packet is processed. In the delayed reservation, the required bandwidth is reserved from the time at which the burst will arrive at the node. In this case, the BHP must carry the offset time between itself and its corresponding data burst. In general, immediate reservation is simple and practical to implement but incurs higher blocking because of inefficient bandwidth allocation. On the other hand, the implementation of delayed reservation is more complex but leads to higher resource utilization and a lower blocking probability (Vokkarane 2004).

A reserved resource can be released in two ways: either implicitly or explicitly (Vokkarane 2004). In an *explicit release* technique, an intermediate node releases the resources allocated to a burst on receipt of an explicit release message. With *implicit release*, the control packet has to carry additional control information such as the burst length. This permits an intermediate node to know when to release its resources. Obviously, an implicit release technique leads to better resource utilization. Based on the reservation and release mechanisms, the

Figure 10: Resource reservation and release schemes

signaling techniques can be classified into four categories (Figure 10): (1) immediate reservation and explicit release, (2) immediate reservation and implicit release, (3) delayed reservation and explicit release, and (4) delayed reservation and implicit release. We can easily observe that techniques that employing delayed reservation and implicit release result in higher bandwidth utilization, and a lower blocking probability.

OBS Signaling Protocols

Different signaling protocols have been proposed for the implementation of the OBS technology. The most important ones are *just enough time*, *just in time*, *tell and go* (TAG), and *tell and wait* (TAW).

Just Enough Time. Figure 11a illustrates the work of the just-enough-time signaling protocol (Vokkarane 2004). As shown in the figure, a source node first sends a burst header packet to the destination node. BHP is processed at each intermediate node. If the reservation is successful, then the switch will be configured before the burst's arrival. Meanwhile, the burst waits at the source in the electronic domain. After a predetermined offset time, the burst is sent optically through the established data path. The offset time is calculated based on the number of hops from source to destination and the switching time of a core OBS

node. Offset time is calculated as $OT = h \times \delta + ST$, where h is the number of hops between the source and the destination, δ is the burst header processing time at a given node, and ST is the switch reconfiguration time (Qiao and Yoo 1999). If at any intermediate node the reservation is unsuccessful, then the burst will be dropped.

The implementation of JET requires maintaining information related to the starting and finishing times of all scheduled bursts on each channel of each output port of every switch, which makes the system relatively complex. On the other hand, JET is able to detect situations in which no transmission conflict occurs, although the start time of a new burst may be earlier than the finishing time of an already accepted burst—that is, a burst can be transmitted in between two already reserved bursts. Thus, bursts can be accepted with a higher probability in JET.

Just in Time. Just in time (Baldine et al. 2002) is similar to JET except that it employs immediate reservation and explicit release instead of delayed reservation and implicit release. Based on an immediate reservation approach, the JIT signaling protocol is simpler to implement but less efficient in terms of network resource utilization.

Tell and Wait. Tell and wait (Vokkarane 2004) is a two-way signaling protocol that has been proposed to

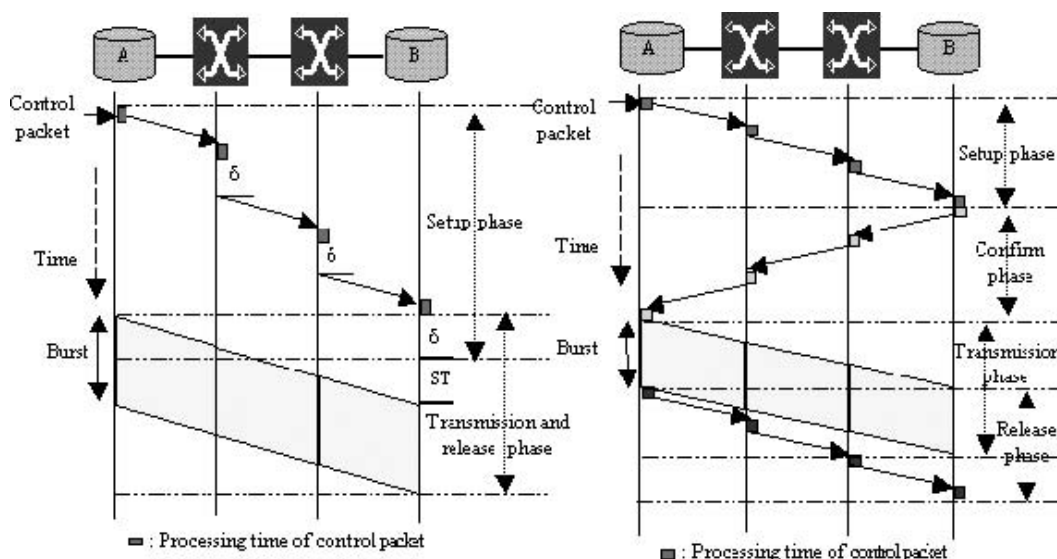

Figure 11: (a) JET signaling and (b) TAW signaling

Figure 12: Optical label structure per class

provide a connection setup over an OBS network. In TAW (Figure 11b), BHP is sent along the burst's route to collect channel availability information at every node along the path. At the destination, a channel assignment algorithm is executed, and the reservation period on each link is determined based on the earliest available channel times of all the intermediate nodes. A CONFIRM message is sent in the reverse direction, which reserves the channel for the requested duration at each intermediate node. If the CONFIRM packet reaches the source successfully, then the burst is sent into the core network.

Tell and Go. Another one-way OBS signaling protocol is the tell-and-go approach (Vokkarane 2004). In this method, the data burst must be delayed at each intermediate OBS node to allow time for the burst header to be processed and for the switch to be configured. This requires the use of FDL buffers at each OBS node to delay data bursts, which may increase both the complexity and the cost of a switching node.

Signaling in OLS Networks

The fundamental concept behind OLS is an efficient and transparent packet-forwarding method using an optical label-switching mechanism. New signaling information in the form of an optical signaling label that contains routing and control information such as the source, destination, priority, and the data payload length is associated with each packet. Each optical label-switching router will receive and process this optical label, look up the forwarding table, and take necessary steps to forward the packet. If the packet is to be routed to a wavelength where there is already another packet being routed, OLSR will use one or more of the following three switching conflict-resolution mechanisms: wavelength conversion, FDL buffering, or deflection routing. Different label-based addressing schemes have been proposed for the implementation of OLS technology. Each addressing scheme relies on a specific optical label class. Four optical label

classes have been defined in Yoo (2003): CLASS_A, CLASS_B, CLASS_C, and CLASS_D. Figure 12 shows the structure of these labels.

A CLASS_A label is a simple destination-oriented forwarding label similar to the IP header. It is deterministic and requires no label swapping. *Optical time to live* indicates the expected lifetime of the optical packet. Compared to the conventional TTL, which overestimates the remaining lifetime in long fiber links and underestimates it in low-loss optical routers, the OTTL directly measures the remaining lifetime of the optical packet (Yoo 2003). The entire content of the CLASS_A optical label is deterministic and requires no label swapping. Often there is a need for additional traffic engineering beyond the simple destination-oriented packet forwarding. The CLASS_B label uses the three experimental bits (EXP) for traffic-engineering purposes for a given destination. Therefore, several different label-switching paths can be defined for the same destination. The CLASS_C label abandons the destination-oriented forwarding but relies on label-switching paths set up through the *constraint route label-distribution protocol* CR-LDP or RSVP-TE (Dutta and Rouskas 2002; Kaheel et al. 2002). The CLASS_D optical label is for circuit switching in which OLSR will cease to switch packet by packet or burst by burst; instead, it will be attached to a circuit flow. For packet switching, CLASS_A will be dominantly a popular format even though CLASS_B and CLASS_C may also be used. For burst switching, CLASS_C will be dominantly used, although CLASS_B and CLASS_A can also be used. CLASS_D will be used for circuit switching (Yoo 2003).

Examining Figure 12, we note that for the different proposed optical labels, the priority bits distinguish between the *class of service* (CoS), the QoS defines the quality of service, and the *type of service* (ToS) field defines service type. CoS may be used for a priority-based differentiated packet forwarding, which only provides a relative QoS differentiation and not an absolute QoS guarantee. QoS bits are used to provide a guaranteed assurance of QoS parameters. ToS specifies the type of

applications such as real-time applications. For example, IP telephony packets may have low-priority CoS and allow high packet loss QoS but will require real-time ToS.

GMPLS Signaling

The ability to control switched packets, *time division multiplexed* (TDM) network traffic, and optical network components make GMPLS flexible enough to be positioned in the direct migration path from electronic to all-optical network switching. The five main interface types supported by GMPLS are (1) the *packet-switch capable* (PSC) interface, (2) the *layer-2 switch capable* (L2SC) interface, (3) the *time division multiplexing capable* (TDMC) interface, (4) the *lambda switch capable* (LSC) interface, and (5) the *fiber-switch capable* (FSC) interface (National Communications System 2002). The management of these interfaces has required many extensions of the MPLS technology. Obvious modifications to the label have been made, and the necessity for a new method of managing the network links has been identified. Slight modifications have been made to MPLS signaling protocols (e.g., CR-LDP and RSVP-TE) to support the multiple interfaces of GMPLS. Basically, the MPLS protocol has morphed into a more generalized structure to support a larger array of network technologies (National Communications System 2002).

Generalized Label

In MPLS, labels are integrated in the cell and packet structure for in-band control plane signaling. With the different interfaces it is impossible to embed label specific information—in terms of fiber port or wavelength switching—into the traffic packet structure. Therefore, virtual labels have been added to the MPLS label structure. These labels are composed of specific indicators that represent wavelengths, fiber bundles, and fiber ports, and they are distributed to GMPLS nodes via out-of-band GMPLS signaling (National Communications System 2002). GMPLS out-of-band signaling leads to a control channel separation issue. In fact, when we send the control information out of band, the label is separated from the data flow that it is attempting to control. GMPLS provides a means for identifying explicit data channels, which allows the control message to be associated with a particular data flow (National Communications System 2002).

Generalized LSP

The handling of LSPs under GMPLS is different from that of MPLS. MPLS does not provide for bidirectional LSPs. Each directional LSP has to be established in turn. With GMPLS, the LSP can be established bidirectionally. The required traffic engineering for the bidirectional LSP is the same in both directions, and it is established for both directions via only one signaling message. This allows for reductions in latency related setup time.

Another difference between MPLS LSPs and GMPLS LSPs is the ability to handle multiple adjacent links, which may reduce the number of link advertisements that need to be maintained, thus increasing the scalability of GMPLS. Just like MPLS, GMPLS labels only contain information about a single level of hierarchy.

The difference for GMPLS is that this hierarchy can be based on fiber, wavelength, time slot, or packet or cell. For example, if a connection is desired from one PSC interface to another and the traffic traverses physically separate fibers, a unique LSP will have to be established for each level in turn. First, the FSC LSP, then the LSC LSP, then the TDMC LSP, and finally the PSC LSP would have to be established via GMPLS signaling (National Communications System 2002).

Link Management Protocol

The *link management protocol* (LMP) protocol (National Communications System 2002) was developed to address several link specific problems that surfaced when generalizing the MPLS protocol across different interface types.

The following is a list of the proposed responsibilities of LMP as it relates to GMPLS.

- **Control channel management:** This management is used to establish and maintain control channels between LMP adjacent nodes. The control channel can be used to exchange routing, signaling, and other control messages.
- **Link connectivity verification:** Such verification is used to confirm the physical connectivity of the data links between the nodes. A pair of nodes exchange test messages on a periodic basis to verify the physical connectivity of the data links. The verification messaging must be transported through the data channel, not the control channel.
- **Fault management:** This management provides a fault localization procedure to localize failures. It can localize the path failure by quickly reporting the status of one or more data links. It is designed to work for both unidirectional and bidirectional LSPs.

Network Restoration and Reliability

In addition to the above-presented extensions required for the development of the GMPLS protocol, GMPLS adds techniques for fault detection, fault localization, fault notification, and fault alleviation using either protection or restoration schemes (National Communications System 2002). Fault detection occurs within the equipment nearest to the fault. LMP provides procedures for fault localization within both optical and opto-electronic networks. The protocol sends ChannelFail messages over control channels that are separate from the data plane. Separation of the control and data planes allows support for fault localization independently of the data transmission method, whether it happens to be ATM, synchronous optical network, WDM, or frame relay. GMPLS handles failures using combinations of protection and restoration schemes. GMPLS supports 1+1, 1:1, and 1:N. GMPLS path restoration precomputes alternative restoration paths. To do so, GMPLS accelerates the rerouting of failed LSPs and improves the reliability of the LSP restoration after a failure. GMPLS provides fault notification for restoration with its addition of Notify messages within RSVP-TE (National Communications System 2002).

SWITCHING PERSPECTIVES

The challenges and perspectives of the switching techniques are typically organized around three issues: IP-based switching, network engineering, and QoS provision.

IP-Based Switching

As presented earlier, *IP-over-WDM* (IP-WDM) has been considered the most promising solution for the next-generation Internet backbone. Such IP-WDM architecture will combine IP routers with WDM switching systems to provide a global networking infrastructure for both legacy and emerging IP services. Efforts are being made to reduce the gap between the electrical IP layer and the optical WDM layer. Current IP-WDM networking adopts wavelength routing mainly based on OXCs and the GMPLS control plane. In such an architecture, no wavelength sharing is possible between two distinct all-optical connections, which may lead to inefficient network resource utilization. The realization of subwavelength granularity over a wavelength-routed network requires the use of an optical-electrical-optical conversion at each switch, which leads to a scalability problem of electronic IP routers to match the huge transmission capacity of WDM fibers.

To overcome the problem of inefficient bandwidth utilization, an all-optical WDM switching technology with a finer switching granularity is required for the implementation of the next-generation optical Internet. Recently, optical packet switching, which is capable of packet forwarding at the optical layer, has emerged as a highly promising technology for the optical Internet (Sivalingam and Subramaniam 2005; Papadimitriou, Obaidat, and Pomportsis 2002). This approach would bypass the electronic switching bottleneck and provide an optical switching solution that matches transmission needs. Nevertheless, the accomplishment of such progress faces significant challenges because OPS requires practical, cost-effective, and scalable implementations and necessitates the development of several optical components such as an optical synchronizer for packet delineation, optical memory for packet buffering and traffic engineering, and optical components for all-optical packet header recognition and swapping. To achieve these objectives, different research activities are underway. Photonic memory and optical packet header processing constitute the most important active research areas toward the implementation of the OPS technology.

Network Engineering

Processing packet headers at the optical level is a critical issue. In Naoya and Kubota (2005), an all-optical packet header processing method is proposed. The method assumes that the header has an optical code-based label of the destination node. An optical label processor analyzes the headers optically based on a set of optical correlators working as a label bank, which stores optical codes corresponding to the destination addresses in the routing table. Label recognition is based on parallel optical correlation in the time or frequency domain

(or both) between an input optical label (code) and the labels in the label bank. Each correlator decodes the input label of each packet header and outputs the signal, which has high or low value in matched and unmatched cases, respectively. A high-value signal opens a gate switch of a destination port, whereas a low-value signal keeps other switches closed. Three label-processing methods, based on different optical correlators, have been investigated in Naoya and Kubota (2005): (1) those based on planar lightwave circuits with binary phase shift keying code labels, (2) those based on multisection fiber Bragg gratings with multiwavelength labels, and (3) a holographic multiple correlator with on-off keying labels.

In addition to the above-presented propositions toward all-optical header processing, which is needed for high-speed processing for a broadband photonic network, different research activities are being conducted, including (1) the development of easy-to-use optical buffer memory, (2) the definition of efficient techniques for planning and dimensioning WDM optical networks, and (3) the definition of different mechanisms related to traffic management and QoS support. Because of technological constraints, using FDLs remains the most feasible way to implement optical buffers. Recently, in spite of optical technology's relative immaturity, different propositions have been made toward optical buffer development. In fact, an optical memory has various advantages over FDL buffers such as compactness, random access capability, long-term storage, large capacity, and easy control. A prototype of a "photonic" memory has been proposed in Takahashi (2004).

QoS Provision

QoS support constitutes a crucial issue in the development of all-optical WDM networks to provide QoS support for applications with diverse QoS demands. Therefore, different research activities are being conducted in developing QoS support over all-optical WDM networks. The development of the OLS technology constitutes an attempt to have an IP-over-WDM architecture that is able to provide QoS support for IP applications. In fact, OLS constitutes an adaptation of the MPLS technology for all-optical WDM networks, which may provide QoS support, considering the efficiency of MPLS in terms of traffic forwarding, signaling, and QoS guarantees. Several schemes have been proposed to provide a QoS support in IP-WDM architecture. In Chen, Hamdi, and Tsang (2001) and Zhang et al. (2004), an early dropping mechanism and a wavelength grouping scheme have been proposed to provide an absolute QoS guarantee over an OBS network. In Lazzez et al. (2006), a priority-based contention resolution has been proposed to provide a relative QoS differentiation over an OBS network. The analysis of these QoS mechanisms shows that the majority of them represent nothing but simple adaptations of those proposed for traditional electronic networks (e.g., ATM and IP). Unfortunately, this does not allow a high level of resource usage. Thus, the development of appropriate QoS mechanisms, taking into account the optical nature of WDM, will constitute an active area of research.

In addition to QoS support issues, optical networks face another crucial issue: the guarantee of security as required by different applications. Security concerns are part of the QoS provision. WDM networks are vulnerable to various forms of service denials or eavesdropping attacks. Attacks on WDM networks can be classified into three broad categories (Médard, Chinn, and Saengudomlert 2001; Papadimitriou, Papazoglou, and Pomportsis 2003): (1) quality-of-service degradation in which the attacker overpowers legitimate optical signals with attack signals, (2) traffic analysis and eavesdropping in which the attacker analyzes the traffic and attempts to degrade its quality, and (3) service denial in which the optical signal is disrupted by the attackers. Although most of the traditional security issues pertaining to traditional networks are applicable to optical networks equipped with converters, the nature of the signal makes it hard to apply security mechanisms and cope with network speed. The development of mechanisms to prevent and detect these types of attacks is an active area of research but one still in its infancy.

CONCLUSION

The emergence of multimedia applications is driving the demand for high-speed transmission to support ever-increasing bandwidth requirements. WDM technology has the capacity to transmit data at speeds of as much as a Terabit/s. Thus, an all-optical switching technology that is able to match WDM transmission capabilities is required to efficiently use this huge transmission capacity. In the evolution of optical networking, the most important switching techniques are wavelength routing, optical burst switching, optical packet switching, and optical label switching. In this chapter, we have presented a detailed overview of the optical switching techniques and discussed the main issues in the development of these services. Mainly, we have addressed the routing and wavelength assignment problem, protection and restoration, contention resolution, and QoS support—that is, the major concerns in the development of WDM all-optical networks. In addition, we focused on the signaling issue and presented some of the existing schemes proposed in the literature for the development of the considered optical switching techniques.

As optical technology advances and optical switching vision become closer to reality, different challenges emerge. Challenges and perspectives of optical switching techniques are organized around three major issues: IP-based switching, network engineering, and QoS provision; these are active areas of research in the development of all-optical WDM networks. Even though different schemes have been developed, additional schemes may still be necessary to provide better QoS provision and achieve more efficient resource utilization over a WDM optical network.

GLOSSARY

Generalized Multiprotocol Label Switching (GMPLS): A multiplatform control plane technology to support not only devices that perform packet switching but also devices that perform switching in

time, space, and wavelength domains. The capacity of controlling not only switched packets but also TDM network traffic and optical network components makes GMPLS flexible enough to be placed in the direct migration path from electronic to all-optical network switching.

Multiprotocol Label Switching (MPLS): A recent switching technology proposed for IP networks for a more efficient packet forwarding, QoS management, and traffic engineering. The principle of MPLS is that packets are assigned a label, and packets are forwarded along a path where each router makes forwarding decisions based solely on the contents of the label.

Optical Burst Switching (OBS): In optical burst switched networks, bursts of data consisting of multiple packets are switched through the network all-optically. A control message is transmitted ahead of the burst to configure the switches along the burst's route. The burst follows the header without waiting for an acknowledgment that resources have been reserved and switches have been configured along the path.

Optical Label Switching (OLS): An extension of MPLS for OPS networks in which new signaling information is added in the form of optical labels. The optical label contains routing and control information such as the source, destination, priority, and packet length that will propagate through the network along with the data payload. Each optical label-switching router will sense the optical label, look up the forwarding table, and take the necessary steps to forward the packet.

Optical Packet Switching (OPS): A packet-switching scheme that is capable of dynamically allocating network resources with decisions made at the packet level. In an OPS network, individual photonic switches are combined to form a network. In packet-switched networks, bit-level synchronization and fast clock recovery are required for packet header recognition and packet delineation.

Optical Switching: The capacity of traffic units switching in the optical domain—that is, without the need of an optical-electrical-optical conversion at switching nodes. Different optical switching techniques have been proposed for WDM optical network. The most important are wavelength routing or optical circuit switching, optical burst switching, optical packet switching, and optical label switching.

Wavelength Division Multiplexing (WDM): A fiber-optic transmission technique that multiplexes different wavelength signals onto a single fiber. Each fiber has a set of parallel optical channels, each using different light wavelengths. It employs light wavelengths to transmit parallel-by-bit or serial-by-character data. WDM is an essential function for optical networks that allows the transmission of data (IP, ATM, SONET-SDH, etc.), over the optical layer.

Wavelength Routing (WR): The first optical switching technique proposed for WDM optical networks. It follows the main concepts of traditional circuit-switched networks. It is used in network backbones. To set up a communication channel, a route between the source-destination pair is chosen with appropriate wavelengths allocated on the links along the route.

INTRODUCTION

The *synchronous optical network* (SONET) is a standard for optical transport defined by the American National Standards Institute (ANSI). The standard was initiated by Bellcore (now Telcordia) on behalf of the regional Bell operating companies to provide a common framework for optical telecommunications. A similar standard defined by the European Telecommunications Standards Institute for Europe—the *synchronous digital hierarchy* (SDH)—is now used everywhere outside of North America and Japan.

SONET and SDH is a physical-layer standard that was originally conceived to provide high-capacity links in a circuit-switched network environment. Both SONET and SDH are based on a structure that has a basic frame and speed. Multiple lower-level SONET and SDH signals can be *time division multiplexed* (TDM) to form higher-level signals. SONET defines rates, formats, and optical parameter specifications for optical interfaces ranging from 51.84 Mb/s (OC-1) to 39.8 Gb/s (OC-768) capacities. Other reasons for the worldwide deployment of SONET and SDH transport infrastructures include:

1. highly survivable and reliable networking because of standardized protection switching architectures;
2. powerful *operations, administration, maintenance, and provisioning* (OAM&P) capabilities that allow service providers to efficiently monitor the network performance and operations remotely; and
3. multivendor interworking and interoperability because of mature standards.

It has been widely established that data traffic has overtaken voice traffic in terms of *wide area network* (WAN) bandwidth utilization. Obviously, most of this traffic growth is driven by the growth of the Internet. Demand for high-speed corporate services across wide

areas is rapidly growing as companies become increasingly geographically diverse, e-commerce data exchange proliferates, and direct access to offsite data storage is required. Thus, there is growing need to transport *Internet protocol* (IP), Ethernet, and *storage area networking* (SAN) traffic over SONET infrastructures to provide metro and wide-area connectivity. Because the SONET data rate hierarchy was optimized to transport payloads of voice traffic, it requires new mechanisms to carry packet data efficiently. New protocols have been developed to transport all types of packets, including Ethernet frames, using SONET pipes. These mechanisms include *packet over SONET* (POS), virtual concatenation, and emerging protocols such as the *generic framing procedure* (GFP).

The organization of the chapter is as follows. We first examine the SONET system and its layered architecture. SONET's multiplexing hierarchy is covered next along with a discussion of the *synchronous transport signal 1* (STS-1) frame structure and mapping of non-SONET payloads. Then we examine use of pointers to synchronize SONET payload in a SONET frame. The concept of virtual tributaries to map legacy digital hierarchy data signals (DS-1 to DS-3) into a SONET STS-1 frame is covered next. This is followed by a description of SONET overhead, which allows simpler multiplexing and greatly expanded OAM&P capabilities. Next we consider mapping of high-speed nonmultiplexed data payloads into concatenated SONET frames. A description of popular SONET network elements and configurations follows next. The concepts of protection switching and self-healing SONET rings are discussed in following sections. We then describe data transport over SONET and SDH using PPP/HDLC and ATM/AAL5 framing. This is followed by a discussion of GFP and virtual concatenation mechanisms for flexible provisioning of Ethernet, SNA, and other data services that use SONET transport.

SONET SYSTEM ARCHITECTURE

As defined by the American National Standards Institute (ANSI) (1995, "T1.105-2001"), SONET is a hierarchy of links that are terminated by *network elements* (NEs) that incorporate different layers of functionality. In SONET terminology, a *section* is a single fiber span between adjacent SONET network elements or regenerators. A *line* is a span between adjacent multiplexers and usually encompasses multiple sections. A *path* is a span between SONET terminals at the end of network and usually encompasses multiple lines. Figure 1 illustrates the transport hierarchy as defined in SONET standard.

SONET functionality is divided into four layers—optical, section, line, and path—as shown in Figure 2. All of these layers need not be implemented by every SONET network element.

Although SONET has a layered architecture, it is important to note that it mainly deals with the physical layer of the OSI reference model. A layer 3 in SONET has no relationship with the layer 3 (network layer) of the OSI protocol stack. As in layered architectures, each SONET layer requires the services of the layers below it to perform its functions properly. A description of SONET layers follows.

The *optical layer* provides transport of bits across an optical fiber and converts STS-*N* electrical frames into optical carrier (OC) signals.

The *section layer* performs framing, scrambling, and other functions associated with the preparation for physical transport across a single section.

The *line layer* multiplexes multiple path layer payloads into SONET STS-*N* frames. Its main functions are to provide synchronization, line error and status monitoring, and protection switching.

The *path layer* maps non-SONET payloads—DS-1, DS-3, fiber distributed data interface (FDDI), ATM cells, and so on—into SONET signals. It also provides end-to-end error and status monitoring and path protection.

In SONET terminology, a *regenerator* (also called a *repeater*) is called the *section-terminating equipment* (STE). It implements the optical and section layer functions. The SONET equipment that implements three lower-layer functions of the SONET architecture is called the *line-terminating equipment* (LTE). It is either a line multiplexer

Figure 2: SONET functional layers

(e.g., STS-1 to STS-*N*), an *add-drop multiplexer* (ADM), or a *digital cross-connect system* (DCCS). The equipment that implements all four layers of the SONET architecture is called the *path-terminating equipment* (PTE). The PTE is a SONET terminal or *terminal multiplexer* (TM). For example, an STS-1 SONET terminal assembles twenty-eight DS-1 signals and inserts path overhead to form a 51.84 Mb/s STS-1 signal.

Figure 3 illustrates the functional layers implemented in section-, line-, and path-terminating equipments. Often, PTE and LTE are implemented in one piece of equipment. Note that all SONET equipment types implement the optical and section layer functions. Line layer functions are found in the multiplexers and end terminal equipment. The path layer function occurs only at the end terminal equipment.

SONET MULTIPLEXING HIERARCHY

The SONET standard uses a 51.84 Mbps electrical signal, known as the *synchronous transport signal-1* (STS-1), as a basic building block to extend the digital transmission hierarchy into the multi-Gigabit/second range (ANSI 1995, "T1.105-2001"). Higher-rate SONET signals are produced by interleaving bytes from the lower-level STS signals. For example, an STS-*N* signal is formed by byte-interleaving *N* STS-1 signals. Each STS-*N* electrical signal has a corresponding *optical carrier level-N* (OC-*N*) signal. The optical OC-*N* signal is formed by scrambling the electrical STS-*N* signal using the standardized polynomial and then modulating an optical source. The

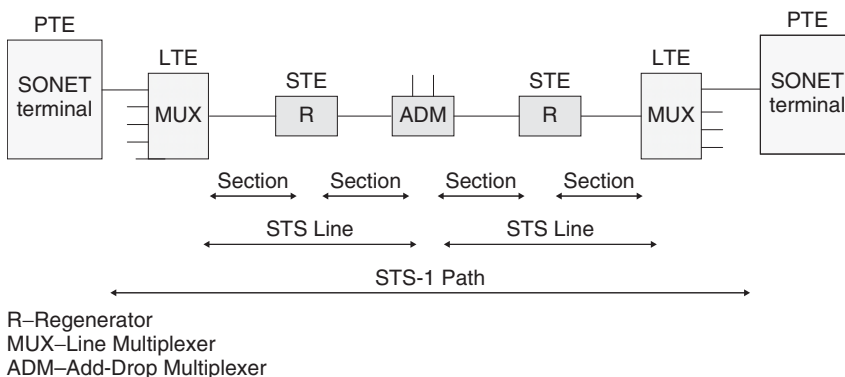

Figure 1: Section, line, and path in SONET

Figure 3: Functional layers in section-, line-, and path-terminating equipment

Table 1: SONET and SDH Hierarchy

SONET Electrical Signal (STS-N)	Optical Signal (OC-N)	Bit Rate (Mbps)	SDH Electrical Signal (STM-N)
STS-1	OC-1	51.84	N/A
STS-3	OC-3	155.52	STM 1
STS-12	OC-12	622.08	STM-4
STS-48	OC-48	2488.32	STM-16
STS-192	OC-192	9953.28	STM-64
STS-768	OC-768	39813.12	STM-256

frame format used by SDH is the *synchronous transport module* (STM), with STM-1 being the base level signal at 155.52 Mb/s [International Telecommunication Union–Telecommunication Standardization Sector (ITU-T) 2003]. The STM-1 signal is converted to an OC-3 optical signal for transmission. Both SONET and SDH have a hierarchy of signaling speeds Table 1 shows the SONET and SDH digital hierarchy. Notice that the rate of an STS or STM-N signal is simply N times the rate of an STS or STM-1 signal.

STS-1 Frame

SONET uses a frame structure that has the same 8-kHz repetition rate as traditional telephone TDM systems. Figure 4 illustrates the structure of the SONET STS-1

frame. SONET uses a frame length of 125 μ sec or a frame rate of 8000 frames per second. Each STS-1 frame can be viewed as a nine-row by ninety-column structure, a total of 810 bytes. The STS-1 line rate = 8 bits/byte \times 9 rows \times 90 columns \times 8000 frames/sec = 51.84 Mb/s. The order of transmission of bytes is row by row from top to bottom, left to right (the most significant bit first).

The STS-1 frame is divided into two main areas: *transport overhead* and the *synchronous payload envelope* (SPE). The first three columns constitute the transport overhead: a total of twenty-seven bytes. The first three rows (nine bytes) of the transport overhead are used for the *section* overhead. The remaining six rows (eighteen bytes) of the transport overhead are used for the *line* overhead. The SPE may start anywhere within the remaining

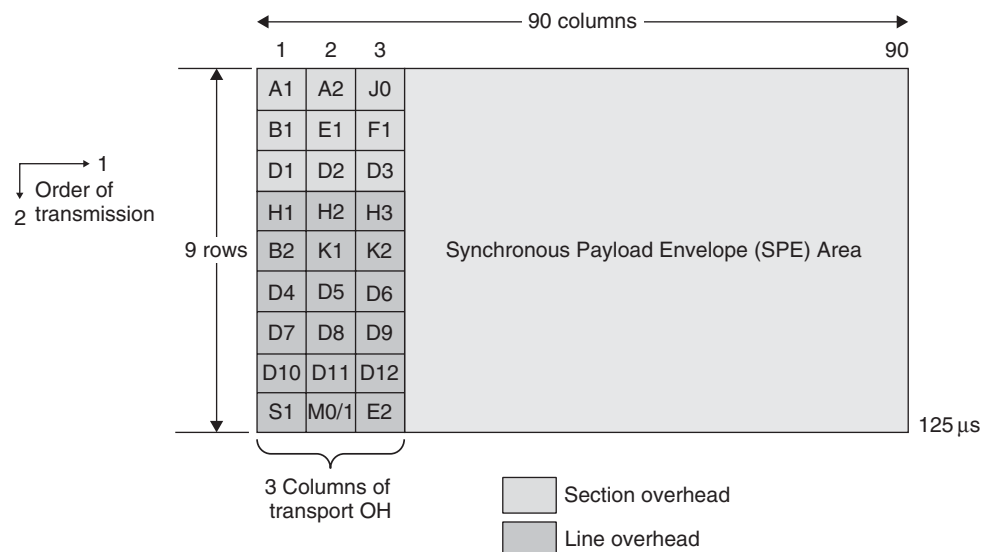

Figure 4: SONET STS-1 frame format

Figure 5: Floating of SPE in two consecutive frames

eighty-seven columns of the STS-1 frame. Unless the SPE happens to start at the fourth column of the first row (rare), it occupies a portion of two consecutive frames as displayed in Figure 5. SPE column 1 (nine bytes) contains the *path overhead* (POH). Two columns in SPE (columns 30 and 59) are not used for payload but are designated as the *fixed stuff* columns. The 756 bytes in the remaining eighty-four columns are designated as the STS-1 *payload* capacity. The bit rate of the STS-1 payload is $8 \text{ bits/byte} \times 9 \text{ rows} \times 84 \text{ columns} \times 8000 \text{ frames/sec} = 48.384 \text{ Mb/s}$.

Mapping of Non-SONET Payloads

SONET was designed to be highly flexible in the types of services that it can carry in its payload. Any type of service, ranging from voice to high-speed data and video, can be mapped into the payload of an appropriate STS-1

or higher level signal (ANSI 1995, "T1.105.02-2001"). A slow-speed mapping function allows DS1, DS2, and *European Conference of Postal and Telecommunications Administrations* (CEPT-1) signals to be combined into an STS-1 signal. A DS3 signal can be mapped into an STS-1 signal, and a CEPT-4 signal can be mapped into an STS-3 signal. Mappings have also been defined for streams of packet information into SONET. For example, ATM streams can be mapped into an STS-3c signal. Packet-over-SONET allows IP packet traffic to be mapped into STS-3c or higher level signals. Figure 6 shows how a SONET multiplexer handles a wide range of payloads.

POINTERS

SONET uses *pointers* to compensate for clock variations in the network. Because of slight differences in the clocks at different nodes, the frames originating from them will not be aligned perfectly. To multiplex these signals, it is necessary to decouple the SPE from the STS-1 frame. The pointers allow payload to *float* within the SPE area to accommodate the phase and clock rate differences.

The first two bytes (H1 and H2) of the line overhead in the STS-1 frame are used as a pointer. The pointer bytes perform two functions: (1) locate the first byte of the STS-1 SPE (where the SPE begins) and (2) indicate the need for frequency justification. The sixteen bits of the STS-1 pointer are classified into three fields as shown in Figure 7. A description of the fields follows.

New data flag (NDF): four bits. $\text{NDF} = 0110 \Rightarrow$ normal operation, $\text{NDF} = 1001 \Rightarrow$ ignore previous content of pointer bytes.

Spare field: two bits.

Pointer (offset) value field: ten bits. Indicates the offset in bytes from the H3 byte location to the first byte of the STS-1 SPE. A value of 0 means that the SPE starts in row 4,

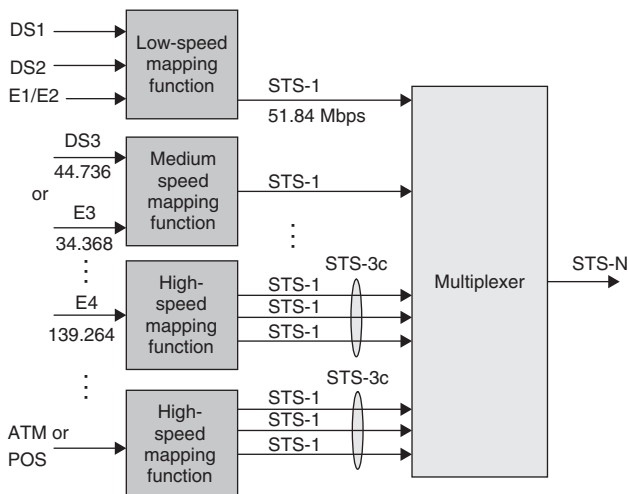

Figure 6: Payload mappings

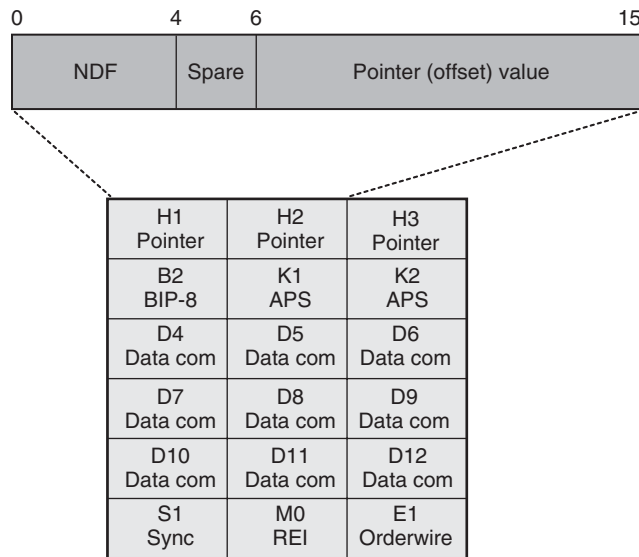

Figure 7: Details of pointer bytes

column 4. The pointer bits are alternately labeled as IDIDIDIDID, where I = increment bit, D = decrement bit. The I and D bit designations have additional meaning for positive and negative justification.

Positive Stuffing

When input payload stream is slower than output, a stuff byte is required from time to time so that payload catches up with the frame stream. The additional byte is stuffed in location right after the H3 byte as shown in Figure 8a. This is known as *positive stuffing*. At the receiver, the byte after H3 is ignored. This operation is indicated to the receiver by inverting the I bits of the pointer value. The pointer is incremented by 1 in the next frame (to indicate that the SPE now starts one byte later), and the subsequent pointers contain the new value.

Negative Stuffing

If the input payload stream is faster than the frame rate, an extra SPE byte is transmitted from time to time for the frame to catch up. The extra byte, which is written in the H3 byte location as shown in Figure 8b, is known as *negative stuffing*. This operation is indicated to the receiver by inverting the D bits of the pointer value. Whenever the extra byte is inserted, the pointer is decremented by 1 in the next frame (to indicate that the SPE now starts one byte earlier), and the subsequent pointers contain the new value.

Table 2 illustrates how the pointer field bits are manipulated in a specific example to indicate to the receiver the forthcoming stuffing operation.

STS-N FRAME

The STS- N frame is an array of $N \times 810$ bytes. The STS- N frame is produced by interleaving bytes of the N synchronized STS-1 signals, in effect producing a frame that has nine rows, $3 \times N$ transport overhead columns, and $87 \times N$ SPE columns. Before N STS-1 signals can be interleaved, each incoming STS-1 signal first needs to be synchronized to the local STS-1 clock of the multiplexer. This is accomplished by terminating the section and line overhead of each incoming STS-1 signal and then mapping its SPE into a new STS-1 frame that is synchronized to the local clock as shown in Figure 9. The pointer in the new STS-1 frame is adjusted as necessary, and the mapping is done on the fly. This procedure ensures that all of the incoming STS-1 frames are mapped into STS-1 frames that are synchronized with respect to each other.

Figure 10 illustrates the structure of an STS-3 frame. Note that the transport overhead of the constituent STS-1 signals are byte-interleaved in the first nine columns of the new STS-3 frame. The composite SPE, formed by byte-interleaving individual SPEs, floats in consecutive STS-3 frames as discussed earlier. To multiplex k STS- N signals into an STS- kN signal, the incoming signals are first de-interleaved into STS-1 signals, and then the above procedure is applied to all kN STS-1 signals.

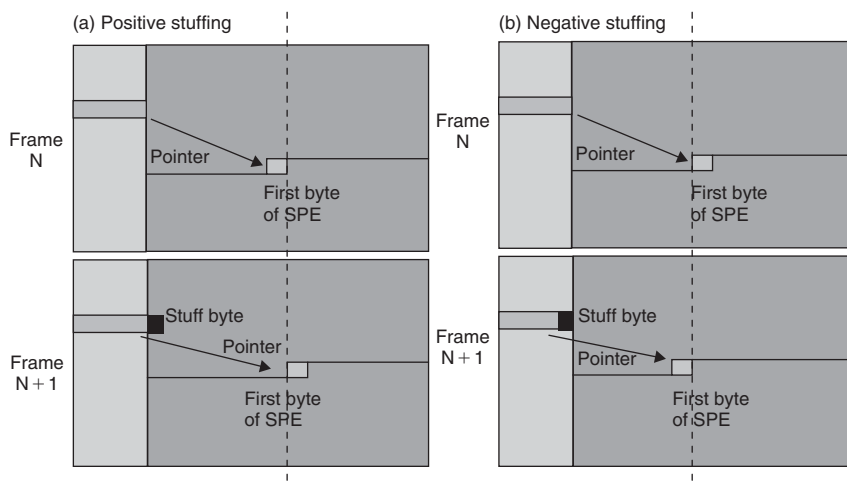

Figure 8: SPE byte stuffing

Table 2: Positive and Negative Stuffing Examples

State	NDF Bits	I D I D I D I D I D	Pointer Value	Frame Number
Initial	0110	0 0 0 1 0 1 1 0 0 1	67	$N-1$

	1001	0 0 0 1 0 1 1 0 0 1	67	$M+3$

Figure 9: Synchronous multiplexing in SONET

VIRTUAL TRIBUTARIES

SONET is designed to carry broadband payloads. Legacy digital hierarchy data rates (DS-1 to DS-3) are lower than STS-1. To make SONET backward-compatible with the legacy digital hierarchy, SONET defines synchronous formats at sub-STS-1 levels called *virtual tributaries* (VTs). Instead of using all eighty-four payload columns of an STS-1 frame for data from one source, the SPE is divided into VTs that are capable of transporting signals at lower data rates.

Four types of VTs have been defined to accommodate existing digital signals as shown in Table 3. A STS-1 SPE

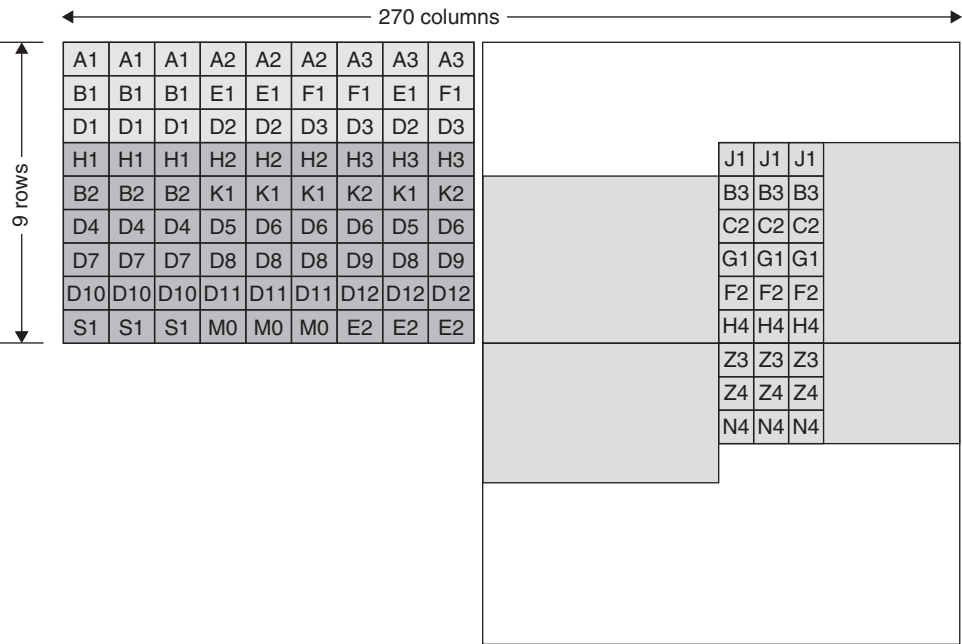

Figure 10: SONET STS-3 frame structure

Table 3: Virtual Tributaries in SONET

VT Type	Payload	Bit Rate (Mb/s)	Size of VT
VT1.5	DS-1	1.728	9 rows, 3 columns
VT2	CEPT-1	2.304	9 rows, 4 columns
VT3	DS-1C	3.456	9 rows, 6 columns
VT6	DS-2	6.912	9 rows, 12 columns

designed to carry VT traffic is divided into seven *virtual tributary groups* (VTGs). Each VTG occupies twelve columns of the STS-1 SPE. A VTG can contain only one size of VTs; however, a different VT size is allowed for each VTG. A VTG may contain four VT1.5s, three VT2s, two VT3s, or one VT6. When two or more VTGs are inserted into an STS-1 frame, they are interleaved column by column. The columns of individual VTs within a VTG are interleaved as well. Because multiplexing is synchronous, an individual VT containing a DS-1 can be extracted without demultiplexing the entire STS-1 signal. This improved accessibility considerably simplifies switching and grooming at the VT or STS level.

Figure 11 illustrates how virtual tributaries are synchronously multiplexed into an STS-1 SPE. Here the STS-1 signal is used to transport seven DS-2 signals using VT6 tributaries.

SONET OVERHEAD

SONET provides substantial overhead information, allowing simpler multiplexing and greatly expanded operations, administration, maintenance, and provisioning capabilities. The path overhead is inserted at the transmit end SONET terminal and terminated at the receive end terminal to carry out necessary path layer functions. The line overhead information is created by adjacent LTEs to communicate with each other to implement line layer functions. The STEs add and terminate section overhead. It is used between adjacent NEs such as regenerators to implement section layer functions such as framing and error detection, among others.

Section Overhead

The section overhead displayed in Figure 12 occupies the first three rows of the transport overhead, which is originated, accessed, and processed by the STE. This overhead supports the following functions: framing, performance monitoring (STS-*N* signal), local orderwire, and data

communication channels to carry information for OAM&P. A description of section overhead bytes follows.

Framing (A1 and A2): Two bytes, A1 and A2, in each STS-1 indicate the beginning of an STS-1 frame. The A1, A2 bytes pattern is F628 hex. When four consecutive errored framing patterns have been received, an *out-of-frame* condition is declared. When two consecutive error-free framing patterns have been received, an *in-frame* condition is declared. A1 and A2 are not scrambled.

Section BIP-8 (B1): One byte, B1, from the first STS-1 of an STS-*N* is used for section error monitoring. The B1 bytes of the other STS-1s of the STS-*N* frame are not defined. B1 byte is calculated using *bit interleaved parity* (BIP) code. For error checking, bit 1 of the BIP-8 byte is calculated to give even parity over all bit 1's in the previous block. Bit 2 is calculated to give even parity for all bit 2's, bit 3 for bit 3's, and so on through bit 8, which is calculated to give even parity for all bit 8's in the previous block. At the next STE, the parity byte is used to check for bit errors.

Section Trace (J0) or Section Growth (Z0): This byte is used to trace the origin of an STS-1 frame. It is not standardized.

Orderwire (E1): One byte, E1, is allocated from the first STS-1 of an STS-*N* frame as a local orderwire channel for voice communication between STEs (e.g., regenerators). One byte of a SONET frame is 8 bits/125 μ sec or 64 kb/s, which is the same rate as a PCM voice channel. The E1 bytes of the rest of the STS-*N* frame are not defined.

Section user channel (F1): This byte is located in the first STS-1 of the STS-*N* and is set aside for the network operator. The corresponding byte locations of the second through *n*th STS-1 are not defined.

Section data communication channel (D1, D2, D3): Three bytes—D1, D2, and D3—are allocated from the first STS-1 of an STS-*N* frame. This 192 kb/s message channel can be used for OAM&P and other communication functions between two STEs. The *data communication channel* (DCC) is often called the *embedded operations channel* (EOC) in SONET.

Line Overhead

Line overhead consists of eighteen bytes (in the last six rows of the transport overhead as shown in Figure 13) that are originated, accessed, and terminated by the LTE.

H1 Pointer	H2 Pointer	H3 Pointer
B2 BIP-8	K1 APS	K2 APS
D4 Data com	D5 Data com	D6 Data com
D7 Data com	D8 Data com	D9 Data com
D10 Data com	D11 Data com	D12 Data com
S1 Sync	M0 REI	E1 Orderwire

Figure 13: Line overhead bytes in STS-1

This overhead supports the following functions: locating the SPE in the frame, performance monitoring, automatic protection switching, multiplexing or concatenating signals, and line maintenance. A description of line overhead bytes follows.

Pointer (H1, H2): Two bytes, H1 and H2, in all STS-1 frames within an STS-*N* signal are allocated to a pointer that indicates the offset in bytes between the pointer and the first byte of the STS-1 SPE. The pointer is used to align the STS-1 SPE in an STS-*N* signal as well as to perform frequency justification.

Pointer action byte (H3): One byte, H3, in each of the STS-1 signals of an STS-*N* frame is used for frequency justification purposes. It carries an extra SPE byte in the event of negative justification. Otherwise, its value is not defined.

Line BIP-8 (B2): One byte, B2, in each of the STS-1 signal of an STS-*N* frame is used for line-error monitoring. It is also calculated using BIP code with even parity over all bytes in the previous STS-1 frame before scrambling, and it is placed in the B2 byte location before scrambling.

Automatic protection switching (APS) channel (K1, K2): These bytes are located in the first STS-1 of the STS-*N* and are used on the protection line for automatic protection switching signaling between LTEs. These bytes are defined only for the first STS-1 of an STS-*N* signal.

Line data communication channel (D4–D12): Nine bytes, D4–D12, are allocated for line data communication. This 576 kbps message-based DCC can be used for OAM&P and other communication functions between two LTEs. The D4–D12 bytes of the rest of the STS-*N* frame are not defined.

Path Overhead

The POH consists of nine bytes in rows 1 to 9 of the first column of the STS-1 SPE as illustrated in Figure 14. POH provides for communication between the point of creation of an STS SPE and its point of termination. This overhead

Figure 14: Definition of path overhead bytes in STS-1

supports functions such as the following: performance monitoring of the STS SPE, signal label (the content of the STS SPE, including status of mapped payloads), path status, and path trace. A description of path overhead bytes follows.

STS path trace (J1): This byte is used to repetitively transmit a sixty-four-byte, fixed-length string so that a receiving PTE can verify its continued connection to the intended STS transmitting PTE.

Path BIP-8 (B3): This byte is used for path error monitoring. The B3 byte is calculated before scrambling over all bytes of the previous STS SPE using BIP code with even parity.

STS path signal label (C2): This byte is used to indicate the type of payload being transported in the STS SPE, including the status of the mapped payloads. The following is a partial list of C2 byte assignments:

- 0×00 , unequipped
- 0×01 , equipped, nonspecific payload
- 0×02 , VT-structured STS-1 SPE
- 0×04 , asynchronous DS-3 mapping
- 0×13 , ATM cell mapping
- 0×15 , asynchronous FDDI mapping
- 0×16 , POS mapping

Path status (G1): This byte conveys information about the path-termination status or performance back to the PTE that originated the STS.

Path user channel (F2): This byte is for network operator communications between STS path-terminating NEs.

CONTIGUOUS CONCATENATION

Superrate services, such as the transport of a router or ATM switch output or uncompressed high-quality or high-definition video signals, require multiples of STS-1 rate. To enable this high-bandwidth transport, multiple contiguous SPEs are transported (and switched) across the SONET or SDH network as a *single concatenated SONET* (STS- Nc) frame, where c indicates concatenated. Because concatenated signals STS- Nc are not channelized, the access to individual STS-1 signals is neither required nor provided Table 4. outlines supported contiguous concatenation for

Table 4: Contiguous Concatenation Containers for SONET and SDH

SONET	SDH	Payload Capacity (Mb/s)
STS-1	VC-3	48.38
STS-3c	VC-4	149.76
STS-12c	VC-4-4c	599.04
STS-48c	VC-4-16c	2396.16
STS-192c	VC-4-64c	9584.64

Figure 15: Concatenated payload STS- Nc

both SONET and SDH. For the SONET standard, these are denoted as STS- Nc , and for SDH as VC-4- Nc . Most SONET interfaces on routers are concatenated.

An STS- Nc contains a single synchronous payload envelope as well as a single column of path overhead, which always appears in the first STS-1 as shown in Figure 15. The number of fixed-stuff columns is given by $N/3 - 1$. Thus, an STS-3c contains $3/3 - 1 = 0$, or no fixed-stuff columns, whereas an STS-12c contains $12/3 - 1 = 3$ fixed-stuff columns. STS- Nc payload = $N \times 780$ bytes. Thus, the number of bytes in the payload of the STS-3c frame is more than that of STS-3 by 18 bytes. One can think of an STS-3c as three STS-1 frames pasted together to create a single, larger frame. SONET equipment treats these interfaces as a single entity.

Figure 16 illustrates which overhead bytes are used with an STS-3c concatenated SONET frame. The unused bytes cannot be used for payload and are simply ignored. For example, the B1 byte in the section overhead and the K1 and K2 APS bytes in the line overhead are undefined and ignored except in the first STS-1 of the STS-3c. The SONET standard specifies use of the H1 and H2 bytes in the line overhead section to indicate whether or not the frames are channelized. The first set of pointers (H1, H2) performs exactly the same functions as STS-1 payload pointer does. For example, if $(H1, H2) = 0110\ 00\ 0000000001$, then the pointer offset is 1. All other pointer bytes ($H1^*$, $H2^*$) should set bits 7 to 16 to 1, and set the new data flag bits to 1001. In other words, ($H1^*$, $H2^*$) use values of 10010011 and 11111111 for these bytes. Channelized interfaces use the H1 and H2 bytes to form a ten-bit pointer that indicates the byte location where a new frame begins. The pointer supports values between 0 and 782. An STS-1 includes eighty-seven columns of SPE. An STS-3c includes $3 \times 87 = 261$ columns. However, the H1 or H2 pointer field is ten bits. Receiving SONET interfaces resolve this problem by tripling the value in the pointer field of the first STS stream when the value falls within the range of 0 and 782. Thus, it sees a pointer value of 1 as 3, and a pointer value of 782 as 2346. For $(H1, H2) = 0110\ 00\ 0000000001$, the J1 byte will reside in column 13.

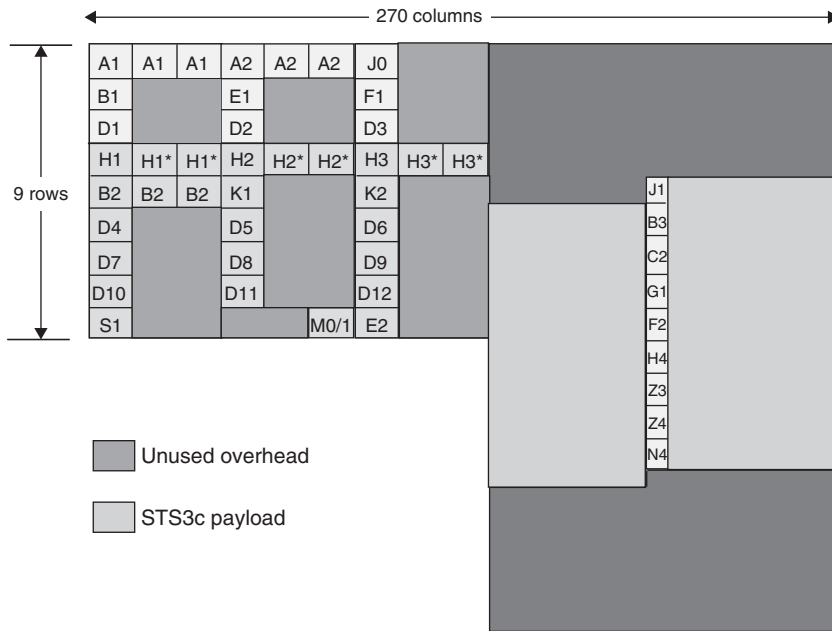

Figure 16: Definition of overhead bytes in STS-3c

SONET NETWORKS

SONET transport networks primarily deploy following three broad classes of network elements: terminal multiplexers, add-drop multiplexers, and digital cross-connect systems.

The *terminal multiplexer* is an end-point device in the SONET network. TMs are used to provide access to the SONET network for various types of traffic using legacy interfaces such as DS-1 and DS-3 or in data-oriented forms such as FDDI via an appropriate bridge or router. TM multiplexes these signals into STS payloads for transport over an OC- N fiber link. The demultiplexer portion of a TM terminates an OC- N fiber link on the network side and provides access to individual signals. The TM is a point-to-point device and is commonly deployed in a point-to-point SONET link.

The add-drop multiplexer is the most widely deployed SONET NE. An ADM is a fully synchronous, byte-oriented multiplexer capable of adding and dropping legacy DS- n or SONET OC- M ($M \leq N$) signals onto one of two SONET OC- N signals. Note that SONET ADMs have two sets of OC (line) interfaces instead of one as in the TM. At an

add-drop site, only those signals that need to be dropped or inserted are accessed. The remaining traffic continues through the network. An ADM enables *drop and repeat* (also known as *drop and continue*), a key capability in CATV application. With drop and repeat, a signal terminates at one node, is duplicated (repeated), and is then sent to the next and subsequent nodes.

The DCCS has a switching fabric capable of cross-connecting STS- M and STS- N line-side ports. Normally, N is greater than the M , but it can be the same. If $N > M$, an incoming STS- N is first demultiplexed into a number (N/M at most) of STSMs, which are switched through the STS- M fabric and reassembled into STS- N if they are continuing on, or are dropped in the office as STS- M s through the ports shown at the bottom. There could be many (thousands) of STS- N and STS- M ports on a single DCCS.

All three types of NEs shown in Figure 17, have been widely deployed in the network and continue to be deployed in significant volumes. In intercity networks, a typical ADM being installed today would likely have STS-48 or STS-192 line-side ports and a mix of STS-3 and STS-12 drop-side ports.

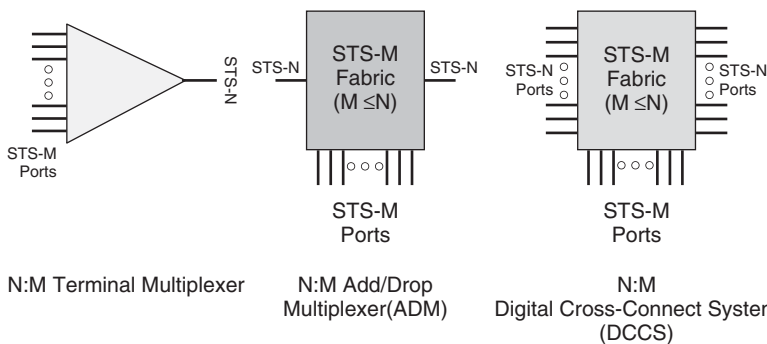

Figure 17: Widely deployed SONET network elements

SONET Network Configurations

A *point-to-point* link, as shown in Figure 18, consists of two SONET multiplexers linked by a fiber pair with or without a regenerator in the path. This implementation represents the simplest SONET configuration.

A *point-to-multipoint* (linear add-drop) link consists of ADMs interconnected in a linear fashion to facilitate adding and dropping tributary channels at intermediate points in the network. At each ADM, only the signals that are destined for that site are accessed and dropped, and transit signals are passed through. Signals generated locally and destined for other sites are inserted at the ADM. Figure 19 displays a SONET linear add-drop system.

SONET *rings* are formed by interconnecting a number of ADMs (as many as sixteen) to form a closed loop network. A ring provides redundant bandwidth to protect services against failures; if a fiber cable is cut, the SONET nodes have the intelligence to send the services affected via an alternate path through the ring without interruption. Figure 20 illustrates a SONET ring topology.

Figure 18: Point-to-point SONET link

Figure 19: Point-to-multipoint SONET link

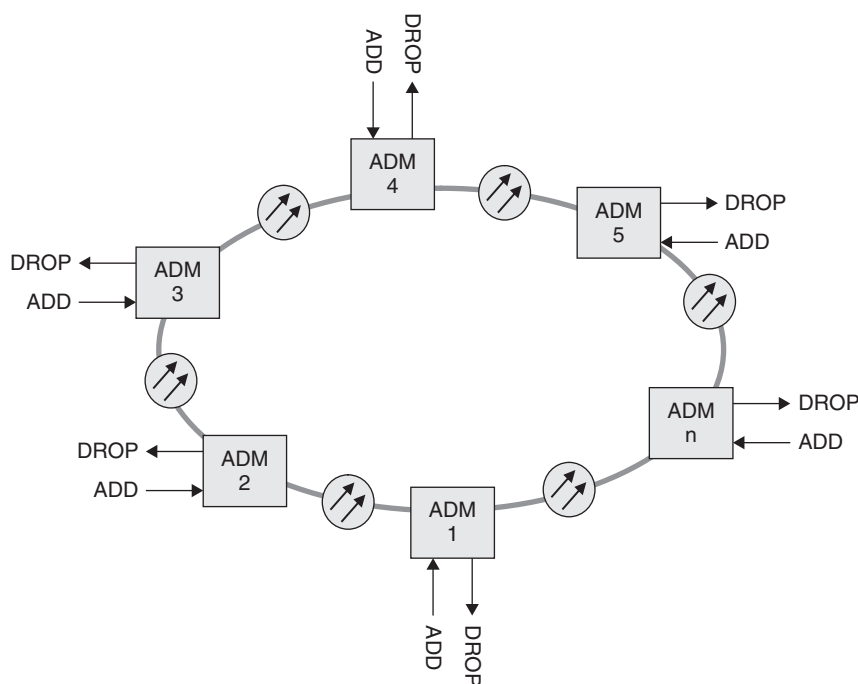

Figure 20: SONET ring

PROTECTION SWITCHING

The SONET standard defines automatic protection switching schemes that provide linear protection against failures at the line layer. Recall that in SONET terminology, a line connects two multiplexers with a single OC-N optical signal. Therefore, protection at the line level applies to a multiplexed signal while it traverses the line between two multiplexers. Figure 21 shows two such SONET multiplexers connected in a 1+1 ("one plus one") configuration using two SONET lines: a *working* line and a *protection* line.

At the upstream node, the signal is *bridged* electrically into working and protection lines that carry the same payload across the two lines. At the downstream node, the two received signals are monitored for failures. The monitoring looks for loss of signal, loss of framing, bit-error-rate levels, as well as alarm signals in the overhead. A selector in the downstream node picks the better signal based on the information provided by the two monitors and does not need to coordinate with the upstream node. Recovery from failures can be done quickly because the monitoring and selection functions are typically implemented in hardware. However, the 1+1 APS scheme is inefficient because it uses twice the bandwidth required by an unprotected signal.

Figure 22 shows a 1:1 ("one for one") APS arrangement. In this approach, the signal is only transmitted in the working line during normal operation. The optical signal that is received in the working line is monitored for degradation, and a request to switch to the protection line is sent on a reverse signaling channel when a failure is detected. On receipt of the request, the upstream node switches the signal to the protection line. The 1:1 APS scheme takes more time to recover from failure than the 1+1 APS scheme because of the need to signal for

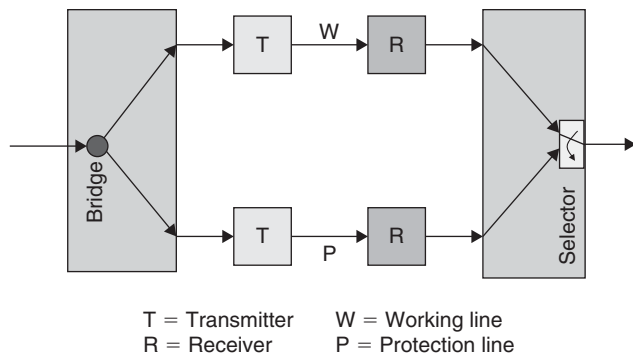

Figure 21: 1+1 linear APS scheme

a switchover. However, the 1:1 scheme can be more efficient in bandwidth usage because the protection line can be used to carry extra traffic when there are no failures. The extra traffic is preempted when the protection line is needed to protect working traffic. The K1 and K2 bytes in the line overhead of a SONET frame are used to exchange requests and acknowledgments for protection switch actions.

Figure 23 shows that the 1:1 APS scheme can be generalized to a 1: n APS scheme where one protection line protects n working lines. The scheme assumes that the working lines are unlikely to fail at the same time. This assumption is reasonable if the lines use diverse transmission routes. In both 1:1 and 1: n APS schemes, the working signal is switched back to its original line once the fault has been repaired.

The SONET linear APS specifications require that fault recovery be completed within 50 milliseconds after the fault has been detected in all of the above schemes.

SELF-HEALING SONET RINGS

The main advantage of ring topology is protection: The ring offers two different ways of passing traffic from ingress to egress. The two main standardized ring protection architectures are the two- and four-fiber SONET *bidirectional line switched rings* (BLSRs) and *unidirectional path switched rings* (UPSRs) (ANSI 1995, "T1.105.01-2000"; Wu 1995). In SDH terminology (ITU-T 1998), BLSRs are

Figure 23: 1: n linear APS scheme

called *multiplex section shared protection rings* (MSPRings) and UPSRs are referred to as *subnetwork connection protection* (deployed in) *physical rings* (SNCPRings).

Unidirectional Path Switched Ring

The unidirectional path switched ring provides protection at the path level. Figure 24 shows a two-fiber ring in which data travel in one direction in one ring and in the opposite direction in the other ring. By convention, working traffic flows clockwise and protection traffic

Figure 24: Protection switching in UPSR

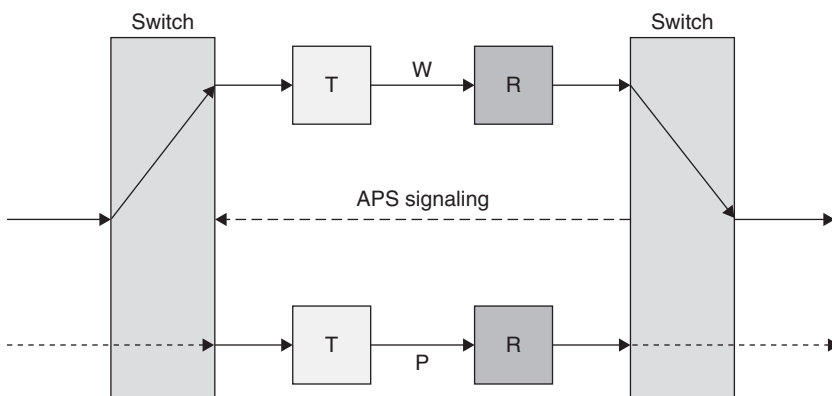

Figure 22: 1:1 linear APS scheme

flows counterclockwise. At each ADM—say, node 1 in Figure 24a—the path signal to another node—say, 3—is bridged into both the working fiber and the protection fiber. Thus, information can flow between any pair of nodes in the ring along two paths, providing 1 + 1 protection at the path level. For example, Figure 24a shows a path signal inserted at node 4 that travels around the ring in both directions and exits at node 2. In UPSR, each exit node monitors the two received path signals and selects the better one. For example, suppose that a fiber is cut between two nodes—say, nodes 4 and 1 in Figure 24b. Node 1 can no longer receive the working signal in the clockwise direction, so it inserts a path alarm indication in the overhead of every affected path signal. A selector at the receiver then selects the path that arrives in the protection fiber as shown in Figure 24b. In this example, we see that the selector in node 2 switches to the counterclockwise signal to receive the path signal from node 4.

UPSR rings can provide fast path protection, but they are inefficient in terms of bandwidth usage because two paths are used to carry every signal. If a path uses an STS- N signal, then the path will use STS- N in every hop in both rings. The UPSR is most often deployed for hubbed transport scenarios. The lower speed UPSR rings in the access portion of a network collect traffic from various remote sites and carry to a large central hub where a DCS directs the traffic to other parts of the network.

Bidirectional Line Switched Ring

SONET rings can also be configured to provide protection at the line level. In a four-fiber bidirectional line switched ring, adjacent ADMs in the ring are connected by a working fiber pair and a protection fiber pair. Suppose that failure disrupts the working pair between nodes 2 and 3 as shown in Figure 25. The BLSR operation recovers from this failure by switching both working channels to the protection channels between nodes 2 and 3. In effect, line APS protection is used in identical fashion to linear ADM networks. This protection scheme is called *span switching*.

Figure 25: Span switching in BLSR

Figure 26: Ring switching in BLSR

Now suppose that the working pair and the protection pair between adjacent nodes fail together as shown in Figure 26. In this case, BLSR uses the protection pair in the directions away from the failure to restore the two working lines that spanned the failure. The nodes on either side of the failure bridge their working line onto the protection line that flows in the direction away from the failure. In effect, the working lines that traversed the failed path are now routed to their adjacent node the long way around the ring as shown in Figure 26. This protection scheme is called *ring switching*. SONET requires that fault recovery using either path or ring switching be completed within 50 milliseconds after the fault has been detected.

In the four-fiber BLSR, each fiber span supports full ring bandwidth. Thus, the total network bandwidth can be calculated using the following formula:

$$\text{Four-fiber BLSR bandwidth} = \text{ring speed} \times \text{number of spans} - \text{total STS pass-through node traffic}$$

Thus, in a perfect BLSR network, where all traffic originates and terminates on adjacent nodes, the total ring bandwidth equals $N \times \text{ring speed}$, where N = number of spans. If the BLSR in Figures 25 and 26 is operating at OC-48, then the maximum ring bandwidth is OC-192. This bandwidth capability is in stark contrast to a UPSR based OC-48 network, where the total ring capacity is equal to the ring speed (OC-48). The reason for this lies in the fact that for each circuit created, the UPSR restoration mechanism creates two copies of the circuit, routing one copy on each of the counter rotating fibers. These two copies consume bandwidth on each fiber span around the entire ring. BLSR, therefore, offers more bandwidth around the ring and flexibility to manage it efficiently compared with UPSR. Further, the protection fibers in BLSR can be used to carry extra traffic when there are no faults in the ring. On the other hand, BLSR requires fairly complex signaling to implement span or ring switching. The capability of BLSRs to manage bandwidth flexibly and recover from fault within 50 msec are key reasons for

their wide scale deployment in interexchange carrier and incumbent local exchange carrier backbone networks.

DATA TRANSPORT OVER SONET OR SDH

SONET and SDH standards were developed primarily for the transport of constant bit rate applications. This is evident in many characteristics of these technologies. As an example, bandwidth is provisioned via a rigid hierarchy of bit rates (STS-1, STS-3, STS-12, STS-48, etc.). However, with the explosion of IP and other packet-switched data traffic, solutions for the transport of data over SONET and SDH systems were developed. Because SONET and SDH are connection-oriented layer 1 protocols and IP is a layer 3 protocol, the transport of IP over SONET and SDH requires a layer 2 protocol. The following framing protocols are used to encapsulate IP packets: packet over SONET, frame relay, and asynchronous transfer mode.

Packet over SONET

IP datagrams are encapsulated into *point-to-point protocol* (PPP) data frames (Malis and Simpson 1999). The PPP formats data frames using a byte-oriented version of the HDLC protocol. The PPP data frames are then mapped byte-synchronously into contiguously concatenated SONET frames (e.g., STS-12c, STS-48c). HDLC provides flag-based delineation of the IP datagrams across the synchronous transport link. Byte stuffing is used to enable transparent operation. Each HDLC frame begins and ends with the flag byte 0 × 7E as shown in Figure 27. At the transmit side, the data bytes in each datagram are monitored for the flag sequence and an escape sequence (0 × 7D). If the flag sequence occurs anywhere within the information field of the HDLC frame, it is changed to the sequence 0 × 7D 0 × 5C. Likewise, the occurrences of the escape sequence, 0 × 7D, are converted to 0 × 7D 0 × 5D. As a result, the signal to be transported grows by

one byte for each byte requiring transparency processing. At the receive end of transmission, the stuffed patterns are removed and replaced with the original fields. The byte-stuffed transparency processing becomes difficult to implement in 10 Gb/s and 40 Gb/s SONET equipment.

IP or ATM over SONET

This approach utilizes ATM as the data-link layer with its excellent traffic management capabilities as a significant bonus for multimedia applications. The IP over ATM mapping can be described as a three-step process. First, each IP datagram is encapsulated into an *ATM adaptation layer type 5* (AAL5) frame using multiprotocol logic link control and *subnetwork attachment point* (SNAP) encapsulation (Grossman and Heinanen 1999). Second, the resulting AAL5 common part convergence sublayer *protocol data unit* (PDU) is segmented into forty-eight-byte payloads for ATM cells as illustrated in Figure 28. Lastly, the ATM cells are mapped into a contiguously concatenated SONET or SDH (e.g., STS-48c or VC-4-16c) frame. This protocol stack introduces a certain bandwidth overhead. It has been repeatedly reported that the classical IP over ATM mapping results in an overhead (“cell tax”) of 18–25 percent, in addition to the approximately fixed 4 percent overhead needed for SONET.

Example: Mapping of ATM Cells in STS3c Frame

ATM cells are mapped into SONET STS-3c SPE “directly” (without any additional overhead) as shown in Figure 29. The only requirement is that the STS-3c byte boundaries are preserved in such a mapping (i.e., bytes of the ATM cell coincide with those of the STS-3c SPE). Because the STS-3c payload capacity (260 × 9 = 2340 bytes) is not an integer multiple of the ATM cell length (53 bytes), a cell is allowed to cross the SPE boundary. For instance, if an ATM cell starts right after the POH J1 byte (that defines the beginning of the SPE), the SPE will contain forty-four full ATM cells and eight bytes of the forty-fifth

Figure 27: Frame format for PPP/HDLC frame

Figure 28: Frame format for ATM/AAL5 frame

Figure 29: Mapping of ATM cells in STS-3c frame

ATM cell. The “tail” forty-five bytes of the forty-fifth cell will begin directly following the POH J1 byte of the next SPE. Thus, ATM cells always span the SPEs. That is of no concern to SONET or SDH, because the cell delineation is an ATM layer function. Cells are mapped row-wise into the frame. Cells could contain data or be empty. The SONET delivers bytes in the SPE to an ATM switch, which has to make sense out of the bytes. The STS-3c payload rate is $9 \times 260 \times 8/125\text{msec} = 149.76\text{ Mb/s}$, which provides maximum ATM payload capacity of $149.76\text{ Mb/s} \times (48/53) = 135.63\text{ Mb/s} \Rightarrow 87.21\text{ percent efficiency}$.

The tremendous acceptance of Ethernet and *Gigabit Ethernet* (GbE), *enterprise system connect* (ESCON), *fiber connection* (FICON), *fiber channel* (FC), and *storage area networking* (SAN) applications has created pressure on carriers for efficient transport of these services in metropolitan area and wide area network environments. Unfortunately, the line and data rates of GbE, Fiber Channel, ESCON, and FICON are not well matched to standard SONET or SDH contiguously concatenated payload rates. For example, the 1.0-Gb/s data rate of GbE does not fit into STS-12c or VC-4-4c at 622 Mb/s and wastes bandwidth if mapped singly into a 2.5-Gb/s STS-48c or VC-4-16c. This has led to a new set of enhancements that will make the transport network better suited to carrying data signals, driving its evolution toward increased efficiency and flexibility in supporting new data over transport services. These include the generic framing procedure, virtual concatenation, and the *link capacity adjustment scheme* (LCAS). Virtual concatenation, GFP, and LCAS enable generalized mappings of variable-length multiprotocol packets into SONET or SDH, and they also allow for flexible and elastic data transport over SONET or SDH networks (Scholten et al. 2002; Hernandez-Valencia, Scholten, and Zhu 2002; Bonenfant and Rodriguez-Moral 2002).

GENERIC FRAMING PROCEDURE

Generic framing procedure is a recently standardized (ITU-T 2005) framing procedure that provides a standard means of mapping, in a highly efficient way, a wide variety of data signals into SONET or SDH frames. GFP provides a generic mechanism to adapt traffic from higher-layer client signals over SONET or SDH. Client signals may be

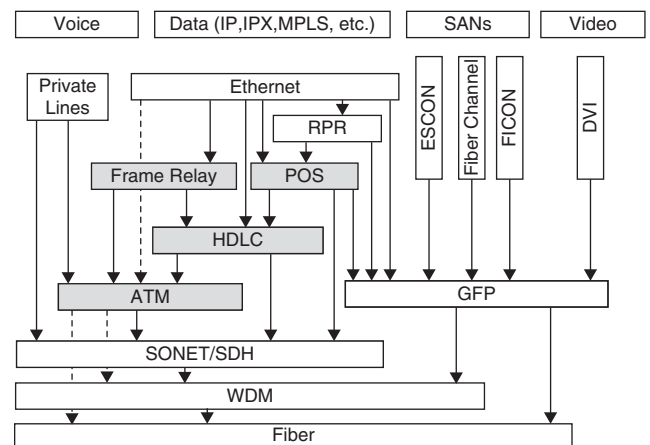

Figure 30: Protocol stacks for mapping data services over GFP

variable-length packets (e.g., IP or PPP or Ethernet MAC) or block code-oriented constant-bit-rate streams such as ESCON, FICON, or FC. GFP has extremely low overhead requirements and robust frame-delineation qualities, making it a more efficient and flexible data-services mapping scheme. Figure 30 illustrates choice of transport options for end-user applications such as voice, data, storage, and video traffic over the public network infrastructure. Note that IP data services that have previously been mapped to SONET and SDH through ATM and HDLC can now be mapped efficiently through Ethernet and GFP. In addition, nontraditional data services such as fiber channel, ESCON, and FICON can also be encapsulated using GFP, thereby eliminating the need for proprietary mapping solutions into SONET and SDH frames.

Two types of GFP frames have been defined by the ITU standard: *frame-mapped GFP* (GFP-F) and *transparent mapped GFP* (GFP-T). The decision on which mode to use depends on the underlying service to be transported.

Frame-mapped GFP is a mapping mechanism in which a single client protocol data unit (e.g., an IP packet or Ethernet frame) is received and mapped in its entirety into a single GFP frame. In this adaptation mode, the client or GFP adaptation function may operate at the

data-link layer (or higher layer) of the client signal. Client PDU visibility is required. GFP-F mappings are currently defined for Ethernet MAC payloads (10/100/1000M/GbE) and IP or PPP payloads.

Transparent-mapped GFP frames are slightly different. GFP-T mapping provides a block code-oriented adaptation mode in which the client or GFP adaptation function operates on the coded character stream rather than on the incoming client PDUs. Transparent GFP provides a way for a number of client data characters to be mapped into efficient block codes for transport within a GFP frame. With this type of mapping, block-coded client characters are decoded and then mapped into the payload area of a fixed-length GFP frame and may be transmitted immediately without waiting for the reception of an entire client data frame (as in the case of GFP-F). Transparent mapping is intended to facilitate the transport of 8B or 10B block-coded client signals for services that require especially low transmission latency, making GFP-T ideally suited for FC, ESCON, and FICON transport service.

A GFP frame consists of three main components: the core header, the payload header, and the payload area. Figure 31 illustrates the format of a GFP frame. The GFP core header carries information about the size of the GFP frame itself and allows GFP frame delineation independent of the content of the higher-layer PDUs. The GFP core header is four bytes long and consists of two fields:

- The *payload length indicator* (PLI) field is a two-byte field indicating the size in bytes of the GFP payload area. It indicates the beginning of the next GFP frame in the incoming bit stream as an offset from the last byte in the current GFP core header. PLI values in the range 0–3 are reserved for GFP internal usage and are referred to as GFP *control* frames. All other frames are referred to as GFP *client* frames.

- The *core header error control* (cHEC) field is a two-byte field containing a *cyclic redundancy check* (CRC-16) sequence that protects the integrity of the core header. The cHEC sequence is computed over the core header bytes using standard CRC-16. The CRC-16 enables both single-bit error correction and multibit error detection.

The GFP *payload area* covers all remaining bytes of the GFP frame following the GFP core header. It consists of a payload header and a payload information field. The variable-length payload information field may include from 0 to 65,531 bytes. The payload information field may optionally be followed by a *payload frame check sequence* (FCS).

- The *payload header* is a variable-length area 4–64 bytes long. It carries information about the payload type (Ethernet, fiber channel, etc.) and consists of two mandatory fields: the type field and an accompanying *type header error correction* (tHEC) field.
- The *payload type* field is a mandatory two-byte field of the payload header that indicates the content and format of the GFP payload information. As shown in Figure 31, the type field consists of a *payload type identifier* (PTI), a *payload FCS indicator* (PFI), a *extension header identifier* (EXI) and a *user payload identifier* (UPI).
- The tHEC field is a two-byte field that contains ISO CRC-16 sequence to protect the integrity of the type field. The tHEC sequence is computed over the type field bytes, enabling both single-bit error correction and multibit error detection.
- The *payload frame check sequence* (pFCS) is an optional four-byte-long frame check sequence. It contains a CRC-32 check sequence that protects the contents of the GFP payload information field.

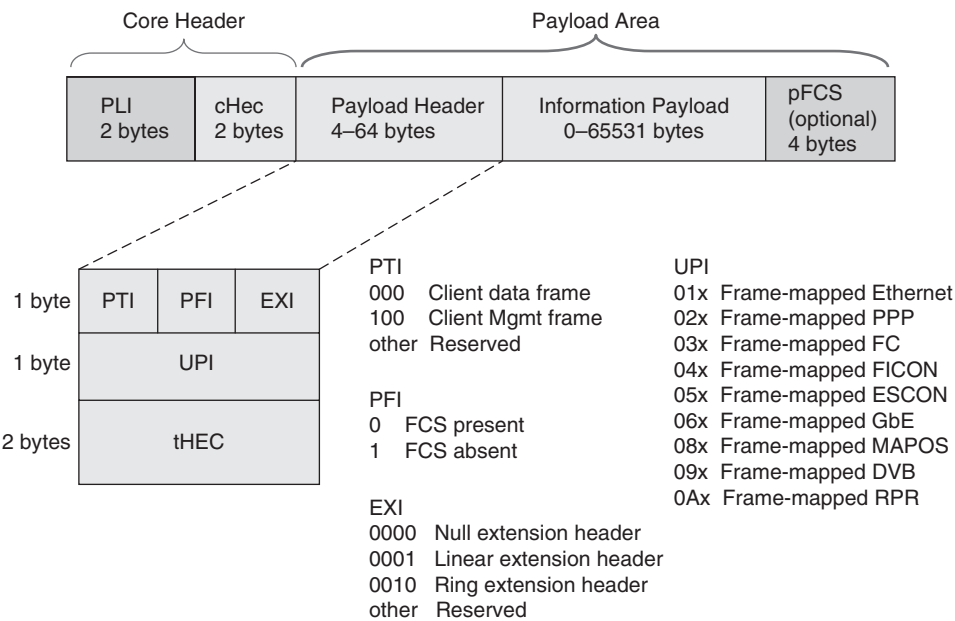

Figure 31: GFP frame format

VIRTUAL CONCATENATION

Earlier we discussed contiguous concatenation to accommodate high-speed data applications that use protocols such as ATM, POS, and others that require high-bandwidth mappings over SONET and SDH. Although contiguous concatenation has been successfully introduced and deployed for years, it presents major deficiencies. Contiguous concatenation keeps the SONET payload concatenated through the whole SONET and SDH transport. Therefore, all NEs along the path must support contiguous concatenation. In addition, data and line rates of GbE, fiber channel, ESCON, and FICON are not well matched to standard SONET or SDH contiguously concatenated payload rates, so using GFP with current contiguous concatenation schemes results in suboptimal use of the bandwidth. As an example, the 1.0 Gb/s data rate of GbE does not fit into STS-12c or VC-4-4c at 622 Mb/s and results in approximately 60 percent of wasted bandwidth if mapped into a 2.5-Gb/s STS-48c or VC-4-16c.

To address these limitations, virtual concatenation, defined in ITU standard G.707 (ITU-T 2003), was developed to allow any number of SONET or SDH channels to be bonded to create a customized *virtual concatenation group* (VCG) that can be any multiple of some basic SONET or SDH rate. In high-order virtual concatenation, this basic rate would be an STS-1, VC-3, STS-3c, or VC-4. Thus, virtual concatenation is an inverse multiplexing procedure where a VCG can be created in multiples of 50 or 150 Mb/s, and multiple LAN or SAN data signals can be transported over single OC-48, STM-16, OC-192, or STM-64 lines with much better bandwidth utilization. Control packets, which contain the necessary information for reassembling the original data stream at its destination PTE, are inserted in some of the currently unused SONET or SDH overhead bytes (H4 byte for high order, and Z7 (SONET) and K4 (SDH) for low order). Furthermore, each virtually concatenated group of signals is transported as individual SPEs across the SONET or SDH network without requiring any upgrades. The receiving end PTE is responsible for reassembling the original byte stream. In this manner, virtually concatenated channels may be deployed on the existing SONET or SDH network with a simple end-point node upgrade.

As presented in Table 5, VCAT provides a much more efficient use of the transport bandwidth for data user interfaces. With VCAT, an OC-48 link can carry two full

GbE signals with 95 percent of the link used through seven virtual STS-3cs or VC-4s each instead of just one GbE signal with 42 percent of the link used through an STS-48c or VC-4-16c.

In summary, virtual concatenation enables SONET or SDH transport pipes to be filled more efficiently with data services by grouping individual SONET or SDH containers into a virtual high-bandwidth “link” matched to the required service bandwidth.

Link Capacity Adjustment Scheme

The link capacity adjustment scheme as defined by the ITU (ITU-T 2004; Bonenfant and Rodriguez-Moral 2002) is a complementary technology to virtual concatenation. LCAS is a method to dynamically increase or decrease the bandwidth of VCGs. This brings *bandwidth-on-demand* capability for data clients such as Ethernet when mapped into VCGs. Signaling messages are exchanged within the SONET or SDH overhead (H4 or Z7/K4 bytes) in order to change the number of tributaries being used by a VCG. The number of tributaries can be increased or decreased in response to an identified change in service bandwidth requirement or in response to a fault condition of an existing VCG member. LCAS works by ensuring synchronization between the sender (PTE) and receiver (PTE) during the increase or decrease of the size of a virtually concatenated circuit in such a way that it does not interfere with the underlying data service. In addition to providing a resiliency mechanism for VCAT, LCAS gives service providers the flexibility to tailor service bandwidth for customers on demand.

In summary, VCAT and LCAS combined can be extremely useful when provisioning data packet transport services over an existing SONET network. In this case, VCAT is used to provision point-to-point connections over the SONET network, and LCAS provides resiliency to VCAT connections and allows for fine tuning of the network transport resources.

CONCLUSION

SONET and SDH systems have stood the test of time and have been the preferred optical transport technology for more than two decades now. The reasons for the wide popularity of networks based on SONET or SDH standards include multivendor interworking, self-healing

Table 5: Bandwidth Efficiency Using Virtual Concatenation

Service	Bit Rate (Mb/s)	Efficiency	
		Without VCAT	With VCAT
Ethernet	10	STS-1 (20%), VC-2 (20%)	VT1.5-7v (93%), VC-12-5v (97%)
Fast Ethernet	100	STS-3c (47%), VC-4 (67%)	STS-1-2v (99%), VC-3-2v (99%)
Gb Ethernet	1000	STS-48c (42%), VC-4-16c (42%)	STS-3c-7v (95%), VC-4-7v (95%)
Fiber channel	1062.5	STS-48c (43%), VC-4-16c (43%)	STS-3c-6v (98%), VC-4-7v (98%)

architectures, enhanced OAM&P capabilities, and ease of signal grooming and multiplexing. Until recently, however, SONET networks have been primarily used to transport multiplexed voice signals and private-line frame relay and ATM services. The growth of these high revenue-generating services over the years has resulted in large-scale deployments of metropolitan and long-haul SONET and SDH networks worldwide. Today, however, data transport is driving the demand for increased bandwidth in WANs. Although several ATM and HDLC-based data mappings over SONET and SDH are widely deployed, each has its own limitations. GFP provides—for the first time—a standard means of mapping, in an extremely efficient way, a wide variety of data signals into SONET and SDH frames, enabling compliant equipment from different manufacturers to transport both traditional and nontraditional data signals over a SONET or SDH infrastructure. Coupled with complementary developments in the standardization of virtual concatenation and automatic link capacity adjustment schemes, GFP holds the promise of rendering existing SONET and SDH transport networks capable of increasingly efficient data transport, leveraging existing infrastructures to offer new services.

GLOSSARY

- Add-Drop Multiplexer (ADM):** A time division multiplexer capable of extracting and inserting lower-rate signals from a higher-rate multiplexed signal without completely demultiplexing the signal.
- Automatic Protection Switching (APS):** The ability of a network element to detect a failed working line and switch the traffic to a spare (protection) line.
- Concatenated STS- N_c :** An STS- N_c signal in which synchronous payload envelopes from the N STS-1s have been combined to carry the high-capacity payload. It is transported as a single entity unlike an STS- N signal.
- Concatenated Virtual Tributary:** A virtual tributary ($VT \times N_c$) that is composed of $N \times VT$ s combined. Its payload is transported as a single entity rather than separate signals.
- Contiguous Concatenation:** The process of joining multiple consecutive SONET STS-1 signals to create a single, larger capacity concatenated SONET frame.
- Digital Cross-Connect System (DCCS):** Network equipment that allows lower-level TDM bit streams to be rearranged and interconnected among higher-level TDM signals. DCCS can be used for “grooming” telecommunications traffic, switching traffic from one circuit to another in the event of a network failure, and supporting automated provisioning, among other applications.
- Enterprise System Connection (ESCON):** An optical serial interface between IBM mainframe computers and peripheral devices such as storage and tape drives. ESCON is capable of half-duplex communication at a rate of 17 Mbytes/second over distances of as much as 43 kilometers.
- Fiber Channel (FC):** Technology designed for especially high-performance, low-latency data transfer among various types of devices as defined by a family of ANSI standards. Data rates of 100, 200, 400, and 1200 Mbytes/sec are defined for fiber-optic links for distances as much as 50 kilometers.
- Fiber Connection (FICON):** An input-output technology developed by IBM to connect mainframes to storage devices at higher speeds and greater distances than the earlier ESCON. FICON supports full duplex data rates of 100, 200, and 400 Mbytes/second and distances of as much as 100 kilometers.
- Fixed Stuff:** A bit or byte that has a reserved function. Fixed stuff locations, sometimes called *reserved* locations, do not carry overhead or payload.
- Generic Framing Procedure (GFP):** Allows mapping of variable-length, higher-layer client signals over a transport network such as SDH and SONET. The client signals can be protocol data unit (PDU)-oriented (such as IP, PPP, and Ethernet frame) or can block code-oriented (such as fiber channel).
- Gigabit Ethernet (GbE):** Describes various technologies for transmitting Ethernet packets at a rate of 1 Gigabit per second as defined by the IEEE 802.3-2005 standard.
- Grooming:** Consolidating or segregating traffic for efficiency.
- Line:** One or more SONET sections, including network elements at each end, that are capable of accessing, generating, and processing line overhead.
- Line Overhead:** Eighteen bytes of overhead accessed, generated, and processed by line-terminating equipment. This overhead supports functions such as locating the SPE in the frame, multiplexing or concatenating signals, performance monitoring, automatic protection switching, and line maintenance.
- Line-Terminating Equipment (LTE):** Network elements such as add-drop multiplexers or digital cross-connect systems that can access, generate, and process line overhead.
- Link Capacity Adjustment Scheme (LCAS):** A method to dynamically increase or decrease the bandwidth of virtual concatenated containers. The LCAS protocol is specified in ITU-T G.7042.
- Network Element (NE):** Equipment that is part of a SONET transmission path and serves one or more of the section, line, and path-terminating functions.
- Optical Carrier Level 1 (OC-1):** The optical equivalent of an STS-1 signal.
- Optical Carrier Level N (OC- N):** The optical equivalent of an STS- N signal.
- Overhead:** Extra bytes (or bits) in a digital stream used to carry information besides user data. Transport overhead in a STS-1 frame is an example of overhead information.
- Path:** A logical connection between a point where an STS or VT is multiplexed to the point where it is demultiplexed.
- Path Overhead (POH):** Overhead accessed, generated, and processed by path-terminating equipment. Path overhead consists of nine bytes in the first column of the STS-1 SPE. POH provides for communication between the point of creation of an STS SPE and its point of disassembly.
- Path-Terminating Equipment (PTE):** Network element that terminates the SONET STS path layer.

PTE interprets and modifies or creates the STS path overhead.

Payload: The portion of the SONET signal available to carry user information such as DS1 and DS3.

Pointer: Portion of the line overhead (2 bytes) that locates the beginning of an SPE.

Section: The span between two SONET network elements capable of accessing, generating, and processing only SONET section overhead.

Section Overhead: Nine bytes of overhead accessed, generated, and processed by section-terminating equipment. This overhead supports functions such as framing the signal and performance monitoring.

Section-Terminating Equipment (STE): Equipment that terminates the SONET section layer. STE interprets and modifies or creates the section overhead.

Synchronous: A network in which transmission system payloads are synchronized to a master (network) clock and traced to a reference clock.

Synchronous Digital Hierarchy (SDH): The ITU-T defined world standard of transmission with a base transmission rate of 155.52 Mb/s (STM-1); it is equivalent to SONET's STS-3.

Synchronous Optical Network (SONET): An ANSI standard for optical transport that defines optical carrier levels and their electrically equivalent synchronous transport signals.

Synchronous Payload Envelope (SPE): The major portion of the SONET frame format used to transport user payload and STS path overhead. The STS SPE may begin anywhere in the frame's SPE.

Synchronous Transfer Module (STM): An element of the SDH transmission hierarchy. STM-1 is SDH's base-level transmission rate equal to 155.52 Mb/s. Higher rates of STM-4, STM-16, STM-64, and STM-256 are also defined.

Synchronous Transport Signal Level 1 (STS-1): The basic SONET building block signal transmitted at 51.84 Mb/s data rate.

Synchronous Transport Signal Level N (STS-N): The signal obtained by multiplexing N STS-1 signals together.

Virtual Concatenation (VCAT): An inverse multiplexing technique used to split SONET or SDH bandwidth into logical groups that may be transported or routed independently.

Virtual Tributary (VT): A signal designed for transport and switching of sub-STS-1 payloads.

Virtual Tributary Group (VTG): A nine row by twelve column structure (108 bytes) that carries one or more VTs of the same size. Seven VT groups can be fitted into one STS-1 payload.

INTRODUCTION

The access network is part of a carrier network that connects subscribers to a service provider's *central office* (CO) over the public ground (Wikipedia, undated). With the recent development of optical fiber technologies, a dramatic increase in bandwidth has been facilitated in the backbone network through the penetration of *wavelength-division multiplexing* (WDM) technology, which provides tens of Gigabits per second (Gbps) per wavelength. At the same time, *local area networks* (LANs) have been scaled up from 10 Mbps to 100 Mbps and are being upgraded to Gigabit Ethernet speeds. However, the access network in between only runs at sub-Megabit or even kilobit bandwidth speeds. The tremendous growth of Internet traffic has accentuated the growing gap between the capacities of the backbone and local networks, and the serious bottleneck of the much lower capacities of these in-between access networks. Such a mismatch is the so-called last mile problem from the service provider's point of view—or the first mile problem from the end users' perspective—and it calls for the upgrading of the current access network with a low-cost and high-speed solution to provide broadband access services.

The most widely deployed broadband access solutions are the *digital subscriber line* (DSL) and the cable modem. For truly high-speed broadband access, significant worldwide efforts of fiber-optic access—in particular, the deployment of *fiber to the home* (FTTH)—are led by telecommunications giants such as AT&T, Verizon, and NTT. Among diverse approaches, the *passive optical network* (PON) is especially attractive. Compared to DSL and cable modem, a PON lowers the cost of network deployment and maintenance with the provisioning of much higher bandwidth. The PON standards of current interest include *broadband PON* (B-PON) [International Telecommunication Union, Telecommunications (ITU-T) 1998], *Ethernet PON* (EPON) [Institute of Electrical and Electronics Engineers (IEEE) 2004], and *Gigabit-capable PON* (G-PON) (ITU-T 2003a). The next-generation fiber-optic access network is likely to take advantages of WDM

technologies to achieve the ultimate bandwidth, and WDM-PON is considered a promising solution.

This chapter presents an overview of the wired access technologies, including DSL, cable modem, and diverse PONs. The rest of this section covers the introduction of DSL, cable modem, and major features of fiber-optic access. The second section presents various PONs in detail, including the network architecture, enabling technologies, and *media access control* (MAC). The chapter conclusion provides a summary of the ongoing developments in the area of PONs. Readers who are interested in wireless broadband access technologies can refer to the chapter "Wireless Broadband Access" for more details.

ACCESS TECHNOLOGIES

The Digital Subscriber Line

Telecommunications typically use twisted-pair copper wires to provide voice services to their customers. The demand for more bandwidth has resulted in the deployment of DSL equipment to provide simultaneous voice and higher-speed data services. DSL modems contain an internal signal splitter that carries voice signals on low frequencies (from 0 to 4kHz) and data signals on the unused higher frequencies (Mervana and Le 2001), allowing simultaneous access to the wire by the telephone and the computer.

As shown in Figure 1, DSL services are *point-to-point* (P2P) dedicated public network access between a service provider's CO and the customer's site (Ooghe et al. 2003). The term *xDSL* covers several similar yet competing forms of DSL including *asymmetric DSL* (ADSL), *symmetric DSL*, *high-data-rate DSL*, *rate-adaptive DSL*, and *very-high-speed DSL* (Starr et al. 2002). DSL is distance-sensitive, and the supported data rate varies with transmission length. Essentially, customers with longer telephone line runs from their houses to the CO experience lower performance rates compared to neighbors who might live closer to the CO (Ouyang et al. 2003). A typical ADSL system provides 8 Mbps downstream

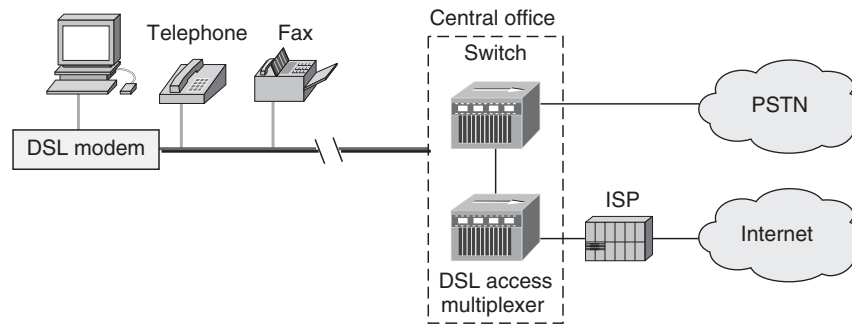

Figure 1: DSL network

bandwidth with a wire length of 9000 feet or 1.5 Mbps downstream bandwidth with 18,000 feet. DSL draws significant attention from service providers because it delivers data services to dispersed locations with relatively small changes to the existing telecommunications infrastructure.

The major problems with sending a high-frequency signal such as that used in DSL over an unshielded pair of copper wires include signal fading and cross talk. As the length of wires increases, the signal at the customer side may become too weak to be correctly detected. If the power is increased at the CO, then the signals tend to transfer to wires in the same bundle, resulting in cross talk and severely impaired performance.

Cable Modem

Cable companies offer Internet access through the traditional *cable TV* (CATV) network. The Internet access requires two types of equipment: a cable modem at the customer's end and a *cable modem termination system* (CMTS) at the cable provider's end (Fellows and Jones 2001). The CMTS located at the cable operator's network hub is a data switching system specifically designed to route data from many cable modem users over a multiplexed network interface. It controls access to cable modems on the network. Traffic is routed from the CMTS

to the backbone of a cable *Internet service provider* (commonly called an ISP), which in turn connects to the Internet (International Engineering Consortium, undated).

Figure 2 illustrates the elements and services in the cable modem network. Data traveling upstream from individual users to the CMTS are filtered by upstream demodulators for further processing by the CMTS. For data traveling downstream from CMTS to the users, a cable headend combines the data channels with the video, audio, and local programs and transmits them throughout the cable distribution network. At the user location, a one-to-two splitter separates the coaxial cable line serving the cable modem from the line that serves the TV sets.

Different from DSL, cable modem service uses a shared cable line to provide service to an entire neighborhood (Dutta-Roy 2001). Essentially, all cable customers in the region belong to the same LAN. Cable modem speeds vary widely. Although cable modem technology can theoretically support rates as high as 30 Mbps, most providers offer service with between 1 Mbps and 6 Mbps bandwidth for downstream (from CMTS to individual users) and bandwidth between 128 Kbps and 768 Kbps (Azzam 1997) for upstream (from individual users to CMTS).

Besides the signal fading and cross-talk problems, cable modem has its own technical difficulties. One is that the original CATV infrastructure is designed to

Figure 2: Cable modem network

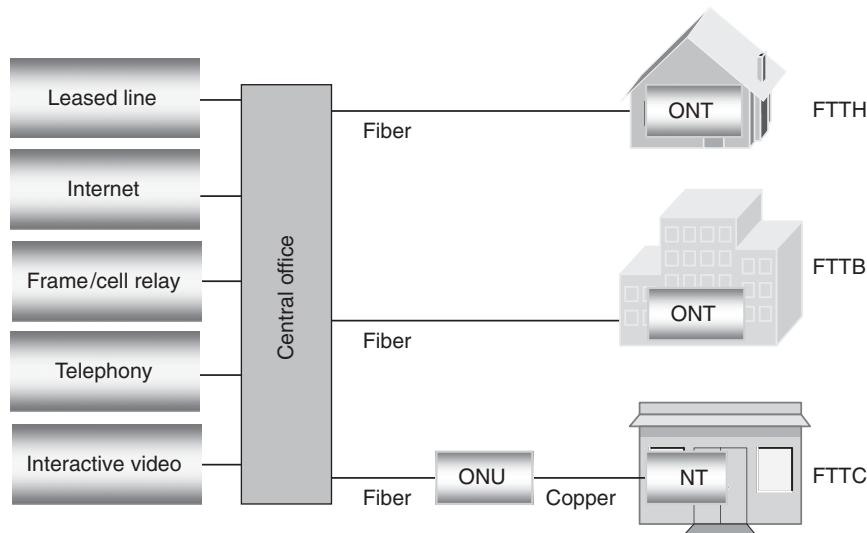

Figure 3: Fiber-optic network

broadcast TV signals in just one direction: from the CATV provider to home end users. The Internet, however, is a two-way system in which data also need to flow from the subscriber to the service provider. To enable the two-way transmission, the upstream channel capacity has to be significantly increased by encroaching on the service provider's content bandwidth. Moreover, cable modem technology is based on shared bandwidth, and many factors may influence the delivered services. The speed of shared bandwidth fluctuates, depending on the number of subscribers in the network, and it is difficult to gauge an exact download speed. In rural areas with fewer subscribers, cable modem is bound to provide faster download speeds than in a metropolitan area. In DSL, the connection between the subscriber and the CO is dedicated, and the customers tend to have a more constant transmission speed.

Fiber-Optic Access

With the expansion of services offered over the Internet, neither DSL nor cable modem can remain successful as bandwidth demands grow significantly beyond their supported levels. Besides, DSL has severe problems with respect to distance and noise limitations, and cable modem is not optimized to carry data traffic because of its inherent asymmetry in capacities for upstream and downstream data transmission (Green 2004). It is desired to upgrade the current access network with a low-cost and high-speed solution for broadband access services.

Recent developments in optical fiber technologies, especially the maturity of integration and new packaging technologies, have enabled fiber-optic access network as a promising solution for the provisioning of high bit rate at a reasonable cost. Fiber-optic technology offers a mechanism that enables sufficient network bandwidth for the delivery of new services and applications. The supported access network architecture includes FTTH, *fiber to the building* (FTTB), and *fiber to the curb* (FTTC) (Keiser 2006). In the FTTH and FTTB architectures, an optical fiber is extended into the subscriber's home or building;

in the FTTC architecture, the optical fiber reaches a small cabinet located near the subscribers from where the signal is converted to feed the subscribers over copper telephone wires or coaxial cables (see Figure 3).

The connection between the CO to the subscriber could be P2P or *point-to-multipoint* (P2MP). In the P2P connection, each subscriber is connected to a CO through a dedicated fiber. Network upgrading for higher capacity is straightforward and the power budget is sufficient for an extremely long link reach. To provide the P2P connection, each subscriber requires a separate fiber port in the CO, and the transceiver count must be twice the number of subscribers. The overall cost of running and managing active components at both ends of a fiber is prohibitive for broadband access. Without the benefits of large-scale cost sharing as in the backbone network, the access network must strive to minimize cost. Therefore, the P2MP connection is a better option because it provides sharing among multiple subscribers. This enables cost sharing of a transceiver and a large portion of the fiber infrastructure, reducing system costs significantly. On the other hand, MAC protocols are required to allocate the shared network resources among the associated subscribers.

PASSIVE OPTICAL NETWORKS

With the goal of eliminating the bottleneck of broadband access, passive optical networks are drawing much attention from both research communities and service providers. As illustrated in Figure 4, a typical PON consists of one *optical line terminal* (OLT), which is located at the provider CO, and n associated *optical network units* (ONUs) or optical network terminals (ONTs) that deliver data to end users. In the FTTC architecture, an ONU terminates the circuit at the subscriber's end, whereas an ONT terminates the circuit in the FTTH and FTTB architecture. A single fiber extends from the OLT to a $1:n$ passive optical splitter, fanning out n single fiber drops to connect to the associated ONUs and ONTs (Luo and Ansari 2005a).

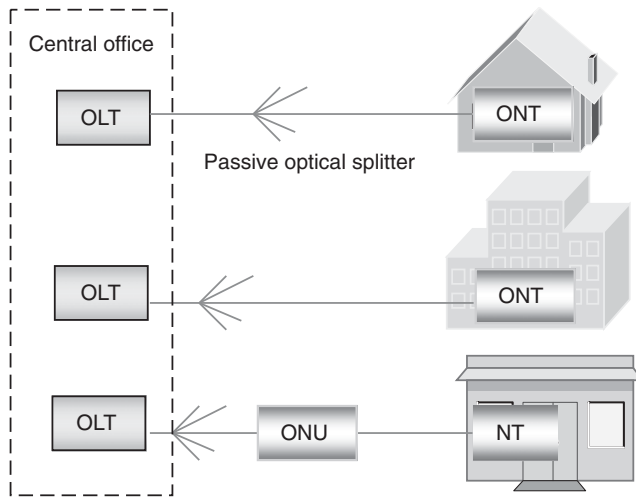

Figure 4: Passive optical network

PON networking is a full duplex technology that uses inexpensive optical splitters to divide a single fiber coming from the backbone network into separate drops feeding individual subscribers in the access network. The passive elements of a PON include fiber-optical cables and a passive optical splitter. The splitter is a simple device with no electronics. It allows the downstream traffic from the OLT and the upstream traffic to the OLT to be split from and combined onto the shared portion of the fiber. The less expensive and longer-lived passive components are located in the optical distribution network, replacing the active electronic components such as regenerators, repeaters, and amplifiers in DSL or cable modem. The employment of passive optical splitters reduces the feeder fiber counts in PONs. The OLT, ONUs, and ONTs are the active elements, being located at the end points of a PON. The OLT supports management functionalities at the CO and is capable of managing tens of downstream links in a PON. ONUs and ONTs are known as the *customer premise equipment* and must support only their own link to the CO. As a result, the ONU and ONT devices are less expensive whereas the OLT devices tend to be more capable and more expensive. By eliminating the intermediate powering, PONs are easier to maintain and provide lower overall system cost to the service providers.

The basic communications architecture in a PON is a P2MP network in which the OLT serves as the control point for the entire PON and the ONU or ONT serves as the subscriber points or controlled points. Optical signals transmitted across a PON are either split into multiple fibers in the downstream from the OLT to ONUs or ONTs, or combined onto a single fiber in the upstream from ONUs or ONTs to the OLT by the optical splitter. Compared to the P2P network, a PON has the advantage of minimizing the number of optical transceivers and reducing the CO wiring and space requirements. The aforementioned PON architecture is beneficial under the following scenarios (Corning Cable Systems 2005). First, no active devices are desired in the outside plant, and deploying large electronics platform is restricted. Second, the service coverage is typically in the distance of 10 km to approximately 20 km. Third, the expensive

fiber installation and maintenance cost prevents dedicated P2P connection.

The available medium access technologies are *wavelength-division multiple access (WDMA)*, *code-division multiple access (CDMA)*, and *time-division multiple access (TDMA)* (Kramer and Mukherjee 2001). In WDMA, each ONU or ONT transmits its data to the OLT using a specific wavelength laser. The OLT must have a transmitter array to support multiple ONUs or ONTs, thus increasing the cost of the access network. CDMA encodes data with a special code associated with each channel, and the interchannel interference increases as the number of ONUs or ONTs increases. Reducing such interference calls for complicated signal-processing chips and would add more cost to maintain a CDMA-based access network. Furthermore, to provide CDMA among the data from different ONUs or ONTs, the network components must be able to handle a signal rate that is much higher than the data rate, thereby raising the network price tremendously. By dividing the upstream channel into time slots, TDMA allows ONUs and ONTs to transmit their data in different exclusive time slots (as exemplified in Figure 5b). Only one transmitter is needed at the OLT to multiplex the upstream data no matter how many ONUs or ONTs are connected. A new ONU or ONT can be easily added by the control protocol. To support TDMA, synchronization is required between the OLT and the ONUs or ONTs. Without the benefits of large-scale cost sharing, access networks must strive to minimize cost. Service providers desire to fulfill the medium access with as low a cost as possible while achieving as fine a granularity as possible and building the access networks as scalable as possible. Toward this end, TDMA and *time-division multiplexing (TDM)* were chosen by the PON standard bodies (IEEE 2004; ITU-T 1998, 2001, 2003a, 2003b, 2004a, 2004b) for upstream and downstream data transmission, respectively.

Employing TDMA in the upstream transmission requires a tight synchronization mechanism between the OLT and the associated ONUs or ONTs (Van Caenegem 2004). Consequently, the ranging procedure during activation and registration is necessary to automatically adjust time offsets of individual ONUs or ONTs. Ranging ensures that the bursts coming from different ONUs or ONTs are lined up in the right time slots and correctly received by the OLT. Employing TDM in the downstream transmission brings on the concern of data security. Each ONU or ONT receives the same copy of downstream data, and a proper data-encryption mechanism is required to prevent eavesdropping.

The process of transporting data downstream to the end users in a PON is different from that of transporting data upstream to the OLT. Different wavelengths are employed for the two directions to avoid collisions and interactions between the downstream and upstream traffic flows. As illustrated in Figure 5a, in the downstream transmission, data are broadcasted from the OLT to each ONU or ONT using the entire bandwidth of the downstream channel, and all of the downstream data are carried in one wavelength (e.g., 1490 nm). ONUs and ONTs selectively receive frames destined to themselves by matching the addresses in the received data. The "broadcast and select" architecture allows downstream multimedia services

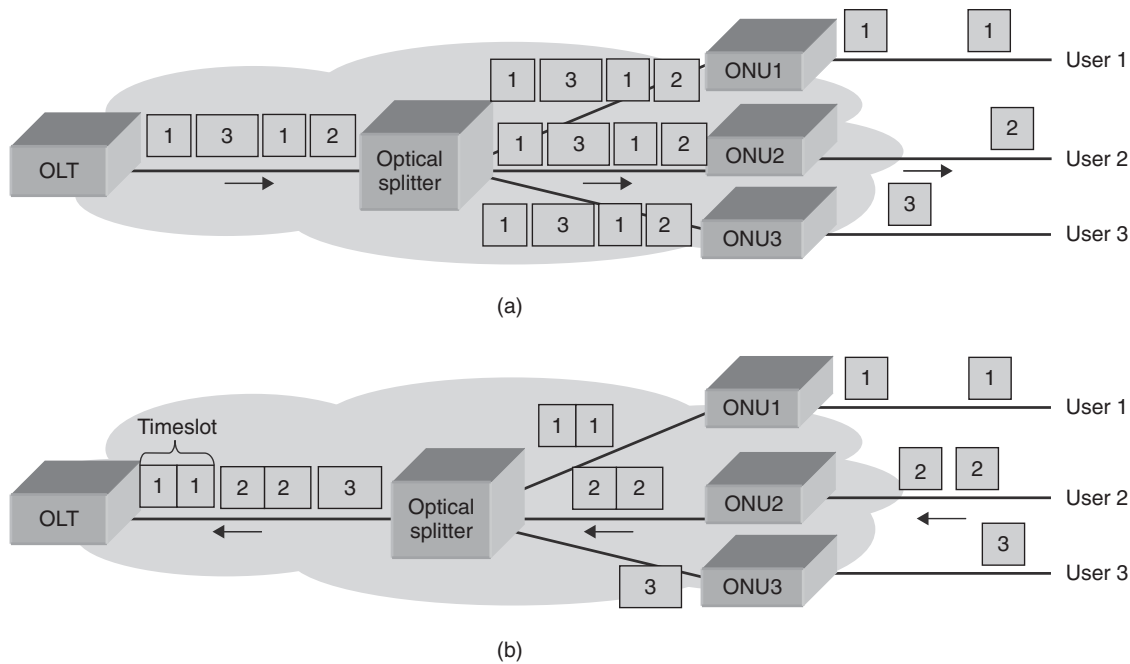

Figure 5: PON transmission: (a) downstream and (b) upstream

such as video broadcasting. In the upstream direction, as illustrated in Figure 5b, multiple ONUs or ONTs share the common upstream channel, and another wavelength (e.g., 1310 nm) is employed for the upstream traffic. Only a single ONU or ONT may transmit during a time slot in order to avoid data collisions. Because of the directional nature of the passive optical splitter, each ONU or ONT transmits directly to the OLT but not to other ONUs or ONTs. An ONU or ONT buffers the data from the end users until its time slot arrives. The buffered data would be “burst” out to the OLT in the exclusively assigned time slot at the full channel speed. The result is that the basic P2MP architecture of a PON can support P2P communications between the OLT and an ONU or ONT.

PON technologies are evolving according to the development of optical devices and high-speed networking. Several different PON standards—including B-PON, EPON, and G-PON—have been approved to facilitate broadband access. The most significant difference between each “flavor” of PON is the supported line rates and the type of bearer packets. The rest of this section will elaborate on their characteristics.

Broadband PONs

Asynchronous transfer mode (ATM) PON, or APON, was introduced in the 1990s by the Full Service Access Network (FSAN) group. The International Telecommunications Union (ITU) ratified ITU-T G.983 recommendation (ITU-T 1998) with extensions such as ONU and ONT management and control interface specification, survivability, and *dynamic bandwidth assignment* (DBA). In addition, the name APON was soon changed to *broadband PON* (B-PON) to more appropriately reflect its functionality. B-PON adopts ATM cells as the transmission data unit and inherits the features of the ATM technology

such as multiservice capability and support of different quality-of-service (QoS) classes.

In the downstream transmission from the OLT to ONUs or ONTs, each frame is composed of fifty-six ATM cells for the basic line rate of 155 Mbps, or two hundred and twenty-four ATM cells for 622 Mbps. *Physical layer operation, administration, and maintenance* (PLOAM) cells are inserted into the downstream frame, containing grants for upstream transmission as well as *operation, administration, and maintenance* (OAM) and *OAM and provisioning* (OAM&P) messages (“APON” 2002). Upstream transmission from ONUs or ONTs to the OLT is in the form of ATM cell bursts. Each ATM cell is appended with a three-byte physical overhead, allowing burst transmission and reception. The basic upstream line rate of 155 Mbps is constructed by the data frame of fifty-three cells. The typical link rates over B-PON are asymmetrical 622 Mbps/155 Mbps and symmetrical 155 Mbps or 622 Mbps. A new amendment with a 1.25-Gbps downstream line rate was added in 2003. Figure 6 shows the B-PON frame format of the symmetric 155-Mbps line rate.

B-PON is the leading PON technology in North America, making up 81 percent of its PON revenue in year 2004. Verizon planned to pass 3 million premises by the end of 2005, and AT&T is deploying PONs at the rate of 300,000 homes a year (“PON and FTTx, update” 2005).

Ethernet PONs

A B-PON suffers from the complexity of the ATM transport layer, and it faces the problems posed by the provisioning (i.e., it requires ATM-based CO equipment), complexity (in timing requirements and protocol complexity), and subsequent cost of components. EPON was proposed by the IEEE 802.3ah Ethernet in the First Mile (EFM) Task Force (IEEE, 802.3ah Task Force 2004) to

Figure 6: B-PON frame format

tackle the aforementioned issues, and it has been ratified as the IEEE 802.3ah standard (2004). It adopts Ethernet frames as the transmission data unit and simplifies timing and lowers costs by using symmetrical 1.25-Gbps data streams using standard Ethernet optical components.

EPON relies on the *multipoint control protocol* (MPCP) (Luo and Ansari 2005a) to control the P2MP connection between each OLT and its associated ONUs or ONTs. MPCP is a frame-based protocol, defined as a function within the MAC control sublayer. It uses messages, state machines, and timers to control the access to a P2MP topology, and it introduces five new 64-byte MAC control messages to provide the transmission of Ethernet frames over EPON (Luo and Ansari 2005b). REGISTER_REQUEST, REGISTER, and REGISTER_ACK messages are utilized in the auto_discovery process to register a new ONU or ONT. GATE and REPORT messages are used for upstream bandwidth negotiation. As shown in Figure 7, the GATE message is sent downstream by the OLT, informing a particular ONU or ONT of its dedicated transmission time slot, whereas the REPORT message is sent by an ONU or ONT to the OLT, containing the transmission request. By allocating the upstream transmission from ONUs or ONTs into exclusively dedicated time slots, an EPON avoids data collision and is able to support higher speed than the original Ethernet in which carrier sense multiple access with collision detection is applied.

As compared to B-PON, EPON is tailor-made to carry the rapidly growing Internet protocol (IP) traffic. Transporting IP traffic over B-PON is quite inefficient. B-PON has to segment the variable-length IP packets into many fixed-length and much shorter ATM cells. This excessive segmentation causes a considerable delay in the communication process. Furthermore, the so-called ATM cell tax—that is, the 5-byte cell header—causes an onerous overhead in the transmission of IP packets over B-PON. By contrast, EPON encapsulates the IP packets in the Ethernet frames, with the length ranging from 64 bytes to 1518 bytes, thus reducing the time-consuming segmentation process relative to B-PON. In addition, Ethernet is a widely used LAN

protocol all over the network world. If Ethernet were used in the access network, then it would be unnecessary to convert between protocols as required in B-PON.

The REPORT and GATE mechanism is provided for bandwidth negotiation without specifying any particular bandwidth allocation algorithm (Luo and Ansari 2005c). Therefore, as compared to B-PON, EPON MAC does not support QoS directly, and the proper upstream DBA architecture over EPON is of high interest to both industry and academia (Ma, Zhu, and Cheng 2003). The typical proposals are *fixed bandwidth allocation* (FBA) (Kramer, Mukherjee, and Pesavento 2002), *limited bandwidth allocation* (LBA) (Kramer, Mukherjee, and Pesavento 2002), *excessive bandwidth reallocation* (EBR) (Assi et al. 2003), and *limited sharing with traffic prediction* (LSTP) (Luo and Ansari 2005d).

FBA grants each ONU or ONT a fixed time-slot length in every service cycle. A *service cycle* is defined as the time that each ONU or ONT transmits its data once to the OLT. Without the overhead of the queue status report and the transmission grant, FBA is simple to implement. On the other hand, an ONU or ONT will occupy the upstream channel for its assigned time slot even if there is no frame to transmit, thus resulting in the increased delay for all of the Ethernet frames buffered in other ONUs or ONTs. Many frames could be backlogged in the buffers while the upstream channel is lightly loaded or even idle, hence leading to underutilization of the upstream channel.

LBA tracks the traffic load by adopting the REPORT and GATE mechanism to facilitate the bandwidth negotiation. Each ONU or ONT reports the local queue status by piggybacking a REPORT message at the end of its time slot. The granted time-slot length by the OLT varies according to the dynamic traffic, and the time-slot length is upper-bounded by the maximum bandwidth parameter in the service level agreement.

Extended from LBA, EBR exploits the leftover bandwidth from the lightly loaded ONUs or ONTs by redistributing it among the heavily loaded ONUs. Therefore, each

Figure 7: An example of bandwidth negotiation over EPON

heavily loaded ONU or ONT may obtain an additional bandwidth to facilitate its upward data delivery.

During the time of bandwidth negotiation, each ONU or ONT experiences a waiting time, which ranges from sending the bandwidth requirement to sending the buffered data. More data will be enqueued at the buffer during the waiting time. LSTP reduces data delay and loss by taking consideration of the data arrived during the waiting time. In LSTP, online traffic prediction is conducted based on network traffic self-similarity, and ONUs or ONTs prereserve a portion of the upstream bandwidth to transmit these data, thus resulting in latency reduction and improved bandwidth utilization.

EPON is firmly entrenched in Asia. NTT had reached 1.7 million EPON customers by fall 2004 and expects to reach 30 million subscribers by 2010. In 2004, Asia/Pacific accounted for 93 percent of the world PON subscribers, and most of them are supported by EPON ("PON and FTTx update," 2005).

Gigabit-Capable PONs

G-PON is the continuation and evolution of B-PON. It supports Ethernet, ATM, and TDM traffic over the P2MP PON network topology. The ITU-T G.984 recommendation (ITU-T 2003a) family specifies a physical media dependent layer (ITU-T 2003b), a transmission convergence layer (ITU-T 2004a), and the ONU and ONT control interface over G-PON (ITU-T 2004b). The G.984 series differs from the previous G.983 series primarily in that higher line bit rates are described. G-PON offers the line rate of as much as 2.5 Gbps upstream and 2.5 Gbps downstream. The B-PON and G-PON systems are not interoperable. As a consequence of this difference, the G.984 series deals with many technical issues and features in a manner different from the G.983 series, including frame format, ranging method, OAM functionalities, data security, and physical layer requirements and specifications.

G-PON surpasses B-PON capabilities because of its more efficient packet transport protocol and the support for forward error correction. The *G-PON encapsulation method* (GEM) is defined in G-PON to transport packet based services. GEM maps all traffic across the G-PON network using a variant of generic framing procedure (ITU-T 2001). It facilitates the transmission of Ethernet,

ATM, and TDM data units by traffic flow identification and packet and fragment delineation through the GEM header (Van Caenegem 2004). The GEM header contains important information such as payload length, port ID, payload type, and error detection. The encapsulation of ATM cells is an evolution of the existing B-PON standard. GEM fragments the packets, reassembles them at the receiver, and forwards them to the higher layer, thus supporting a native transport of triple play with voice, video, and data services. With B-PON, all services must be mapped over an ATM layer. With EPON, all services must be mapped over Ethernet. The employment of GEM does not require an added encapsulation layer, resulting in a dramatic increase of bandwidth utilization: Both of the downstream and upstream line rates are as high as 2.5 Gbps—a significant increase over B-PON and EPON.

As shown in Figure 8, G-PON defines a framing format of 125 μ s for the downstream services, with the header of each frame containing the OAM information. The fixed frame delivers 8 kHz of clock information, facilitating synchronization between the OLT and ONUs or ONTs. In the upstream, ONUs and ONTs burst out their data. The burst payload consists of a variable number of GEM packets carrying Ethernet and TDM traffic. An ATM partition may be contained in a burst to carry multiple ATM cells (Angelopoulos et al. 2004).

G-PON inherits the OAM mechanism from B-PON by taking over the PLOAM message and major features of the ONU and ONT management and control interface. The ITU-T G.984.4 recommendation (ITU-T 2004b) specifies the information exchange between the OLT and ONUs or ONTs, including connection establishment and release across the ONU or ONT and a configuration request, as well as automatic system event notification. These salient characteristics enable G-PON with QoS support to provide diverse broadband services.

Compared to EPON, G-PON provides higher line rate with more flexibilities (1.25 Gbps or 2.5 Gbps in the downstream, and 155 Mbps, 622 Mbps, 1.25 Gbps, or 2.5 Gbps in the upstream), facilitating standard compatibility and the capability of tuning to various deployments. Because asymmetry is the distinct feature of access network traffic, the line rate flexibility in G-PON enables the service provider to configure the rates according to the real needs. In addition, G-PON improves data security by embedding

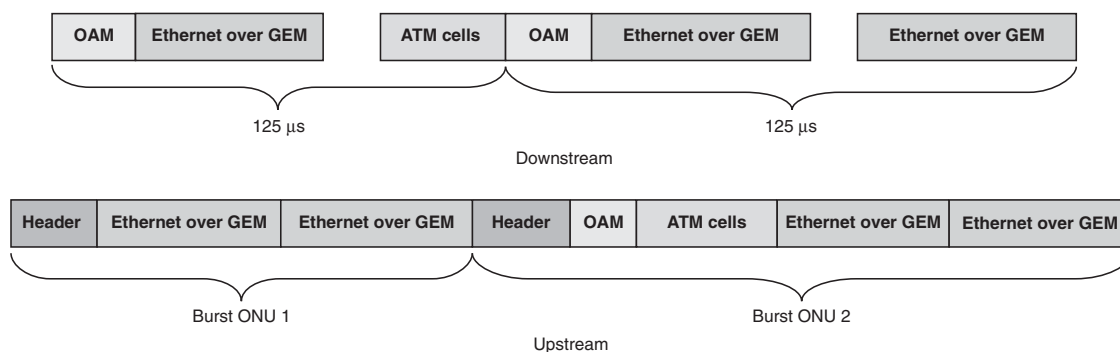

Figure 8: G-PON framing

Table 1: B-PON, EPON, and G-PON

	B-PON	EPON	G-PON
Driven by	ITU-T/FSAN	IEEE EFM	ITU-T/FSAN
Standards	G. 983	802.3ah	G. 984
Max line rate (downstream)	1.25 Gbps	1.25 Gbps	2.5 Gbps
Max line rate (upstream)	622 Mbps	1.25 Gbps	2.5 Gbps
Typical split ratios	1:32	1:16	1:128
Payload	ATM	Ethernet	ATM, TDM, Ethernet
Distance	≤ 20 km	≤ 20 km	≤ 20 km

data encryption using the advanced encryption standard in the downstream broadcast channel (Nortel 2004). The current concern about G-PON is the cost of supporting equipment. The requirement to support 2.5 Gbps in the upstream direction significantly increases the cost of both the transmitter in ONUs or ONTs and the receiver in the OLT (Ossieur et al. 2005). G-PON is likely to be deployed on a larger scale in Northern America, because its larger capacity in the downstream can support in-band video services. Various features of B-PONs, EPONs, and G-PONs are compared in Table 1.

Wavelength-Division Multiplexed PONs

The aforementioned PONs are all TDM-PONs that employ TDM or TDMA for data transmission with the maximum line rate of 2.5 Gbps. Each subscriber can only access the OLT within a limited time interval. The limited bandwidth as a result of this time sharing is not expected to satisfy future bandwidth consuming applications such as high definition TV. As more broadband applications appear, demands from PON subscribers will soon outgrow the TDM-PON capacity. To enable cost sharing among multiple ONUs or ONTs, the corresponding MAC protocols are rather complicated and may hinder the

TDM-PON upgrade. Moreover, the security of the communication link is not guaranteed because each subscriber on the TDM-PON receives all of the data sent to others in the network. This results in a major concern for potential business subscribers. WDM-PON is being studied as the next-generation wired broadband access solution to tackle these issues.

As illustrated in Figure 9, WDM-PON allocates different wavelengths to each ONU or ONT, providing a separate P2P connection between each ONU or ONT and the OLT. The transmission data rate is expected to be much higher than that of TDM-PON. The cost of the wavelength router is shared among all ONUs and ONTs, and the network management is much simpler than TDM-PON. In addition, the P2P connection guarantees downstream data privacy, and only the destined subscribers can receive the data. Independent of the transmission data format and line rate, the P2P connection in WDM-PON is able to further exploit the larger capacity of optical fibers. By delivering all services over a single network platform, this common network architecture will satisfy all future needs for both residential and business subscribers.

Because cost is the main obstacle in the implementation of WDM-PON, tremendous effort is being dedicated to provide scalability (Amitabha et al. 2005), thus reducing

**Figure 9:** A WDM-PON architecture

the cost to support the ever-growing number of subscribers. Besides, research effort on the WDM-PON frame format, coarse WDM, wavelength sources, wavelength routers, network architecture, and suitable protocols works as the impetus to the development of WDM-PON.

CONCLUSION

Driven by both ITU and IEEE, PON is gaining more and more support from the service providers as the solution for broadband access. As compared to DSL and the cable modem, the PON lowers the cost of network deployment and maintenance by eliminating the active electronic components and replacing them with less expensive passive optical splitters. In addition, PON covers longer distances from the service provider CO to customer sites and provides line rates as high as 2.5 Gbps. The cost benefits and capacity improvement of a PON verify the assumption that it will be a dominant architecture for broadband service provisioning. This chapter has illustrated broadband access technologies, especially PON technology for fiber-optic access and the line rates and transmission data units that characterize different “flavors” of TDM-PON. The three existing TDM-PON standards—B-PON, EPON, and G-PON—have been overviewed with emphasis on frame format, bandwidth negotiation, and GEM protocol layer, respectively. They offer packet-based transport at Gigabit per second speeds and will dominate the broadband market in the near future. Nevertheless, WDM-PON has attracted much attention recently because of its high capacity, secure P2P connection, and independency of line rate and frame format. WDM-PON holds promise as the next-generation PON technology of broadband access.

GLOSSARY

Broadband Passive Optical Network (B-PON): A PON standard ratified by ITU-T G.983 recommendations. It uses ATM cells as transmission data units.

Cable Modem: An access technology designed to modulate a data signal over cable television (CATV) infrastructure.

Digital Subscriber Line (DSL): A family of technologies that provide digital data transmission over the wires used in the local telephone network.

Ethernet Passive Optical Network (EPON): A PON standard ratified by the IEEE 802.3ah standard. It uses Ethernet frames as transmission data units.

Generic Framing Procedure: A mapping method defined by ITU-T Recommendation G.7041. It allows mapping of variable-length, higher-layer client signals over a transport network such as SDH or SONET.

Gigabit-Capable Passive Optical Network (G-PON): A PON standard ratified by ITU-T G.984 recommendations. It uses the *G-PON encapsulation method* (GEM) to transmit Ethernet, ATM, and TDM data units.

G-PON Encapsulation Method (GEM): A mapping method adopted in a Gigabit-capable passive optical network (G-PON). It allows a G-PON to natively carry both Ethernet and TDM traffic.

Optical Line Terminal (OLT): The central controller of PONs. It is located at the central office (CO),

supervising all signal activity and arbitrating the data transmission.

Optical Network Terminal (ONT): The active device that delivers broadband access services to the subscribers. It is located in homes or in buildings.

Optical Network Unit (ONU): The active device that delivers broadband access services to subscribers. It is located near to the subscribers (e.g., “in the curb”).

Passive Optical Network (PON): A fiber-to-the-premises configuration in which passive optical splitters are used to enable a single optical fiber to serve multiple premises. A PON consists of an optical line terminal (OLT) at the service provider’s central office and a number of associated optical network units (ONUs) or optical network terminals (ONTs) near or at end users.

Wavelength-Division Multiplexing (WDM): A technology that multiplexes multiple optical carrier signals onto a single optical fiber by using different wavelengths.

Wavelength-Division Multiplexed Passive Optical Network (WDM-PON): A PON technology using WDM to reach multiple subscribers.

- wireless channels (*cont.*)
 - Okumura model, 342, 343
 - path loss modeling, 338
 - path loss over smooth plane, 339–340
 - power delay profile, 347
 - radio wave propagation, 334–338
 - free space propagation, 335
 - indoor propagation, 338
 - mechanism of, 335–337
 - multipath propagation, 336, 337–338, 340
 - statistical parameters of the wireless channel, 347–348
 - statistical wireless channel model, 344–346
 - time dispersion, 347
 - Walfisch-Bertoni model, 343
 - wideband PCS microcell model, 343
- wireless digital subscriber line (WDSL), 317
- wireless fidelity (WiFi), 3, 15, 317
- wireless Internet service providers (WISPs), 15
- wireless local area networks (WLANs)
 - modems, 317
 - orthogonal frequency division multiplexing, 591, 601
 - spread spectrum, 539
 - wireless channels, 338
- WirelessMAN, 602
- wireless modems, 317
- wireless phones, 5, 11
- wireless revolution, 675
- wireless spectrum licenses, 11
- wireless voice market, 9–11
- Wise, F., 868
- Witten, I. H., 199, 203, 210, 229
- Witten-Neal-Cleary adaptive arithmetic coder, 229, 231
- Wolf, E., 828
- Wolf, J. L., 289
- Wolfson, D., 733
- Wong, C. Y., 601
- Wood, D., 873
- Woods, J., 218
- words in data compression, 203
- workgroup switches, 380
- working lines, 939
- workstation, 20
- World DAB, 668, 670
- World Radiocommunication Conference, 671
- WorldSpace, 646, 671
- WorldSpace Satellite Radio, 662, 663
- World War II, 130, 538
- World Wide Web, 80–81
 - see also* Internet
- WR. *See* wavelength routing (WR)
- wraparound order, 184
- Wree, C., 469
- Wright, E. M., 866
- write address control (WAC), 378
- write-once, read many (WORM), 802
- write-once recording, 802–803
- Wu, E., 838
- Wu, S.-T., 700
- Wu, T., 940
- Wu, W., 619, 620
- Wu, X. N., 787
- Wyner, A. D., 502
- Wysocki, P. F., 857
- X.25 protocol stack, 151
- X couplers, 837–839
- XDCAM HD, 300, 301
- Xenophon, 900
- Xia, L., 844
- Xiao, G., 622, 910
- Xiao, X., 287
- Xiao, X. P., 619
- Xiaohua, M., 829, 837
- Xie, C., 463
- Xiong, F., 96, 97, 524, 525, 529, 530, 531, 533, 535
- Xiong, X., 511, 516, 519
- Xiong, Z., 221
- XML encoding rules (XER), 79
- XM Satellite Radio, 646, 662, 663–664, 671
- XPM. *See* cross-phase modulation (XPM)
- Xu, C., 457, 460, 464, 465, 469
- Xu, L., 915, 916
- Xu, Z., 868, 876
- Xue, F., 842
- Yabusaki, M., 675
- Yadin, Y., 460
- Yaeger, R. E., 581
- Yajima, N., 862
- Yamada, N., 803
- Yamada, Y., 854
- Yamagishi, F., 909
- Yamanaka, N., 379
- Yan, T.-Y., 505
- Yang, J., 867, 868
- Yang, J. J., 760, 761, 763
- Yang, T.-S., 864
- Yang, Y. R., 68, 69, 72
- Yang Liao, D., 914
- Yano, M., 909
- Yao, J., 842
- Yao, S., 608, 609, 615, 622, 624, 909, 910, 916
- Yariv, A., 819, 822, 830, 831, 834, 837, 846, 857
- Yasuda, Y., 141, 215, 448
- Y couplers, 840
- Ye, C., 763
- Yegenoglu, F., 584
- Yeh, C., 876
- Yeh, J. W., 31
- Yeh, Y., 377
